is formed as a granular powder, m. p. 99°, which gives a *copper* salt. In contrast to its isomeride, m. p. 133—134°, its tetramic acid derivative is the ethyl compound, m. p. 199°, and not the methyl, m. p. 210—211°.

The methyl ester, m. p. 91°, but not so the isomeride, m. p. 155°, condenses in presence of methyl sodiomalonate in boiling benzene to *methyl benzoylenedimethylpyrrolonecarboxylate*,

$$^{C_6H_4\cdot C:C(CO_2Me)}_{CO—N\cdot CMe_2}{>}CO,$$
in yellow needles, m. p. 165° (compare the ethyl ester, A., 1911, i, 213). Similarly, phthaliminomethylbutanone (*ibid.*) gave benzoylenedimethylpyrrolone (A., 1911, i, 228). *Methyl phthalimino*iso*butyrate*, $C_8H_4O_2:N\cdot CMe_2\cdot CO_2Me$, prepared from the chloride in colourless, rhombic plates, m. p. 78°, combined with methyl alcohol when left with that liquid or when warmed with sodium methoxide solution, and gave the *methyl* ester of *methyl phthalamino*iso*butyrate*

$$CO_2Me\cdot C_6H_4\cdot CO\cdot NH\cdot CMe_2\cdot CO_2Me,$$
in delicate needles, m. p.˙116—117°, thus behaving differently, as was expected, from the phthaliminoacetates and propionates, which give *iso*quinoline derivatives (A., 1900, i, 358). The methyl ester, m. p. 91°, may also be methylated by the action of methyl iodide on the sodium compound. *Methyl phthalimino*iso*butyrylmethylmalonate*,

$$C_8H_4O_2:N\cdot CMe_2\cdot CO\cdot CMe(CO_2Me)_2,$$
forms prisms, m. p. 121°, and on hydrolysis with hydrochloric acid yields *aminomethylpentanone hydrochloride*, $C_2H_5\cdot CO\cdot CMe_2\cdot NH_2,HCl,$

in rectangular tablets, m. p. 164°.   The *hydriodide*, $C_6H_{13}ON,HI$, crystallises in needles, m. p. 141—142°, and gives a *picrate*, m. p. 145°. The *benzoyl* derivative forms silky needles, m. p. 118°, and the *phthalyl* compound crystallises in rhombic tablets, m. p. 70°, whilst the free *base*, $C_2H_5 \cdot CO \cdot CMe_2 \cdot NH_2$, is a colourless, mobile liquid, which, unlike aminomethylbutanone, but like amino*iso*butyrophenone (A., 1911, i, 212), distils without condensation, b. p. 157·5°/762 mm.

α-Phthalylalanyl chloride (A., 1908, i, 182) has also been con-densed with ethyl sodiomalonate, forming a light yellow *sodium* compound, from which carbon dioxide separated *ethyl α-phthalylalanyl-malonate*, $C_6H_4O_2{:}N \cdot CHMe \cdot CO \cdot CH(CO_2Et)_2$, in rhombic plates, m. p. 73—74°. Contrary to the above phthaliminoisobutyrylmalonates, it did not form a tetramic or a pyrrolone derivative. When hydrolysed by means of fuming hydriodic acid, methyl α-aminoethyl ketone *hydriodide*, C_4H_9NO,HI, m. p. 89°, is formed (Künne, A., 1895, i, 685), but hydrobromic acid at 70° led to *α-phthaliminoethyl methyl ketone*, $C_8H_4O_2{:}N \cdot CHMe \cdot COMe$, which formed flat leaflets, m. p. 85—86°.

Phenoxyacetyl chloride was also condensed with methyl sodio-malonate, when the new *sodium* salt was obtained in silky, white needles, from which carbon dioxide separated *methyl phenoxyacetyl-malonate*, $OPh \cdot CH_2 \cdot CO \cdot CH(CO_2Me)_2$, as an oil.

Similarly, *phenoxyisobutyryl chloride*, $OPh \cdot CMe_2 \cdot COCl$, a colourless oil, b. p. 112—113°/12·5 mm., yielded *ethyl α-phenoxyisobutyrylmalonate*, $OPh \cdot CMe_2 \cdot CO \cdot CH(CO_2Et)_2$, in prisms, m. p. 69°. The chloride was obtained from ethyl phenoxy*iso*butyrate, b. p. 127°/12 mm. (compare Bischoff, A., 1900, i, 346), by the action of phosphorus pentachloride on the free acid, and yielded the *amide*, $OPh \cdot CMe_2 \cdot CO \cdot NH_2$, in silky needles, m. p. 116°.
*Ethyl α-phthalimino*isobutyrylcyanoacetate,
$$C_8H_4O_2{:}N \cdot CMe_2 \cdot CO \cdot CH(CN) \cdot CO_2Et,$$
was obtained by adding phthalimino*iso*butyryl chloride to ethyl sodio-cyanoacetate suspended in benzene, and decomposing the new light yellow salt with hydrochloric acid. It forms flat leaflets, m. p. 111°, and has acidic properties, giving an *ammonium* salt,
$$C_{17}H_{15}N_2O_5,NH_4,H_2O,$$
and a *copper* salt. On hydrolysis with dilute hydrochloric acid it yields *α-phthalimino*isobutyryl*acetonitrile*, $C_8H_4O_2{:}N \cdot CMe_2 \cdot CO \cdot CH_2 \cdot CN$, in long needles, m. p. 154°. When left or warmed with dilute alkalis the substance loses water and forms *o-benzoylenecyanodimethylpyrrolone*,
$$\underset{CO—N \cdot CMe_2}{\overset{C_6H_4 \cdot C{:}C(CN)}{\Big>}} CO$$ in yellow prisms, m. p. 273°, which are con-

verted by hydrobromic acid into benzoylenedimethylpyrrolone (*loc. cit.*). The nitrile also dissolves in cold concentrated sulphuric acid with the formation of *phthalimino*isobutyryl*acetamide*,
$$C_8H_4O_2{:}N \cdot CMe_2 \cdot CO \cdot CH_2 \cdot CO \cdot NH_2,$$
in long, flat needles, m. p. 130°. This compound condenses very readily to *o-benzoylenedimethylpyrrolonecarbonamide*,

$$\underset{CO—N \cdot CMe_2}{\overset{C_6H_4 \cdot C{:}C(CO \cdot NH_2)}{\Big>}} CO,$$
which forms long, yellow prisms, m. p. 217°. When warmed with

concentrated sulphuric acid, however, the nitrile takes up $2H_2O$ and forms the *phthaloylic acid* derivative of *amino*isobutyrylacetamide (o-*carboxybenzoylamino*isobutyrylacetamide),

$$CO_2H \cdot C_6H_4 \cdot CO \cdot NH \cdot CMe_2 \cdot CO \cdot CH_2 \cdot CO \cdot NH_2,$$
as a crystalline powder, m. p. 171°, which merely dissolves and undergoes no condensation in alkalis.

Benzoylamino*iso*butyric acid (dimethylhippuric acid) was prepared by benzoylating amino*iso*butyric acid in acetone in presence of pyridine and then converted into the chloride (Mohr, A., 1910, i, 117). The latter was condensed with methyl sodiomalonate, when the expected ester was not obtained, but rather *methyl benzoyldimethyltetra*carboxylate [2 : 4-*diketo*-1-*benzoyl*-5 : 5-*dimethylpyrrolidine*-3-*carboxylate*],

$$\begin{array}{c} NBz \cdot CO \cdot CH \cdot CO_2Me \\ CMe_2 \!\!-\!\! CO \end{array}$$

, which forms rhombic tablets or short prisms, m. p. 154—155°. The substance had an acid reaction, dissolved in ammonia, and gave a *copper* salt and an orange-red coloration with ferric chloride. Hydrolysis with hydrochloric or hydriodic acid gave the salts of aminomethylbutanone. The analogous *ethyl* ester, $C_{16}H_{17}O_5N$, forms short prisms, m. p. 111°. Condensation of the above chloride with ethyl cyanoacetate, however, followed a normal course, and led to *ethyl benzoylamino*isobutyrylcyanoacetate, $NHBz \cdot CMe_2 \cdot CO \cdot CH(CN) \cdot CO_2Et$, which formed colourless rhombohedra, m. p. 165°. The compound forms salts with ammonia and silver, and gives a cherry-red coloration with ferric chloride. Hydrolysis with hydrochloric acid leads to *benzoylamino*isobutyrylacetonitrile, $NHBz \cdot CMe_2 \cdot CO \cdot CH_2 \cdot CN$, which forms long needles.

For the condensation of malonic esters with benzoylmethylamino*iso*butyryl chloride, methylamino*iso*butyric acid, prepared by a modification of Zelinsky and Stadnikoff's general method (A., 1906, i, 425), was benzoylated as above, the *benzoylmethylamino*isobutyric acid, $NMeBz \cdot CMe_2 \cdot CO_2H$, short prisms, m. p. 183°, was treated with thionyl chloride, and the crude product left with methyl sodiomalonate. *Methyl benzoylmethylamino*isobutyrylmalonate,

$$NMeBz \cdot CMe_2 \cdot CO \cdot CH(CO_2Me)_2,$$
forms colourless, short columns, m. p. 125°. It is gradually resolved into its components by boiling water, but is not only hydrolysed, but, furthermore, condensed by hydriodic acid to *phenyltrimethylpyrrolone*,

$$\begin{array}{c} CPh \!\!: \!\! CH \cdot CO \\ NMe \!\!-\!\! CMe_2 \end{array}$$

. This base crystallises in hexagonal tablets, m. p. 100°, b. p. 346—347°/768 mm., and forms a soluble chloride, a sparingly soluble nitrate, iodide and picrate, m. p. 147°, and a platinichloride.   J. C. W.

Condensation of Pyromellitic Anhydride with Benzene and with Toluene. II. ERNST PHILIPPI (*Monatsh.*, 1913, **34**, 705—717. Compare A., 1911, i, 793 ; Mills and Mills, T., 1912, **101**, 2194).—It has not been found possible to produce substances analogous to anthranol in the dinaphthanthracene group by intramolecular elimination of water from reduced derivatives of dibenzoylbenzenecarboxylic acids.

In the condensation of dibenzoylbenzenedicarboxylic acids to diphthaloylbenzene by concentrated sulphuric acid, 2-*benzoylanthraquinone*-

3-*carboxylic acid*, m. p. 283—285°, is obtained as a by-product, but by allowing the reaction to proceed at a lower temperature for a shorter period this substance becomes the main product; the *sodium* and *potassium* salts are sparingly soluble. Reduction of the acid with ammoniacal zinc dust and copper sulphate solution gives a poor yield of 2-*benzylanthracene*-3-*carboxylic acid*, m. p. 235—237°, which can be further reduced by hydriodic acid and phosphorus to 1 : 5-*dibenzyl-benzene*-2 : 4-*dicarboxylic acid*, which decomposes without melting. No dianthranol nor any other condensation product could be obtained by heating this substance with sulphuric acid.

Reduction of diphthaloylbenzene by distillation with zinc dust in an atmosphere of hydrogen under reduced pressure and also by alkaline hyposulphite yielded a sparingly soluble, reddish-brown, crystalline solid; this was unaltered by a temperature of 360°, and from the presence of two hydroxyl groups the structure is probably

$$C_6H_4\!\!<\!\!^{CO}_{CO}\!\!>\!\!C_6H_2\!\!<\!\!^{C(OH)}_{C(OH)}\!\!>\!\!C_6H_4.$$
The product of reduction of diphthaloylbenzene with hydriodic acid and phosphorus was exceedingly difficult to purify; it is an almost colourless *substance*, m. p. 210—215° (decomp.), the composition of which indicates a formula $C_{22}H_{20}$.

The condensation of pyromellitic anhydride with toluene by means of aluminium chloride proceeds in exactly the same way as with benzene; the reaction product is a mixture of two acids of the structure $C_6H_5Me\cdot CO\cdot C_6H_2(CO_2H)_2\cdot CO\cdot C_6H_3Me$, namely, 1 : 5 - *di* - p - *toluoyl-benzene* - 2 : 4 - *dicarboxylic acid* and 1 : 4-*di*-p-*toluoyl*-2 : 5-*benzene-dicarboxylic acid*, which can be separated by fractional crystallisation from nitrobenzene; the former acid has m. p. 245—248°, whilst the latter and less soluble acid decomposes without melting. Reduction of the more soluble isomeride by zinc dust and copper in alkaline solution is exceedingly slow, and yields only the *lactone*,

$$O\!\!<\!\!^{CH(C_6H_4Me)}_{CO}\!\!-\!\!>\!\!C_6H_2\!\!<\!\!^{CH(C_6H_4Me)}_{CO}\!\!-\!\!>\!\!O,$$
a yellow solid which does not melt below 240°. The same lactone is also obtained when the reducing agent is a mixture of phosphorus and hydriodic acid, but in this case it is accompanied by 1 : 5-*di*-p-*tolylbenzene*-2 : 4-*dicarboxylic acid*, a yellow solid, m. p. near 238°.

<div align="right">D. F. T.</div>

Hydrogenation of Santonin in Presence of Palladium Black. GUIDO BARGELLINI (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 443—447). —The action of hydrogen on an alcoholic solution of santonin in the presence of palladium black yields a dihydrosantonin and a tetra-hydrosantonin. The alcoholic solution of santonin containing palladium black is treated with hydrogen at 40—50 cm. pressure until the volume corresponding with the dihydro-compound has been absorbed (for 5 grams this takes fifteen to twenty minutes). The *dihydrosantonin*, $C_{15}H_{20}O_3$, so obtained, has m. p. 148—150°, $[a]_D + 23°$ (in 2·106% alcoholic solution), and gives with alcoholic potassium hydroxide a yellow solution having a green fluorescence. It yields a *semicarbazone*, $C_{16}H_{23}O_3N_3$, which forms microscopic needles, m. p. 238—239°.

When the hydrogenation is continued until a further equal amount of hydrogen has been absorbed, a *tetrahydrosantonin*, $C_{15}H_{22}O_3$, is obtained; it forms colourless laminæ, m. p. 154—155°, $[a]_D + 61\cdot5°$ (in 2·234% alcoholic solution). This substance does not become yellow when exposed to light, and is stable towards permanganate; it yields no coloration with potassium hydroxide.   R. V. S.

Combination of Phenolcarboxylic Acids. III. FERDINAND MAUTHNER (*J. pr. Chem.*, 1913, [ii], 87, 409—415).—A continuation of previous work (A., 1911, i, 725; 1912, i, 267).

Methyl p-3:5-*dimethoxybenzoyloxybenzoate*, prepared by shaking an ethereal solution of 3:5-dimethoxybenzoyl chloride with methyl *p*-hydroxybenzoate dissolved in aqueous sodium hydroxide, crystallises in colourless needles, m. p. 91—92°. *Methyl* m-3:5-*dimethoxybenzoyloxybenzoate*, from methyl *m*-hydroxybenzoate, has m. p. 66—67°.

Methyl m-3:5-*dimethoxybenzoyloxy*-p-*methoxybenzoate*, from 3:5-dimethoxybenzoyl chloride and methyl vanillate, has m. p. 89—90°.

Methyl 2-(3′:5′)-*dimethoxybenzoyloxy*-3-*naphthoate*, from methyl 2-hydroxy-3-naphthoate, has m. p. 119—120°.

3:4:5-Trimethoxybenzoyl chloride reacts with methyl *m*-hydroxybenzoate, yielding *methyl* m-3:4:5-*trimethoxybenzoyloxybenzoate*, m. p. 143—144°, and with methyl 2-hydroxy-3-naphthoate to form *methyl* 2-(3′:4′:5′)-*trimethoxybenzoyloxy*-3-*naphthoate*, m. p. 149—150°.

Methyl m-4-*methoxybenzoyloxybenzoate*, prepared from anisoyl chloride and methyl *m*-hydroxybenzoate, has m. p. 79—80°.

All the compounds described above crystallise in colourless needles.

The 3:4:5:2′:6′-pentamethyl ether of dimethyl gallate (A., 1911, i, 725) has m. p. 173—174°.   F. B.

Tetra-alkylation of *cyclo*Hexanone and β-Methyl*cyclo*hexanone and Trialkylation of Menthone. ALBIN HALLER (*Compt. rend.*, 1913, 156, 1199—1206. Compare A., 1908, i, 987; 1909, i, 108, 654; 1910, i, 219, 300; 1912, i, 269).—By the use of sodamide as condensing agent, all the hydrogen atoms attached to the two carbon atoms adjacent to the ketone group in the substituted or non-substituted *cyclo*hexanones can be substituted by alkyl groups, chiefly methyl and allyl, condensation of the *cyclo*hexanone on itself taking place to a certain extent at the same time. This latter condensation is increased if the methyl iodide is replaced by its higher homologues for substitution. The tetra-, penta-, and hexa-alkyl*cyclo*hexanones so obtained give neither oximes nor semicarbazones. The substitution is performed by dissolving the ketone (1 mol.) in anhydrous ether, or preferably toluene in some cases, adding the sodamide (1 mol.) in fine powder, and when all action has ceased adding the alkyl iodide in theoretical quantity. On the crude product obtained by treatment with water and then drying, this treatment is repeated two or three times. By this means the following compounds have been prepared:

1:1:3:3-*Tetramethylcyclohexan-2-one*, $CH_2\!\!<^{CH_2\cdot CMe_2}_{CH_2\cdot CMe_2}\!\!>CO$, b. p. 185—186°, $D^{17\cdot5}$ 0·8936, n_D^{18} 1·447, which on reduction with sodium

and alcohol gives the corresponding *alcohol*, b. p. 195—197°/767 mm., D^{17} 0·9001, n_D^{17} 1·455, giving a *phenylurethane*, m. p. 97—98°.

Attempts to prepare the ethyl derivatives by similar methods gave a mixture of small quantities of mono- and di-ethyl derivatives and a large amount of other condensation products.

1 : 1 : 3 : 3 - *Tetra-allylcyclohexan-2-one*, b. p. 170—171°/18 mm., D^{17} 0·9490, n_D^{16} 1·4920, giving on reduction the secondary *alcohol*, b. p. 171—173°/15 mm., D^{15} 0·9523, n_D^{17} 1·4975, which gave no phenylurethane.

1 : 2 : 2 : 4 : 4-Pentamethyl*cyclo*hexan-3-one (compare A., 1905, i, 214, 602) was prepared in an active and inactive form. The active ketone had b. p. 201—202°/765 mm., 93—94°/23 mm., D^{20} 0·8979, $n_D^{17·5}$ 1·4515, $[a]_D$ +24°0′, and gave the corresponding *alcohol*, b. p. 210—212°/767 mm., giving a *phenylurethane*, m. p. 105—106°. The inactive ketone had b. p. 202—203°/765 mm., D^{18} 0·8997, $n_D^{17·5}$ 1·4553, and gave the *alcohol*, m. p. 45°, b. p. 213—214°/767 mm., yielding a *phenylurethane*, m. p. 127°.

1-*Methyl*-2 : 2 : 4 : 4-*tetra-allyl*cyclo*hexan-3-one*, b. p. 165—169°/12 mm., D^{15} 0 954, $[a]_D$ +36°17′, on reduction yields the corresponding *alcohol*, b. p. 187—189°/25 mm., D^{17} 0·9613, $n_D^{16·5}$ 1·5054, $[a]_D$ -9°52′, which yields no phenylurethane.

The alkylation of the menthones in order to pass beyond the mono-alkyl stage had to be carried out in toluene as a solvent. The products so obtained were :

Dimethylmenthone, b. p. 108—109°/14 mm., which on reduction gave the *alcohol*, b. p. 245—247°, $[a]_D$ +3°23′, yielding a *phenylurethane*, m. p. 90—91°. Attempts to prepare trimethylmenthone were not successful.

Diallylmenthone has b. p. 146—147°/13 mm., $[a]_D$ +25°50′.

Triallylmenthone has b. p. 166—167°/14 mm., $[a]_D$ +6°40′.   W. G.

Arylsulphonylacetones, Arylsulphonylacetophenones, and Cyanobenzylarylsulphones. Julius Troger and O. Beck (*J. pr. Chem.*, 1913, [ii], 87, 289—311. Compare this vol., i, 169).—A number of arylsulphonylacetophenones, $SO_2R·CH_2·COPh$, and aryl-sulphonylacetones, $SO_2R·CH_2·COMe$, have been prepared by the inter-action of the sodium salts of arylsulphinic acids with ω-chloro-acetophenone and chloroacetone respectively. They resemble the aryl-sulphonylacetonitriles described previously (A., 1905, i, 336, 870), in that they dissolve in aqueous alkali hydroxides, and are reprecipitated un-changed by mineral acids. The mobility of the methylene hydrogen atoms in the arylsulphonyl-ketones is, however, not so great as in the case of the arylsulphonylacetonitriles, since condensation products with amyl nitrite and aromatic aldehydes could not be obtained.

Attempts to prepare arylsulphonylacetophenones by the action of magnesium phenyl bromide on the corresponding arylsulphonyl-acetonitriles proved unsuccessful, the latter compounds being recovered from the reaction unchanged. Acetonitrile and phenylacetonitrile readily react with magnesium phenyl bromide, yielding acetophenone and deoxybenzoin respectively. In the case of chloroacetonitrile, which should give rise to ω-chloroacetophenone, no definite compound

could be isolated from the reaction product. A similar retarding influence of the arylsulphonyl group has been observed with the arylsulphonylacetophenones, which do not react with organo-magnesium compounds, whereas acetophenone readily reacts with magnesium phenyl bromide and magnesium methyl iodide, yielding diphenyl-methylcarbinol and phenyldimethylcarbinol respectively.

o-*Methoxybenzenesulphonylacetone*, OMe·C_6H_4·SO_2·CH_2·COMe, prepared by heating sodium o-methoxybenzenesulphinate with chloroacetone in alcoholic solution, forms white, prismatic needles, m. p. 65°, and yields an *oxime*, m. p. 160·5°.

p-*Ethoxybenzenesulphonylacetophenone*, obtained from sodium p-ethoxybenzenesulphinate in a similar manner, crystallises in white needles, m. p. 67·5°; the *oxime* forms leaflets, m. p. 127°. The following compounds were prepared by heating ω-chloroacetophenone with the sodium salts of arylsulphinic acids in alcoholic solution: *benzenesulphonylacetophenone*, SO_2Ph·CH_2·COPh, which crystallises in white needles, m. p. 96°, and forms an *oxime*, m. p. 134°, a *semicarbazone*, m. p. 194·5°, and a *phenylhydrazone*, yellow needles, m. p. 170°; p-*chlorobenzenesulphonylacetophenone*, white needles, m. p. 132—133° (*oxime*, m. p. 131—132°), a-*naphthalenesulphonylacetophenone* forms white needles, m. p. 89°, and yields an *oxime*, m. p. 173°, and a *phenylhydrazone*, yellow, prismatic columns, m. p. 191—192°; p-*toluenesulphonylacetophenone*, m. p. 110° (*semicarbazone*, m. p. 208·5°); o-*methoxybenzenesulphonylacetophenone* forms stout, prismatic crystals, m. p. 79°, and yields a *phenylhydrazone*, crystallising in yellow prisms, which become yellowish-red at 165°, m. p. 167·5°; p-*ethoxybenzenesulphonylacetophenone*, white, prismatic needles, m. p. 130° (*oxime*, m. p. 150°).

ω-*Benzenesulphonyl*-p-*toluonitrile*, SO_2Ph·CH_2·C_6H_4·CN, obtained by the interaction of ω-chloro-p-toluonitrile and sodium benzenesulphinate in alcoholic solution, crystallises in white needles, m. p. 204·5°. The following sulphones were prepared in a similar manner: ω-p-*chlorobenzenesulphonyl*-p-*toluonitrile*, m. p. 148·5°; ω-p-*toluenesulphonyl*-p-*toluonitrile*, prismatic needles, m. p. 211°; ω-a-*naphthalenesulphonyl*-p-*toluonitrile*, m. p. 162·5°; o-*methoxybenzenesulphonyl*-p-*toluonitrile*, m. p. 121°; ω-p-*ethoxybenzenesulphonyl*-p-*toluonitrile*, m. p. 164°. The above-mentioned sulphones differ from the arylsulphonyl-ketones and nitriles in being insoluble in aqueous alkali hydroxides.   F. B.

The Friedel-Crafts Reaction. VI. GUSTAV HELLER (*Ber.*, 1913, **46**, 1497—1504. Compare A., 1912, i, 357, 358; etc.).—It has already been shown (A., 1912, i, 358; 1908, i, 994) that, whereas, o- and p-chlorotoluenes react normally with phthalic anhydride in the presence of aluminium chloride, the three bromotoluenes behave anomalously, yielding the same o-bromotoluoylbenzoic acid. The behaviour of the chloro- and bromo-toluenes with benzoyl chloride and aluminium chloride has therefore now been investigated.

[With LEOPOLD BUB.]—Benzoyl chloride was introduced into a well cooled mixture of o chlorotoluene and aluminium chloride, and the mixture subsequently warmed; the product was a *phenyl chlorotolyl ketone*, C_6H_3MeCl·COPh, colourless leaflets, m. p. 82—83°, which

was oxidised by chromium trioxide in acetic acid solution to a *chlorobenzophenonecarboxylic acid*, leaflets, m. p. indistinct at 187°. In a similar manner *p*-chlorotoluene gave rise to an isomeric *phenyl chlorotolyl ketone*, m. p. 35—36°, by the oxidation of which no characteristic acid could be obtained.

p-Bromotoluene, as also the *m*-isomeride, again exhibit anomalous behaviour, producing under similar conditions to the above only uncrystallisable oils, which from their inconstant b. p. must be mixtures caused probably by a wandering of the substituent groups during the reaction. On the other hand, *o*-bromotoluene gave an oily product which partly crystallised to a yellow solid, m. p. 173°, a *phenyl hydroxytolyl ketone*, $OH \cdot C_6H_3Me \cdot COPh$; this is the first case of the replacement of bromine by hydroxyl in a Friedel-Crafts reaction, and as the primary reaction occurred in the absence of water, the hydroxy-compound must have been produced from an intermediate substance during the subsequent treatment.

The interaction of phenol, aluminium chloride, and benzoyl chloride yielded a mixture of 4-hydroxydiphenyl-ketone and phenyl benzoate. *o*-Cresol gave the same phenyl hydroxytolyl ketone (*acetyl* derivative, needles, m. p. 68—69°) as was obtained in the above reaction with *o*-bromotoluene. *m*-Cresol produced a yellow oil, from which could be separated two isomeric *phenyl hydroxytolyl ketones*, yellow crystals, m. p. 63°, and colourless needles, m. p. 129° (compare Bartolotti, A., 1901, i, 36), respectively, and *m*-tolyl benzoate. The product obtained with *p*-cresol was exclusively *p*-tolyl benzoate.

It has already been shown that phthalic anhydride condenses with β-chloronaphthalene in the presence of aluminium chloride with the formation of an acid, which by dehydration gives a ketone (Heller and Grunthal, A., 1912, i, 357). Oxidation of the ketone by a mixture of potassium permanganate and nitric acid yielded anthraquinone-2 : 3-dicarboxylic acid; the ketone must therefore be of the structure

2-chloro-6 : 7-phthaloylnaphthalene, $C_6H_4 {<} {\overset{CO}{\underset{CO}{}}} {>} C_{10}H_5Cl$, and the acid must be an *o*-β-chloronaphthoylbenzoic acid, $C_{10}H_6Cl \cdot CO \cdot C_6H_4 \cdot CO_2H$.

D. F. T.

The Condensation of 2 : 5-Dimethoxybenzoyl Chloride with Phenolic Ethers. FERDINAND MAUTHNER (*J. pr. Chem.*, 1913, [ii], **87**, 403—409).—An account of the preparation of a number of methoxybenzophenones from 2 : 5-dimethoxybenzoyl chloride and phenolic ethers by means of the Friedel-Crafts reaction.

2 : 5-Dimethoxybenzoic acid is best prepared by methylating *o*-resorcylic acid with methyl sulphate and aqueous sodium hydroxide at the ordinary temperature; the chloride has b. p. 157—158°/16 mm., m. p. 35—36° (compare Kostanecki and Lampe, A., 1908, i, 442); the *amide* and *anilide* crystallise in lustrous, silky needles, m. p. 148—149° and 124—125° respectively.

3 : 5 : 4'-*Trimethoxybenzophenone*, prepared from the chloride and anisole in carbon disulphide solution in the presence of aluminium chloride, forms colourless needles, m. p. 97—98°.

3 : 5 : 3′ : 4′-*Tetramethoxybenzophenone*, obtained from veratrole in a similar manner, crystallises in colourless needles, m. p. 114—115°.

3 : 5 : 2′ : 4′-*Tetramethoxybenzophenone*, from resorcinol dimethyl ether, forms needles, m. p. 73—74°.

2′-*Hydroxy*-3 : 5 : 3′ : 4′-*tetramethoxybenzophenone*, prepared from pyrogallol trimethyl ether, forms light yellow crystals, m. p. 123—124°.

3 : 5 : 2′ : 4′ : 6′-*Pentamethoxybenzophenone*, from phloroglucinol trimethyl ether, crystallises in small needles, m. p. 132—133°.   F. B.

Benzilbenzoin. ALFRED BENRATH (*J. pr. Chem.*, 1913, [ii], **87**, 416—422).—Klinger's benzilbenzoin (A., 1886, 888) is produced by the photochemical reduction of benzil in solutions of aldehydes and aromatic hydrocarbons (compare Benrath, A., 1906, i, 535). When heated alone or in solution it decomposes into benzoin and benzil. Owing to this decomposition it has no definite m. p. ; it begins to soften at 86°, and is completely fused at a temperature dependent on the rate of heating, the highest recorded temperature being 143°. A mixture of benzil and benzoin in equimolecular proportions shows the same m. p. interval as benzilbenzoin, and hence the latter compound must have the formula COPh·COPh,COPh·CHPh·OH.

The fusion curve of mixtures of benzoin and benzil is recorded ; it shows a eutectic point at 86°.   F. B.

Preparation of Derivatives of *p*-Benzoquinone. FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R.-P. 257834).—When *p*-benzoquinone, its homologues, or halogen derivatives are boiled with naphthylaminesulphonic acids in the presence of sodium acetate they yield compounds which, after further condensation with zinc chloride (or concentrated sulphuric acid), dye wood or silk in reddish-violet to blue shades.

The tinctorial properties of the *disulphonaphthylaminodichlorobenzoquinones* thus obtained from chloroanil with β-naphthylamine-5- and -8-sulphonic acids are tabulated in the original.   F. M. G. M.

Preparation of a Derivative of Anthraquinone. FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R-P. 258439).—When 1-aminoanthraquinone (10 parts) dissolved in 500 parts of cooled 60% sulphuric acid is slowly treated with sodium chlorate (2 parts) dissolved in 40 parts of the same solvent, a blue coloration is rapidly developed, followed by the separation of a deep blue precipitate which can be purified by boiling with alcohol and crystallisation from nitrobenzene.

This *compound* is not apparently obtained when other oxidising agents are employed; it gives a colourless "vat" with alkaline hyposulphite, and on further reduction with stannous chloride furnishes leucoquinizarin.   F. M. G. M.

Behaviour of Dibenzoyl-1 : 5-dibenzylaminoanthraquinone with Alkaline Sodium Hyposulphite. CHRISTIAN SEER (*Monatsh.*, 1913, **34**, 579).—A correction; dibenzoyl-1 : 5-dibenzylaminoanthraquinone is not reduced by alkaline hyposulphite as previously stated (A., 1912, i, 571).   D. F. T.

Preparation of Di- and Tri-anthrimides of the β-Anthra-quinone Series. FARBWERKE VORM. MEISTER, LUCIUS & BRUNING (D.R.-P. 257811).—It is found that dianthrimide can be prepared by heating together β-aminoanthraquinone (22·3 parts), β-chloroanthra-quinone (24·2 parts), and potassium carbonate (7 parts) at 300°, whilst trianthrimide, a brown powder, is obtained in a similar manner from 2 : 6-diaminoanthraquinone (1 mol.) and β-chloroanthraquinone (2 mols.) or from β-aminoanthraquinone and 2 : 7-dichloroanthraquinone.

F. M. G. M.
[**Preparation of an Anthra-quinone Derivative.**] R. WEDEKIND & Co. (D.R.-P. 257832).—The com-pound (annexed formula) is obtained by the condensation of 1-chloro-2-hydroxyanthraquinone; it crystallises from nitrobenzene, does not melt at 300°, and furnishes cotton dyes.

F. M. G. M.

Attempts to Prepare a 3 : 4 : 3′ : 4′-Tetrahydroxy-1 : 1′-di-anthraquinonyl. CHRISTIAN SEER and KARL EHRENREICH (Monatsh., 1913, 34, 631—648).—An unsuccessful endeavour to prepare a tetra-hydroxyanthraquinonyl with the hydroxyl groups disposed in the same positions as in alizarin (compare Scholl and Seer, A., 1911, i, 453).

4-Aminoalizarin proved useless as a starting point, as it was found impossible to convert this through the diazo-compound into 4-iodo-alizarin.

Alizarin dimethyl ether (1 : 2-dimethoxyanthraquinone) can be nitrated at 0° by potassium nitrate and sulphuric acid, or by nitric acid (D 1·51), with the formation of 4-nitro-1 : 2-dimethoxyanthra-quinone, deep yellow, prismatic needles, which give a red solution in sulphuric acid. This substance when suspended in aqueous ammonium sulphide at 100° is reduced to 4-amino-1 : 2-dimethoxyanthraquinone, deep red needles, m. p. 182—185°, the hydrochloride of which, after diazotisation in acetic acid and treatment with aqueous potassium iodide solution, is converted into 4-iodo-1 : 2-dimethoxyanthraquinone, yellowish-brown, prismatic needles, m. p. 172—174°. The position of the iodo-group in this, and therefore of the nitro group in the earlier substance, is proved by its red solution in sulphuric acid changing to a deep green (due to the formation of 3 : 4 : 3′ : 4′-tetramethoxy-μ-benzo-dianthrone, $CO\left\langle\begin{array}{c}C_6H(OMe)_2\\ C_6H_4\end{array}\right\rangle C=C\left\langle\begin{array}{c}C_6H(OMe)_2\\ C_6H_4\end{array}\right\rangle CO$; compare Scholl and Mansfeld, A., 1910, i, 494) when treated with copper powder. Attempts to achieve the desired aim of the research by heating the iodo-compound with aluminium chloride at 150—160° eliminated only two methoxy-groups with the formation of 4 : 4′ di-hydroxy-3 : 3′-dimethoxy-1 : 1′-dianthraquinonyl,

$C_6H_4\left\langle\begin{array}{c}CO\\ CO\end{array}\right\rangle C_6H(OH)(OMe)—C_6H(OH)(OMe)\left\langle\begin{array}{c}CO\\ CO\end{array}\right\rangle C_6H_4,$
microscopic, orange-red prisms, which sublimes above 320°; it dissolves in alkali to a bluish-violet colour, which changes to red on addition of sodium hyposulphite.

Another attempt to achieve the object of the investigation was made by Scholl and Seer's method with phthalic anhydride (*loc. cit.*). For this purpose veratrole was nitrated to 4-nitro-1 : 2-dimethoxy-benzene, and this was reduced by tin and hydrochloric acid. Reduction at water-bath temperature produced, however, a halogen-substituted amino-compound, 2(?)-*chloro*-4 : 5-*dimethoxyaniline*, colourless needles, m. p. 72—73°; *hydrochloride*, needles, which slowly decompose above 150°; this was converted by diazotisation and potassium iodide into 2(?)-*chloro*-1-*iodo*-4 : 5-*dimethoxybenzene*, colourless needles, m. p. 69—70°, which, on heating with copper powder at 270—280° in an atmosphere of carbon dioxide, was converted into 6(?) : 6′(?)-*dichloro*-3 : 4 : 3′ : 4′-*tetramethoxydiphenyl*, colourless needles, m. p. 160—161°, soluble in sulphuric acid to a green solution. The successful reduction of nitrodimethoxybenzene to 4 : 5-dimethoxyaniline could be effected by the gradual addition of tin to the suspension of the solid in hydrochloric acid, and the product could then be converted into 1-iodo-4 : 5-dimethoxybenzene, but it was found that this substance can be more conveniently obtained by the action of iodine and mercuric oxide on an alcoholic solution of veratrole at the ordinary temperature. When heated with copper powder at 260°, the iodo-compound is converted into 3 : 4 : 3′ : 4′-*tetramethoxydiphenyl*, colourless, silky needles, m. p. 130—132°, the solution of which in sulphuric acid passes slowly from golden-yellow to emerald-green. It was not found possible to prepare from the last substance a tetrahydroxydianthraquinonyl of the desired structure; heating with phthalic anhydride and aluminium chloride yielded a complex, deep blue mixture in which the desired substance was probably present. D. F. T

Camphor and Phenols. I. Compounds of Camphor with Quinol, Resorcinol, and Catechol. N. N. Efremov (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 348—362).—Thermal and micrographic examination of mixtures of camphor with the three dihydroxybenzenes demonstrates the existence of the three isomeric compounds,

$$C_6H_4(OH)_2, C_{10}H_{16}O,$$
melting without decomposition at 29·0° (ortho) and 11·5° (meta) respectively. The compound with quinol also melts without decomposing, but it does not correspond with a maximum on the melting-point curve.

The dihydroxybenzenes form with camphor solid solutions containing for resorcinol, 20·0%, for catechol, 15%, and for quinol, 37·5% by weight of camphor.

The eutectic mixtures formed by camphor with the dihydroxybenzenes are viscous liquids prone to supercooling, and crystallise slowly only at −15° to −20° in spherolites having a fine granular structure. In each case the eutectic mixture contains 66·6 mols.% of camphor and has a characteristic yellow colour. T. H. P.

The Constitution of "Terpineol-35°-glycuronic Acid." Juno Hamalainen (*Biochem. Zeitsch.*, 1913, **50**, 220—222).—The conjugation

of the terpineol with glycuronic acid takes place with the scission of
water. The author has administered the alcohol to rabbits, and
succeeded in isolating the acid from the urine in the form of the
anhydrous sodium salt, $C_{16}H_{25}O_7Na$. The urine was first precipitated
with normal and then with basic lead acetate. The precipitate from
the latter contained the lead salt of the glycuronate ; from this the
barium salt was obtained, and was crystallised from a water-alcohol-
ether mixture. By treatment of this with the theoretical amount of
sodium sulphate, a crystalline hydrated sodium salt was prepared.

Essential Oil of Crithmum maritimum (Linn.) from Sardinia.
LUIGI FRANCESCONI and E. SERNAGIOTTO (*Atti R. Accad. Lincei*, 1913, [v],
22, i, 231—237, 312—317).—The oil of this plant from Sardinia
differs from that from a French source described by Delépine, A., 1909,
i, 642 ; 1910, i, 401).—Details are given of the properties of various
fractions of the oil and of the yield from different parts of the plant.
The chemical investigation of the oil shows that the only constituents
common to both are dillapiole and *p*-cymene. The *d*-pinene, dipentene,
and thymol methyl ether of the French oil are not present in the
other, which contains, however, β-phellandrene and a new terpene, to
which the name *crithmene* is applied. There is also a white *substance*
crystallising in leaflets, m. p. 63°, which has the properties of a paraffin.
Crithmene yields an *a-nitrosochloride*, which crystallises in laminæ,
m. p. 101—102°, and a β-nitrosochloride, $C_{10}H_{16}ONCl$, which forms
quadratic plates, m. p. 103—104° ; both are optically inactive. The
tetrabromide is oily. The *nitrolpiperides* prepared from the nitroso-
chlorides have m. p. 138°. The compound with *benzylamine* has m. p.
103—104°. When the nitrosochloride is decomposed with alcoholic
potassium hydroxide and distilled in steam, a white, micro-crystalline
substance, m. p. 131°, is left ; it contains nitrogen, and when heated
with hydrochloric acid does not reduce Fehling's solution. When the
decomposition of the nitrosochloride is effected under somewhat
different conditions, a yellow, stable, crystalline *substance*, m. p.
53—54°, is obtained. The fractions of the oil, b. p. 178--179°, gave a
crystalline *nitrosite*, m. p. 89—90°. The new terpene yields a dihydro-
chloride, m. p. 52°, identical with that of terpinene.   R. V. S.

Constitutional Formula of Orithmene.   III. LUIGI
FRANCESCONI and E. SERNAGIOTTO (*Atti R. Accad.
Lincei*, 1913, [v], 22, i, 382—386. Compare pre-
ceding abstract).—After reviewing the various formulæ
possible for this substance, the authors believe it to
be $\Delta^{1,7-4,8}$-p-*menthadiene* (annexed formula),
This constitution accords with the physical and
chemical properties of the substance.   R. V. S.

Depolymerisation and Transformation of Caoutchouc. G.
STAFFORD WHITBY (*Zeitsch. Chem. Ind. Kolloids*, 1913, 12, 190—193.
Compare this vol., i, 575).—It has been found that certain samples of

caoutchouc undergo a form of degenerative change in which the caoutchouc is converted into resin. During this process the original "tackiness" of the caoutchouc disappears, and the samples assume a smooth, polished appearance and become brittle. The extent to which the transformation occurs may be seen by the fact that a sample of such caoutchouc, which gave 9·9% of resin six weeks after collection, was found to contain 78% at the end of sixteen weeks.

The transformation is accompanied by increase in weight as a result of oxidation. A sample containing 19% of resin was found to have increased in weight to the extent of 4·38% at the end of three weeks. When kept in an air-bath at 100°, the increase in weight during the same period was 1·63%. The change goes on therefore at 100°, but at a slower rate. It is shown that the degenerative process has no connexion with the action of light, and that it is probably due to abnormal conditions, the origin of which must be sought for in the living plant. In this connexion, the function of the latex in the plant is obviously of primary importance, and in the later part of the paper the author puts forward the view that the latex represents a reserve supply of food which is rendered available by the action of an oxydase, and that the degenerative change of the extracted latex bears some relation to this oxidation process. H. M. D.

Chemistry of Caoutchouc. III. Additive Compounds of Caoutchouc with Halogen Hydracids and Halogens. Friedrich W. Hinrichsen, Hermann Quensell and Erich Kindscher (*Ber.*, 1913, **46**, 1283—1287).—Attempts have been made to obtain non-colloidal derivatives from caoutchouc, but without success. Cold benzene or chloroform solutions of pure Para caoutchouc have been saturated with hydrogen chloride, bromide or iodide, but the substances obtained on dilution with light petroleum still showed the Brownian movement when viewed in benzene solution under the ultra-microscope. The analyses were somewhat low for the *dihydrochloride*, $C_{10}H_{16},2HCl$, a white powder, and the *dihydrobromide*, a white powder, which still retained bromine after boiling with alcoholic potassium hydroxide, whilst the *hydriodide*, $C_{10}H_{16},HI$, was a colourless, sticky substance.

Chlorine in cold chloroform gave rise to substitution as well as addition, a white *powder*, which after repeated precipitation from alcohol gave numbers approximating to the formula $C_{10}H_{11}Cl_6$ (compare Gladstone and Hibbert, T., 1888, **53**, 679). The bromination of caoutchouc in ice-cold chloroform is practically independent of the amount of bromine used or of the time, and leads to the tetrabromide. The application of the process to the estimation of caoutchouc will be published later. J. C. W.

Chemistry of Caoutchouc. IV. Action of Iodine on Caoutchouc. Friedrich W. Hinrichsen and Richard Kempf (*Ber.*, 1913, **46**, 1287—1291).—Weber (A., 1900, i, 354) described a compound, $C_{20}H_8I_6$, which he obtained by the action of iodine on caoutchouc in cold chloroform. Such a great absorption of iodine could not be obtained in the present experiments, but it is found that

the process is a photochemical reaction, and, as such, is almost independent of temperature. Small portions of a 1% solution of iodine were quickly rendered colourless in sunlight on addition to a 1% solution of caoutchouc in carbon disulphide, when the end-point corresponded with the absorption of one atom of iodine by two molecules of hydrocarbon. A specific action of short-waved light could not be determined, but the volume of air over the liquid seemed to be of importance. On filtering the bleached and somewhat evaporated solution into light petroleum, a white *powder* was obtained which approximated to the formula $C_{20}H_{27}O_7I$. It gave up iodine when kept, but in an iodine atmosphere in the dark it rapidly absorbed the halogen, and after three weeks had increased in weight by 170%. The glistening black *product* approximated therefore to $C_{20}H_{27}O_7I_8$.   J. C. W.

Chemistry of Caoutchouc. V. Treatment of Caoutchouc with Sulphur Chloride and Sulphur. FRIEDRICH W. HINRICHSEN and ERICH KINDSCHER (*Ber.*, 1913, **46**, 1291—1297. Compare A., 1910, i, 330).—The cold vulcanisation of caoutchouc was studied by mixing a constant weight of caoutchouc in dry benzene with varying amounts of sulphur chloride and, after some time, measuring the excess of reagent. The end-product was found to agree with the formula $(C_{10}H_{16})_2S_2Cl_2$. The action of sulphur was first studied in naphthalene solution, but now systematic experiments have been carried out at 170° in cumene. The product is repeatedly extracted with acetone, when the resulting hard, brown powder is found to contain a proportion of sulphur which approaches to 32% more and more as the initial concentration of sulphur and the time of heating are increased. This corresponds with $C_{10}H_{16}S_2$ (compare Spence and Young, A., 1912, i, 706), and since the substance does not absorb bromine it is regarded as a definite compound. If the uncombined sulphur is extracted by alcoholic sodium hydroxide, however, the product contains less than 26% of sulphur.   J. C. W.

Vulcanisation of Caoutchouc. II. GUSTAV BERNSTEIN (*Zeitsch. Chem. Ind. Kolloide*, 1913, **12**, 193—196. Compare A., 1912, i, 1006).—The "depolymerisation" of caoutchouc under the influence of a rise of temperature, mechanical treatment, and ultra-violet light has been investigated by measurements of the viscosity of xylene solutions of the caoutchouc. Samples of caoutchouc which in xylene solution show widely different viscosities are found to give the same value for the viscosity when subjected to the depolymerising action of heat, light or mechanical treatment until the viscosity has become constant. This result would seem to show that the state of aggregation which is finally attained is independent of the special characteristics of the original caoutchouc.

From measurements of the viscosity of xylene solutions of Hevea Plantation caoutchouc which was heated for five hours at temperatures between 30° and 100°, it has been found that rapid depolymerisation begins at 60—70°. This temperature was found to vary somewhat when caoutchoucs from other sources were examined in the same way.

If sulphur is mixed with the caoutchouc before exposure to ultraviolet light, it is found that vulcanisation takes place as a result of the light treatment. Vulcanisation also occurs when a xylene solution containing caoutchouc and sulphur is exposed to the short-waved rays.

H. M. D.

Synthetic β-Glucosides of the Terpene Alcohols. Juho HÄMÄLÄINEN (*Biochem. Zeitsch.*, 1913, **50**, 209—219).—By the method already described (this vol., i, 497), the following substances were prepared. *Sabinol-tetra-acetyl*-d-*glucoside*, $C_{24}H_{34}O_{16}$, long, glistening needles, m. p. 121° (corr.). *Sabinol-glucoside*, $C_{16}H_{26}O_6,H_2O$, m. p. 65—68° (corr.), $[a]_D^{20}$ of anhydrous substance − 33·60°. This glucoside is hydrolysed by emulsin. d-*Camphenilol-tetra-acetyl*-d-*glucoside*,

$$C_{23}H_{34}O_{10},$$

long, glistening needles, m. p. 128·5—130° (corr.). d-*Camphenilol*-d-*glucoside*, $C_{15}H_{26}O_6,H_2O$, m. p. 95—98° (corr.), $[a]_D^{20}$ of anhydrous substance − 25·47°. This is slowly hydrolysed by emulsin. l-*Fenchyl-tetra-acetyl*-d-*glucoside*, $C_{24}H_{36}O_{10}$, m. p. 119—121·5° (corr.). l-*Fenchyl*-d-*glucoside*, $C_{16}H_{28}O_6$, with $[a]_D^{20}$ − 36·57°. The substance with water of crystallisation has m. p. 124—127° (corr.), m. p. of anhydrous glucoside 130—132·5° (corr.), sinters at 122°. It is slowly hydrolysed by emulsin. r-*Borneol-tetra-acetyl*-d-*glucoside*, $C_{24}H_{80}O_{10}$, m. p. 119·5—122·5° (corr.). r-*Borneol*-d-*glucoside*, $C_{16}H_{28}O_6$, with $[a]_D^{20}$ − 32·99°, m. p. of substance with water of crystallisation 133—134·5° (corr.), and of anhydrous substance 143—144·5° (corr.), sinters at 132°. It is very slowly hydrolysed by emulsin. l-*Borneol-tetra-acetyl*-d-*glucoside*, $C_{24}H_{36}O_{10}$, m. p 124° (corr.). l-*Borneol*-d-*glucoside*, $C_{16}H_{28}O_6,H_2O$, m. p. 132·5—133·5° (corr.). The anhydrous substance has m. p. 138—141° (corr.), and $[a]_D^{20}$ − 60·12°. It is fairly readily hydrolysed by emulsin.

S. B. S.

Helleborein. ERNST SIEBURG (*Arch. Pharm.*, 1913, **251**, 154—183. Compare Thaeter, A., 1898, i, 39).—Helleborein is shown to belong to the group of saponins. On hydrolysis it yields acetic acid, dextrose, arabinose, and two sapogenins called "acid" and "neutral" helleboretin respectively, which are closely related and probably contain a terpene-like nucleus. As the result of pharmacological experiments, the author suggests that helleborein is not a suitable substitute for digitalin in medicine.

Helleborein (Merck), $(C_{21}H_{34}O_{10})_2$, $[a]_D^{20}$ − 2·8°, is amorphous; it furnishes an *acetyl* derivative, $(C_{21}H_{29}O_{10}Ac_5)_2$, m. p. 129—130°, which separates from alcohol in yellow scales, and on treatment with baryta yields a *product*, which is helleborein less one acetyl group (see below), and forms a pale yellow powder. *Benzoylhelleborein*, $(C_{21}H_{29}O_{10}Bz_5)_2$, m. p. 142°, is a snow-white, amorphous substance. When boiled with baryta solution, helleborein loses one molecule of acetic acid, and the latter acid is also formed when the glucoside is treated with bromine water. On hydrolysis, by boiling with dilute sulphuric acid, 1 mol. of acetic acid and 2 mols. each of dextrose and arabinose are formed. The other products of hydrolysis are *acid helleboretin* and *neutral helleboretin*. The former has the formula $C_{21}H_{86}O_7$, and appears to be a lactone, since it does not decompose carbonates and is not completely

soluble in alkali hydroxide solutions. Its behaviour on treatment with melted potassium hydroxide or nitric acid, and on distillation with zinc dust is recorded. Neutral helleboretin, $C_{15}H_{24}O_3$, is a greenish-black mass. The deacetylated helleborein referred to above does not produce hæmolysis, and is not poisonous to rabbits.   T. A. H.

Structure of the Natural Saponins. ANNE W. VAN DER HAAR (*Arch. Pharm.*, 1913, **251**, 217—222. Compare A., 1912, i, 885).— The method of investigation previously described (*loc. cit.*) has been applied to guaiacum-saponin, saponin and sapotoxin from Levantine saponaria root, senegin and digitonin, and it is shown that all five of these saponins give the characteristic colour reaction with sulphuric acid. Further, the sapogenins obtained from them by acid hydrolysis, on distillation with zinc dust, yield products which can be separated by steam distillation into terpene-like oils and non-volatile products. The terpene-like oils give a violet coloration with acetic acid and sulphuric acid, whilst the non-volatile substances give the blue (phytosterol) reaction with this reagent. In the case of the products from the sapogenin derived from senegin, these colour reactions are, however, reversed.   T. A. H.

Strophanthic Acid, a Saponin from the Seeds of Strophanthus Gratus. ERNST SIEBURG (*Ber. Deut. pharm. Ges.*, 1913, **23**, 278—290).—The different varieties of *Strophanthus* do not contain more than 0·2% of strophanthic acid.

The mother liquors obtained in the manufacture of *g*-strophanthin formed the starting material for the isolation of the acid. They were neutralised, diluted with water, freed from fat, and acidified with hydrochloric acid. The crude precipitated acid was repeatedly washed with water, and then precipitated with basic acid acetate; the precipitate was washed with water, and extracted with boiling 80% alcohol; the extract was diluted with water and shaken with *iso*butyl alcohol; from its solution in the latter medium, *g*-strophanthic acid was precipitated by addition of ether as a white, amorphous, voluminous mass, which was acid towards litmus, and readily dissolved in aqueous alkali carbonate and hydrogen carbonate solutions.

g-Strophanthic acid is precipitated from its aqueous solution by phosphotungstic, phosphomolybdic, and picric acids, but not by tannin. It has only feeble reducing action towards the ordinary reagents. It does not contain a methoxy-group. It yield precipitates with the salts of many heavy metals, such as copper, lead, zinc, ferrous and ferric iron, and barium, but the products do not appear to be definite chemical individuals. The solubility of the free acid appears to depend somewhat on the age of the specimens. Ultimate analysis, titration with sodium hydroxide, and analysis of the *silver* and *lithium* salts lead to the formula $C_{21}H_{34}O_{10}$ for the acid, but determination of molecular weight in glacial acetic acid solution indicates the formula $(C_{21}H_{34}O_{10})_4$.

When hydrolysed with 3% aqueous sulphuric acid, and subsequently with 4% alcoholic hydrochloric acid, strophanthic acid yields dextrose and *strophanthigenin*, $(C_{12}H_{18}O_2)_2,3\frac{1}{3}H_2O$, white needles, m. p. about

291°. The latter is faintly acidic in solution, but does not dissolve even in concentrated alkali. With bromine in glacial acetic acid solution, it yields an uncrystallisable *product*, $C_{12}H_{14}Br_2O_2$. Oxidation with potassium permanganate converts it into a crystalline *acid*, which has not been further investigated.

The following colour reactions are shown by *g*-strophanthic acid, and generally with greater readiness by *g*-strophanthigenin, but are not given by *k*-strophanthin, *g*-strophanthin, or *g*-strophanthidin : (1) a trace of substance gives an immediate yellowish-red coloration, with concentrated sulphuric acid, which gradually changes to an eosine-red with greenish fluorescence ; (2) if a dilute solution of the substance in alcohol is mixed with an alcoholic solution of benzaldehyde and evaporated, the residue gives an immediate bright red coloration with sulphuric acid ; (3) if a trace of the substance is dissolved in acetic anhydride and concentrated sulphuric acid cautiously added, a red ring is formed which rapidly becomes violet, then blue, and finally green ; (4) a saturated alcoholic solution of dextrose or arabinose yields with a trace of substance and concentrated sulphuric acid a red ring which quickly turns to violet ; with furfuraldehyde, under like conditions, a blue to green colour is developed ; (5) if rhamnose is used, as in (4), a permanent, deep cherry-red colour is formed ; (6) a solution of the substance in a mixture of nine parts trichloroacetic acid and one part concentrated hydrochloric acid gradually develops a pale violet colour, which becomes more intense and slightly fluorescent.　　　H. W.

Thiophen Analogues of Triphenylethyl. Moses Gomberg and R. L. Jickling (*J. Amer. Chem. Soc.*, 1913, **35**, 446—447).—Attempts have been made to prepare analogues of triphenylmethyl containing other than exclusively aromatic groups.

Thienyldiphenylcarbinyl chloride has m. p. 81° ; when a solution in benzene is treated with molecular silver, it becomes dark red, and an unsaturated hydrocarbon is produced which absorbs oxygen with formation of the peroxide $(C_4SH_3 \cdot CPh_2)O_2$.

Dithienylphenylcarbinol, m. p. 90°, has been prepared by the Grignard synthesis from ethyl benzoate and thienyl chloride.　E. G.

1 : 4-Dithiens. Treat B. Johnson, Robert C. Moran, and Edward F. Kohmann (*J. Amer. Chem. Soc*, 1913, **35**, 447—452).— Johnson and Moran (A., 1912, i, 913) have found that when 2-benzoyl-methylthiol-4-methyl-1 : 6-dihydro-6-pyrimidone is hydrolysed with concentrated hydrochloric acid, it yields 4-methyluracil together with a crystalline compound containing sulphur. A study of the latter compound has shown that it has the structure $S{<}^{CPh:CH}_{CH:CPh}{>}S$, and it has therefore been designated 2 : 5-diphenyl-1 : 4-dithien. Both this substance and the corresponding 2 : 5-ditolyl compound are yellow, but dissolve in concentrated sulphuric acid to form beautiful purple solutions. Characteristic colorations are also produced by strong nitric acid and by solution of bromine in glacial acetic acid. In this respect the dithiens resemble Fries and Volk's thianthren compounds (A., 1909, i, 406). 1 : 4-Dithien, the parent substance of the compounds now

described, has been obtained by Levi and termed by him biophon (A., 1891, 551).

2 : 5-*Diphenyl*-1 : 4-*dithien*, m. p. 118—119°, crystallises in yellow prisms and is exceedingly stable.

2-p-*Toluoylmethylthiol* 4-*methyl*-1 : 6-*dihydro*-6-*pyrimidone*,

$$NH \underset{CO \underline{\hspace{3.5cm}} OH}{\overset{C(S \cdot CH_2 \cdot CO \cdot C_6H_4Me):N}{<>}} CMe,$$
m. p. 194—195°, obtained by the action of p-chloroacetyltoluene on the sodium salt of 2-thio-4-methyluracil, forms colourless, prismatic crystals. On hydrolysis with 20% hydrochloric acid, it yields 2 : 5-*di-tolyl*-1 : 4-*dithien*, m. p. 137—138°, which crystallises in yellow needles.

E. G.

The Hellebore Group. III. Alkaloids of Delphinium Ajacis. OSKAR KELLER and O. VOLKER (*Arch. Pharm.*, 1913, **251**, 207—216. Compare A., 1910, ii, 887, 888).—This plant yields two new alkaloids, which are characterised.

The alkaloids were isolated from an alcoholic extract of the seeds. *Ajacine*, $C_{15}H_{21}O_4N,H_2O$, m. p. 142—143°, crystallises in colourless needles from dilute alcohol, is alkaline in reaction, and yields salts which are readily soluble and difficult to crystallise. The *hydrochloride*, $B_2,HCl,2H_2O$, m. p. 93°, is amorphous, as is also the *aurichloride*, $B_2,HAuCl_4$, and the *platinichloride*, B_4,H_2PtCl_6. The alkaloid absorbs bromine, contains 3 methoxyl groups, is not esterified by benzoyl chloride or acetic anhydride, does not react with methyl iodide or methyl sulphate, and is not affected by nitrous acid. On oxidation, it furnished a product smelling of butyric or valeric acid, and on distillation with zinc dust yielded a substance having an odour of benzaldehyde. On treatment with cyanogen bromide, it furnished a crystalline *compound*, m. p. 132—133°.

Ajaconine, m. p. 162—163°, forms colourless, glancing prisms, but concordant results could not be obtained on combustion, and crystalline salts could not be prepared. It contains no methoxyl groups. With methyl iodide, a crystalline *methiodide*, m. p. 121°, slender needles, was obtained, which appears to have the formula $C_{18}H_{31}O_2N,HI,H_2O$, whence the formula $C_{17}H_{29}O_2N$ is assigned provisionally to the parent base. The latter may be a secondary base, since it reacts with nitrous acid, forming a substance which gives Liebermann's reaction. Ajaconine also yields an amorphous *dibenzoyl* derivative, from which an amorphous *aurichloride* was prepared.

The behaviour of both alkaloids with the usual precipitants and reagents is described. The seeds also contain other alkaloids, which are amorphous.

T. A. H.

Comparative Solubility of Morphine and Narcotine in Pure or Aqueous Acetone and in Distilled Water. GABRIEL GUÉRIN (*J. Pharm. Chim.*, 1913, [vii], **7**, 438).—One litre of pure anhydrous acetone dissolves at 15°, 1·28 grams of morphine and 41·96 grams of narcotine. In a mixture of equal volumes of acetone and water at 15°, the solubilities are morphine 1·32 grams, and narcotine 0·70 gram

per litre. In distilled water at 15°, the solubilities are morphine, 0·288 gram, and narcotine, 0·10 gram per litre. W. P. S.

*apo*Morphine. I. Supposed Formation of *apo*Morphine on Heating or Keeping Morphine Solutions. MORITZ FEINBERG (*Zeitsch. physiol. Chem.*, 1913, **84**, 363—378).—*apo*Morphine is not formed either on prolonged boiling of morphine, morphine hydrochloride, or liquids containing morphine, such as pantopone, or on keeping such solutions with or without the addition of a nutrient substance. The separations occasionally observed from such solutions are due to traces of the sparingly soluble morphine base. Preparations of *apo*morphine obtained in commerce had the theoretical proportion of chlorine, and agreed as to their optical activity. They are therefore to be regarded as pure. E. F. A.

The Polymorphism of Codeine, Thebaine, and Narcotine; a New Type of Spherolites. PAUL GAUBERT (*Compt. rend.*, 1913, **156**, 1161—1163).—Codeine, thebaine and narcotine, and other alkaloids derived from opium, exhibit the phenomenon of superfusion, become solid without crystallisation, and can be kept in this vitreous state for several months. They are all polymorphic, codeine having five crystalline forms, narcotine three, and thebaine two, varying in stability with the temperature, and they also all present curious spherolitic formations at different temperatures. W. G.

The Structure of Ratanhine. GUIDO GOLDSCHMIEDT (*Monatsh.*, 1913, **34**, 659—664. Compare this vol., i, 71).—The estimation of methyl attached to nitrogen in ratanhine indicates the presence of a methylamino-group in this substance, and it is therefore possible that ratanhine is α-methylamino-β-*p*-hydroxyphenylpropionic acid (methyltyrosine). The m. p. is so indefinite that it is of little use as a comparison with the synthetical substance of this structure (Johnson and Nicolet, A., 1912, i, 585), but the action of iodine on alkaline solutions of ratanhine and of the synthetic substance produces apparently the same di-iodo-compound from each. The probability of the above structure for ratanhine is strongly confirmed by the close resemblance of the base, which is obtained by scission of carbon dioxide, with β-*p*-hydroxyphenylethylmethylamine (Walpole, T., 1910, **97**, 945); the free bases, together with the hydrochlorides and platinichlorides, exhibit a close agreement in m. p. It is therefore to be accepted that ratanhine, which is also known by the names surinamine (Blau, A., 1909, i, 51), geoffroyine, angeline, and andirine, is α-methylamino-β-*p*-hydroxyphenylpropionic acid,

$$OH·C_6H_4·CH_2·CH(NHMe)·CO_2H.$$ D. F. T.

Synthesis of 2:3:4-Trimethylpyrrole and of 2:3:4-Trimethyl-5-ethylpyrrole (Isomeric Phyllopyrroles). HANS FISCHER and AMANDUS HAHN (*Zeitsch. physiol. Chem.*, 1913, **84**, 254—261).—Fischer and Krollpfeiffer (this vol., i, 93) have described the formation of the phthalide of a trimethylpyrrole by treating tetramethylpyrrole with phthalic anhydride. Potassium hydroxide

converts this phthalide into the corresponding acid, which after prolonged treatment with glacial acetic acid and hydrogen iodide lov the phthalic acid residue and forms 2 : 3 : 4-trimethylpyrrole, describet by Piloty and Hirsch (A., 1912, i, 925). This alkylpyrrole has marked crystallising properties; it forms a crystalline picrate and an azo-dye, and is oxidised by nitrous acid to an oxime, which is converted into dimethylmaleinimide on hydrolysis.

Heating with sodium ethoxide converts the trimethylpyrrole into the isomeric phyllopyrrole, which does not crystallise.

Tetramethylpyrrole is produced when the above phthalide is heated with sodium methoxide.

On heating indigotin with sodium methoxide in sealed tubes at 230°, the C:C-junction is broken, and dimethylindole is formed as well as a second unknown compound, which crystallises well and forms a picrate, m. p. 176—177°.

3 : 4 : 5-Trimethylpyrrole crystallises in prisms, m. p. 37—38°, becoming red when exposed to the air. The picrate has m. p. 147—148°.   E. F. A.

Complex Acetatoferri-bases Containing Pyridine. RUDOLF F. WEINLAND and CHR. BECK (*Zeitsch. anorg. Chem.*, 1913, **80**, 402—447. Compare A., 1910, i, 296, 635).—When pyridine (5 mols.) is added to a solution of hydrated ferric chloride (1 mol.) in glacial acetic acid (5 mols.), heat is developed and a dark green mass is obtained on cooling. When this is dissolved in chloroform and precipitated with benzene, yellowish-green crystals are obtained. Digestion with absolute alcohol converts this salt, with loss of water, into a brown, octahedral salt, and an exactly similar salt is obtained from ferric bromide. The original chloride yields a yellowish-green iodide with concentrated aqueous potassium iodide, the chlorine being completely eliminated, whilst the chloride is regenerated from the acetate and lithium chloride. These reactions point to the formulæ:

$$\mathrm{Fe_4} \begin{array}{c} (\mathrm{OAc})_6 \\ 3\mathrm{Py} \\ (\mathrm{OH})_2 \end{array} \Big] \mathrm{Cl_4} \quad \text{and} \quad \mathrm{Fe_4} \begin{array}{c} (\mathrm{OAc})_6 \\ 3\mathrm{Py} \\ \mathrm{O} \end{array} \Big] \mathrm{Cl_4}$$
for the green and brown salts respectively. The original crude product is a chloride-acetate, containing more pyridine. The brown solutions of these salts in water slowly decompose, forming a gelatinous precipitate. Benzene does not precipitate a pure tetrabromide from chloroform solution, but a mixed salt containing more pyridine. Removal of water gives a salt corresponding exactly with the chloride.

A solution of ferric acetate and lithium iodide in glacial acetic acid yields an iodide-acetate, composed of two mixed salts. Digestion with absolute alcohol yields a red, octahedral periodide-acetate,

$$\mathrm{Fe_4} \begin{array}{c} (\mathrm{OAc})_6 \\ 4\mathrm{Py} \\ \mathrm{O} \end{array} \Big] \begin{array}{c} \mathrm{I_2 \cdot I_2} \\ (\mathrm{OAc})_2 \end{array}.$$
The iodide obtained from the chloride is a mixed salt. Nitrate acetates have also been obtained.

Ferric acetate, pyridine, and glacial acetic acid yield a compound,

$\text{Fe}_4 \begin{array}{l}(\text{OAc})_6 \\ 3\text{Py} \\ \text{OH}\end{array} \bigg| (\text{OAc})_6.$ Dissolving in chloroform and precipitating

with benzene gives a bright copper-red salt,

$$\text{Fe}_3 \begin{array}{l}(\text{OAc})_5 \\ \text{Py} \\ (\text{OH})_2\end{array} (\text{OAc})_2, \text{H}_2\text{O}.$$
Solutions of ferric chloride in at least 15 mols. glacial acetic acid yield after a time with 2 mols. of pyridine, garnet-red prisms, which contain more chlorine than the previous salts, and appear to contain a complex anion, $\left[\text{Fe}\begin{array}{l}\text{Cl}_5 \\ \text{H}_2\text{O}\end{array}\right]^{-}$ which is already known. The salt is acid and is only stable in presence of an excess of acetic acid. It has the constitution $\text{Fe}_4 \begin{array}{l}(\text{OAc})_6 \\ 5\text{Py}\end{array}\left[\begin{array}{l}(\text{OAc})_2,\text{CH}_3\cdot\text{CO}_2\text{H} \\ \left[\text{Fe}\begin{array}{l}\text{Cl}_5 \\ \text{H}_2\text{O}\end{array}\right]_2\end{array}\right]$,12H$_2$O. It yields a periodide with concentrated aqueous potassium iodide,

$$\text{Fe}_4 \begin{array}{l}(\text{OAc})_6 \\ 5\text{Py} \\ \text{OH}\end{array} \begin{array}{l}\text{I}_3,\text{I}_3 \\ (\text{OAc})_2\end{array}.$$
The iron atoms in the complex cations are regarded as linked together through the acetyl groups by means of subsidiary valencies. The pyridine in these compounds, like the ammonia in the complex chromiacetates, can pass in and out of the cation without, as in metal-ammines, affecting the negative groups.   C. H. D.

Pyridine Derivatives. ERNST SCHMIDT (*Arch. Pharm.*, 1913, **251**, 188—207).—In continuation of work already described (A., 1905, i, 23), attempts have been made to prepare formocholine (trimethylhydroxymethylammonium hydroxide), and in default of this its pyridine analogue, by new methods which will give larger yields. The products obtained in these unsuccessful attempts are described.

Prescott and Baer (A., 1897, i, 95) have shown that by the interaction of methylene iodide and pyridine, methylenedipyridyl iodide, $\text{CH}_2(\text{C}_5\text{H}_5\text{NI})_2$, is formed, and a further study of this reaction under various conditions shows that this is practically the sole product. It forms yellow leaflets, m. p. 220° (decomp.), but after decolorisation by animal charcoal forms colourless tablets, m. p. 222—223°, containing 1H$_2$O from water. The *chloride*,
$$\text{CH}_2(\text{C}_5\text{H}_5\text{NCl})_2,\text{H}_2\text{O},$$

is similar, but remains unmelted at 260°. The *platinichloride* forms yellow needles from alcohol, and does not melt at 260°. The *picrate* forms long, yellow needles, m. p. 230°, and the *mercurichloride*, $\text{CH}_2(\text{C}_5\text{H}_5\text{NCl})_2,4\text{HgCl}_2$, long, glancing needles, m. p. 230°; the mother liquor from the preparation of the latter salt deposits on evaporation a second *mercurichloride*, m. p. 124—126°, containing 1 mol. HgCl$_2$.

Attempts to demethylate pyridylformocholine methyl ether (A., 1901, i, 443) by L. KRAUSS furnished only pyridine.

Re-examination of Prescott and Baer's work (*loc. cit.*) on the interaction of ethylene bromide and pyridine shows that in addition

to ethylenedipyridyl bromide some bromoethylpyridyl bromide (*platinichloride*, $[C_5H_5NCl \cdot C_2H_4Br]_2, PtCl_4$, long needles, m. p. 220°) is formed. In isolating the substance, the mother liquors were treated with platinic chloride, and in this way the following double *platinichlorides* and *aurichlorides* with pyridine were obtained.

(1). $[C_5H_5N, HCl]_2, PtCl_4 + [C_5H_5NCl \cdot C_2H_4Cl]_2, PtCl_4$, reddish-yellow leaflets, m. p. 195°; $C_5H_5N, HAuCl_4 + C_5H_5NCl \cdot C_2H_4Cl, AuCl_3$, glancing needles, m. p. 142—143°.

(2). $[C_5H_5N, HCl]_2, PtCl_4 + C_5H_5NCl \cdot C_2H_4Cl, PtCl_4$, yellowish-brown, nodular crystals, m. p. 180—181°; the corresponding *aurichloride* formed leaflets, m. p. 155°.

Ethylenedipyridyl chloride, $C_2H_4[C_5H_5NCl]_2$, obtained by treating the bromide with silver chloride in water or by the direct action of ethylene chloride on pyridine, crystallises in leaflets or tablets, both forms containing alcohol of crystallisation, and does not melt at 260°. The *aurichloride*, $B, 2AuCl_3$, forms small, leafy crystals from dilute alcohol. The *picrate*, m. p. 246°, forms yellow leaflets. *Chloroethylpyridyl chloride* is a hygroscopic, syrupy mass; the *platinichloride*, m. p. 218° (decomp.), forms needles, and the *aurichloride*, m. p. 135—136°, needles or leaflets, from water.

[With A. SEEBERG.]—On heating bromoethylpyridyl bromide with silver nitrate in aqueous solution, pyridinecholine is produced. This yields an aurichloride, m. p. 117°, crystallising in broad needles or leaflets, a platinichloride, m. p. 179°, forming reddish-yellow tablets, and a *mercurichloride*, m. p. 188—189°, as a colourless, crystalline powder (compare Roithner, A., 1895, i, 319, and Litterscheid, A., 1902, i, 308).

When silver oxide is used the product is pyridineneurine, which yields an aurichloride, m. p. 178°, crystallising in long, yellow needles, and a platinichloride, m. p. 193° (decomp.), forming small tablets.

T. A. H.

Kynurenic Acid. (Miss) ANNIE HOMER (*Proc. Physiol. Soc.*, 1913, xviii; *J. Physiol.*, 46).—The kynurenic acid of dog's urine is 2-hydroxyquinoline-4-carboxylic acid. It has m. p. 288—289°; this is a higher figure than that given by previous workers. ' W. D. H.

The Ten Stereoisomeric Tetrahydroquinaldinomethylene-camphors. WILLIAM J. POPE and JOHN READ (*Proc. Camb. Phil. Soc.*, 1913, 17, [2], 204).—The two enantiomorphously related tetrahydroquinaldines condense readily with the two similarly related oxymethylenecamphors, yielding products of the constitution

$$C_{10}H_{12}N \cdot CH:C \Big\langle {}^{C_8H_{14}}_{CO}.$$
Since each component of the condensation can be obtained in a dextro- and a lævo-rotatory form, four simple optically active condensation products can be obtained, represented by the configurations: (1) *d-D*, (2) *l-L*, (3) *d-L*, (4) *l-D* (*d-* and *l-* represent the configurations of the tetrahydroquinaldine residue, and *D-* and *L-* those of the oxymethylenecamphor nucleus). From these the two racemic compounds (5) [*d-D*, *l-L*] and (6) [*d-L*, *l-D*] can be prepared, whilst in the present

instance the following two pairs of partly racemic compounds are also obtainable: (7) [*d-D*, *d-L*], (8) [*l-L*, *l D*], (9) [*d-D*, *l-D*], and (10) [*l-L*, *d-L*].

It would be anticipated that no resolution of externally compensated tetrahydroquinaldine into its optically active components would be possible with the aid of *d*- or *l*-oxymethylenecamphor. It is shown, however, that on treating externally compensated tetrahydroquinaldine with less than one-half an equivalent of *d*-oxymethylenecamphor, a resolution can be effected because the *l*-base condenses more rapidly than the *d*-isomeride with *d*-oxymethylenecamphor; under these conditions the condensation yields about 80% of the partly racemic compound (9) and 20% of the optically active substance (4), from which *l*-tetrahydroquinaldine may be separated. II. W.

Preparation of Hydroxycarbazole.

Farbenfabriken vorm. Friedrich Bayer & Co. (D.R.-P. 258298. Compare A., 1907, i, 1074; T., 1911, 99, 103).—*Carbazoletrisulphonic acid* is obtained when carbazole (3 parts) dissolved in concentrated sulphuric acid (10 parts) is gently warmed with 3 parts of fuming sulphuric acid (20% SO_3).

Potassium carbazoletrisulphonate forms colourless crystals, and when fused with potassium hydroxide (3 parts), first at 190—200° and subsequently at 220—230°, furnishes the crystalline *potassium hydroxycarbazoledisulphonate*.

1-*Hydroxycarbazole* (annexed formula), colourless leaflets, m. p. 163°, is obtained when the foregoing potassium hydroxycarbazole disulphonate is heated with 5% sulphuric acid during five hours at 180°, and is not identical with the hydroxycarbazole (m. p. 255—256°) prepared by Ruff and Stein (A., 1901, i, 620).

F. M. G. M.

Action of Formic Acid on Triphenylmethane Dyes.

Alfred Guyot and A. Kovache (*Compt. rend.*, 1913, 156, 1324—1327. Compare A., 1912, i, 186, 972).—Hexamethyl-violet and malachite-green are only very slightly reduced by pure formic acid. The addition of sodium formate, however, causes rapid reduction with the evolution of carbon dioxide, which takes place in two stages, the second requiring the presence of a large amount of formate. The hexamethyl violet is first reduced like the simple triarylcarbinols (*loc. cit.*), and gives hexamethyltriaminotriphenylmethane, which then undergoes further reduction to dimethylaniline and tetramethyl-*p* diaminodiphenylmethane, with the evolution of a second molecule of carbon dioxide. This reduction is quantitative, whereas with malachite-green the reduction, whilst proceeding similarly, is never quantitative in the second stage. The authors consider that this action of formic acid establishes evident relationship and a complete continuity between the dyes proper and the carbinols deprived of all auxochrome; between these two groups there only exists a difference in reactional aptitude, which can be attributed to the more or less pronounced basicity of the molecules, and which shows itself in the varying ease with which reduction takes place from one member to another. W. G.

Tetrachlororhodamines. MARCEL BLOCH (*Bull. Soc. ind. Mul-house*, 1913, **83**, 81—84).—When an equimolecular mixture of *m*-dimethylaminophenol and tetrachlorophthalic anhydride is heated at 165°, *tetramethyltetrachlororhodamine phthalate* is obtained, which, by the successive action of sodium hydroxide and hydrochloric acid, is converted into the corresponding *hydrochloride*, green crystals, from which the free *base* is obtained by addition of sodium hydroxide. The latter dyes cotton, wool, and silk in reddish-violet shades exhibiting, in the case of the latter fibre, a magnificent fluorescence. The colours are stable towards light and alkalis. Attempts to esterify the rhodamine were unsuccessful, probably owing to the presence of electronegative atoms in the ortho-position to the carboxyl group.

When *m*-dimethylaminophenol is heated with tetrachlorophthalic anhydride in xylene solution, *o-4-dimethylamino-2-hydroxybenzoyltetra-chlorobenzoic acid*, $NMe_2 \cdot C_6H_3(OH) \cdot CO \cdot C_6Cl_4 \cdot CO_2H$, is formed together with a *substance*, separating from glacial acetic acid in yellow needles, which probably has the formula $C_6Cl_4(CO \cdot O \cdot C_6H_4 \cdot NMe_2)_2$.

By the condensation of tetrachlorophthalic anhydride with *m*- or *p*-phenylenediamine or their alkylated derivatives in glacial acetic acid solution, a series of yellow *compounds* has been prepared which yield colourless salts with hydrochloric acid. Results of analyses are in agreement with the general formula:

$$CO<^{C_6Cl_4}_{O}>C:N \cdot C_6H_4 \cdot NR_2.$$
Tetrachloroaporhodamine (annexed formula) is formed by the condensation of 4-dimethyl-amino-2-hydroxy-*o*-benzoyltetrachlorobenzoic acid with *p*-cresol in the presence of concentrated sulphuric acid, whilst with resorcinol or pyrogallol the same acid yields substituted rhodols.

H. W.

[**Preparation of Hydroxyphenylhydrazinesulphonic Acids and their Condensation Products.**] FARBWERK MÜHLHEIM vorm. A. LEONHARDT & Co. (D.R.-P. 258017).—When the *o*-hydroxyphenyl-hydrazines are condensed with *o*-diketones they give rise to dyes, and the preparation of the following substituted hydrazines by diazotisation and reduction of the corresponding bases is described: *4-hydroxy m-tolylhydrazine-5-sulphonic acid* (I); *2-hydroxy-1-naphthylhydrazine-4-sulphonic acid* (II), and its *tolylsulphonyl* ester (III); *3-nitro-2-hydroxyphenylhydrazine-5-sulphonic acid* (IV), and *5-nitro-4-hydroxy-m-tolylhydrazine* (V), whilst the tinctorial properties of the *compounds* obtained by condensing them with camphorquinone, phenanthraquinone, and other *o*-diketones are tabulated in the original.

F. M. G. M.

Hydrazones of Hydroxy-aldehydes and -ketones; Alkali-insoluble Naphthols. HENRY A. TORREY and CARL M. BREWSTER (*J. Amer. Chem. Soc.*, 1913, **35**, 426—444).—Torrey and Kipper (A., 1907, i, 325 ; 1908, i, 460) have shown that the insolubility of certain phenols in aqueous alkali hydroxides depends (1) on the hydroxyl group being in the ortho-position to a large side-chain, and (2) on the other substituting groups in the benzene nucleus to which the hydroxyl group is attached. In the present paper an account is given of certain naphthol derivatives which are insoluble in alkali hydroxide solutions.

The naphthalene group, $\overset{C:C-}{\underset{C:C-}{|}}$, is more effective in producing insolubility than any other group yet studied. There does not seem to be any marked difference between the derivatives of 1-hydroxy-β-naphthyl methyl ketone (2-acetyl-1-naphthol) and naphthaldehyde; the phenyl-hydrazones, p-bromophenylhydrazones, phenylbenzylhydrazones, α- or β-naphthylhydrazones, and the benzidine compounds of both substances show the same insolubility.

The following compounds of 1-hydroxy-β-naphthyl methyl ketone are described. The *α-naphthylhydrazone*, $OH \cdot C_{10}H_6 \cdot CMe:N \cdot NH \cdot C_{10}H_7$, m. p. 179—180°, insoluble in boiling aqueous sodium hydroxide; the *β-naphthylhydrazone*, m. p. 174—176°, insoluble in warm 10% sodium hydroxide; the *phenylbenzylhydrazone*, m. p. 130—132°, insoluble in boiling 10% sodium hydroxide ; the *azine*, which decomposes at a high temperature and is insoluble in warm 10% sodium hydroxide, and its *acetate*, m. p. 169—170°; the *benzidine* compound,

$$C_{12}H_8(N:CMe \cdot C_{10}H_6 \cdot OH)_2,$$
decomposing at 210°, and insoluble in boiling 10% and 30% sodium hydroxide ; the *semicarbazone*, m. p. 245—250°, easily soluble in cold aqueous sodium hydroxide ; the *β-naphthylimide*,

$$OH \cdot C_{10}H_6 \cdot CMe:N \cdot C_{10}H_7,$$
m. p. 161—162°, insoluble in boiling 10% sodium hydroxide ; and the p-*aminophenol* compound, $OH \cdot C_{10}H_6 \cdot CMe:N \cdot C_6H_4 \cdot OH$, which decomposes at 210—220° and is easily soluble in cold aqueous sodium hydroxide.

1 : 5-*Diphenyl-3-α-naphtholpyrazoline*, $OH \cdot C_{10}H_6 \cdot C_8H_3N_2Ph_2$, m. p. 189° (decomp.), prepared by the action of phenylhydrazine on 2-benzyl-ideneacetyl-1-naphthol (Kostanecki, A., 1898, i, 373), is insoluble in boiling 10% and 30% aqueous sodium hydroxide.

Bromo-1-hydroxy-β-naphthyl methyl ketone, $OH \cdot C_{10}H_5Br \cdot COMe$, has been described in an earlier paper (Torrey and Brewster, A., 1910, i, 48). The *acetyl* derivative, m. p. 95—96°, is insoluble in cold sodium hydroxide solution, but gradually decomposes on warming ; the

a-naphthylhydrazone, m. p. 175—176° (decomp.), is insoluble in boiling 10% sodium hydroxide; the *β-naphthylhydrazone*, m. p. 184 -186° (decomp.), and *phenylbenzylhydrazone*, m. p. 125—126°, are insoluble in warm 10% sodium hydroxide; the *oxime*, m. p. 189—190° (decomp.), yields with sodium hydroxide a green, slightly soluble salt; the *semicarbazone* and *azine* decompose at a high temperature; the former dissolves readily in dilute alkali hydroxide, whilst the latter is insoluble in boiling 10% sodium hydroxide.

The following compounds of 4-nitro-1-hydroxy-β-naphthyl methyl ketone are described. The *phenylhydrazone*, m. p. 222—223° (decomp.), imparts a red colour to cold 10% sodium hydroxide, and gradually dissolves on heating; it is insoluble in a 30% solution, however, and is decomposed when boiled with this reagent. The *a-naphthylhydrazone* decomposes at a high temperature, is insoluble in cold aqueous sodium hydroxide, but on warming renders the solution yellow. The *β-naphthylhydrazone* decomposes at 240°; it is insoluble in cold sodium hydroxide, but decomposes when heated with the solution. 4-*Nitro*-1-*acetoxy-β-naphthyl methyl ketone phenylhydrazone acetate*,

$$OAc \cdot C_{10}H_5(NO_2) \cdot OMe \colon N \cdot NAcPh,$$
has m. p. 197—198°.

β-Hydroxynaphthaldehydephenylhydrazone is insoluble in cold aqueous sodium hydroxide, and decomposes slightly when the solution is heated. The p-*bromophenylhydrazone*, m. p. 194—195° (decomp.), the *phenylbenzylhydrazone*, m. p. 152—153°, and the benzidine *compound*, $C_{18}H_8(N \cdot CH \cdot C_{10}H_6 \cdot OH)_2$, are insoluble in boiling 10% sodium hydroxide. The *semicarbazone*, m. p. above 240° (decomp.), is readily soluble in cold 10% sodium hydroxide. The *phenylhydrazone* of the *acetyl* derivative, $OAc \cdot C_{10}H_6 \cdot CH \colon N \cdot NHPh$, m. p. 164—165°, slowly decomposes when heated with sodium hydroxide solution. The *azine acetate*, $OAc \cdot C_{10}H_6 \cdot CH \colon N_2 \colon CH \cdot C_{10}H_6 \cdot OH$, has m. p. 183—185°. β-Hydroxynaphthaldehyde yields two oximes, one of m. p. 148--150° (Horlacher, *Diss.*, 1899), and the other, m. p. 158—160°.

Bromo-1-*hydroxy-β-naphthyl dibromophenylethyl ketone* (*benzylidene*-2-*acetyl* 1-*naphthol tribromide*), $OH \cdot C_{10}H_5Br \cdot CO \cdot CHBr \cdot CHPhBr$, m. p. 199°, is slightly soluble in boiling 10% sodium hydroxide, but insoluble in a boiling 30% solution.

4-*Bromo*-1-*hydroxynaphthyl furfurylidenemethyl ketone*,

$$OH \cdot C_{10}H_5Br \cdot CO \cdot CH \colon CH \cdot C_4H_4O,$$
m. p. 154—155°, and the corresponding *piperonylidene* compound, decomposing at 209—214°, are insoluble in boiling 30% sodium hydroxide. The p-*nitrobenzylidene* compound, m. p. 194—195°, is slightly soluble in 10% sodium hydroxide, but insoluble in a 30% solution.

o-Hydroxyacetophenonephenylhydrazone is readily soluble in dilute sodium hydroxide. o-*Acetoxybenzaldehydephenylbenzylhydrazone* has m. p. 137—139°. Benzidine bis-salicylaldehyde is insoluble in cold 10% sodium hydroxide, whilst the corresponding azine is readily soluble. 5-*Bromo*-2-*acetoxybenzaldehydeacetylphenylhydrazone*,

$$OAc \cdot C_6H_3Br \cdot CH \cdot N \colon NAcPh,$$

has m. p. 135—136°. 5-*Bromosalicylaldehydeazine*, m. p. 305—307° (decomp.), is readily soluble in cold 10% sodium hydroxide.   E. G.

The Optically Active Semicarbazone and Benzoylphenyl-hydrazone of *cyclo*Hexanone-4-carboxylic Acid. WILLIAM H. MILLS and (Miss) ALICE M. BAIN (*Proc. Camb. Phil. Soc.*, 1913, **17**, 203).—The *semicarbazone* of *cyclo*hexanone 4-carboxylic acid can be obtained in an optically active form by crystallising its *morphine* salt from dilute alcohol, the highest value obtained for the molecular rotation in alkaline solution being $[M]_D + 38·8°$. The *benzoylphenyl-hydrazone* of the acid can similarly be obtained in an optically active form by crystallisation of its *quinine* salt from aqueous alcohol, the highest value found for the molecular rotation in alkaline solution being $[M]_D + 238·6°$.

These optically active compounds agree so closely in their behaviour with the optically active oxime of this acid previously described by the authors (T., 1910, **97**, 1866) that there can be little doubt that the optical activity is due to similar causes in the three cases. The observations, accordingly, lend great support to the view that stereoisomerism in the sense of the Hantzsch-Werner hypothesis exists in the case of semicarbazones and phenylhydrazones.   H. W.

Synthesis of Hydroxypyrrole and Pyrroline Derivatives from Ethyl Aminocrotonate. ERICH BENARY and BOLESLAV SILBERMANN (*Ber.*, 1913, **46**, 1363—1375).—As might be expected, ethyl β-amino-α-chloroacetylcrotonate (A., 1909, i, 888) readily yields pyrrole derivatives when deprived of the elements of hydrogen chloride. The product $NH{<}^{CMe:C·CO_2Et}_{CH=C·OH}$ (I.) gives a coloration with ferric chloride which is considered to be characteristic of a hydroxy-pyrrole, but in some cases it reacts in the tautomeric ketonic form $NH{<}^{CMe:C·CO_2Et}_{CH_2-CO}$ (II.), and yields, *e.g.*, a dipyrroline derivative, $CO_2Et·C{<}^{CO}_{CMe·NH}{>}C:C{<}^{CO}_{NH·CMe}{>}C·CO_2Et$ (III.), on oxidation and an indoxylpyrroline, $CO_2Et·C{<}^{CO}_{CMe·NH}{>}C:C{<}^{CO}_{NH}{>}C_6H_4(IV.)$, on condensation with isatin.

The ester (I.) could not be hydrolysed, but it condenses in cold concentrated hydrochloric acid to form two bi-molecular compounds which can be easily transformed into one another, and to which the formulæ $CO_2Et·C{<}^{C(OH)}_{CMe·NH}{>}C·C{<}^{C(CO_2Et)·}_{CH·NH--}{>}CMe$ (V.) and $CO_2Et·C{<}^{C(OH)_2}_{CMe·NH}{>}C:C{<}^{C(CO_2Et)·}_{CH_2·NH--}{>}CMe$ (VI.) are assigned.

Like other pyrrole derivatives with a free α-position, the ester couples with phenyldiazonium chloride and forms the compound $CO_2Et·C{<}^{C(OH)}_{CMe·NH}{>}C·N:NPh$ (VII).

With nitrous acid it yields the oximino-compound, $CO_2Et·C{<}^{CO}_{CMe·NH}{>}C:N·OH$ (VIII.),

which exists in two forms, but with sodium nitrite and glacial acetic acid it gives a nitroimine, $CO_2Et\cdot C\underset{CMe\cdot NH}{\overset{CO}{<}}>C\!:\!N\cdot NO_2$ (IX.) (compare Scholl, A., 1905, i, 181; 1906, i, 767), which behaves in water as a nitroiminic acid, analogous to nitroic acid (Hantzsch and Kissel, A., 1900, i, 89). The acidity is not due to the hydrogen atom of the imino-group, since this may be replaced by methyl without affecting that property.

The methylated nitroimine (X.) is slowly hydrolysed by cold alkali, when the nitroamide of acetoneoxalic acid (XI.) is formed with elimination of methylamine, alcohol, and carbon dioxide :

$$CO_2Et\cdot C\underset{CMe\cdot NMe}{\overset{CO}{<}}>C\!:\!N\cdot NO_2 \text{ (X.)} \longrightarrow$$

$$CH_3\cdot CO\cdot CH_2\cdot CO\cdot CO\cdot NH\cdot NO_2 \text{ (XI.).}$$
Ethyl 4-hydroxy-2-methylpyrrole-3-carboxylate (I.) is prepared by the addition of ethyl β-amino-α-chloroacetylcrotonate to alcoholic potassium hydroxide. It forms faintly yellow leaflets which decompose at 215°, reduces ammoniacal silver oxide, gives the pyrrole reaction, and produces a brown coloration in alcohol or a red precipitate in water with ferric chloride. It gives a dark red solution in cold concentrated hydrochloric acid which becomes green in time, and contains a mixture which on fractionation from alcohol deposits the *hydrate* of *ethyl 3-keto-5 : 5'-dimethyl-2 : 3'-dipyrroline-4 : 4'-dicarboxylate* (VI.) in reddish-brown needles, which are purified by conversion into the unstable, greenish additive compound with hydrochloric acid and leaving in vacuum. It gives no coloration with ferric chloride, and decomposes at 180°. The alcohol mother liquors contain *ethyl 3-hydroxy-5 : 5'-dimethyl-2 : 3'-dipyrrole-4 : 4'-dicarboxylate* (I.), which is precipitated by water, or obtained from the foregoing compound by the action of water, in the form of almost colourless leaflets which decompose at 157·5°, and give the above compound with hydrochloric acid and a transient green colour with ferric chloride. The indigoid *ethyl bis-2-methylpyrroline-3-carboxylate* (III.) is obtained in brick-red, microscopic needles, decomp. 220— 225°, which give a dark red potassium salt with alcoholic potassium hydroxide. The leuco-compound is grey, but is rapidly oxidised in the air. The *ethyl 2-indoxylpyrrolinecarboxylate* (IV.) is a dark red powder, decomp. 220—225°. *Ethyl 5-benzeneazo-4-hydroxy-2-methylpyrrole-3-carboxylate* (VII.) forms brownish-yellow needles, decomp. 225—226°, which give a red colour with ferric chloride in alcohol.

On treating the ester (I.) with sodium nitrite and dilute hydrochloric acid, the α-form of *ethyl 5-oximino-4-keto-2-methylpyrroline 3-carboxylate* (VIII.) is obtained. It is purified by means of its potassium salt, and then forms light yellow needles, decomp. 175°. When a few drops of hydrochloric acid are added to the warm alcoholic solution, the β-form crystallises in olive-green leaflets. *Ethyl 5-nitroimino-4-keto-2-methylpyrroline-3-carboxylate* (IX.) forms shining yellow, flat needles with $1H_2O$, which dissolve in dilute alkalis, give precipitates with silver and lead salts, and respond to the Liebermann and Thiele-Lachman reactions. Both the hydrate

and the anhydrous compound give a brown *additive* compound, $C_8H_9O_5N_3.NH_3$, with ammonia.

Ethyl β-methylamino-α-chloroacetylcrotonate,

$$NHMe \cdot CMe \vdots C(CO \cdot CH_2Cl) \cdot CO_2Et,$$

from ethyl methylaminocrotonate and chloroacetyl chloride in presence of pyridine in ether, forms long, white needles, m. p. 50·5—51°. With alkali it yields *ethyl 4-hydroxy-1 : 2-dimethylpyrrole-3-carboxylate* as a very hygroscopic mass, which, with nitrous acid, gives the analogous iso*nitroso*-compound, $C_9H_{12}O_4N_2$, in lemon-yellow needles, decomp. 162·5°, which are hydrolysed by cold sodium hydroxide to the *acid*, $C_7H_8O_4N_2$, colourless needles, decomp. 154—155°. The *nitroimino*-compound (X.) is formed by the action of sodium nitrite and glacial acetic acid in orange needles with $1H_2O$, decomp. 200°, which give a brown *additive* compound with ammonia, and dissolve in sodium carbonate solution. The addition of dilute hydrochloric acid after eighteen hours to the red solution in sodium hydroxide precipitates *acetylpyruvonitroamide* (XI.) in colourless needles, decomp. 258°, which reduce ammoniacal silver oxide, and give a red coloration with ferric chloride. With phenylhydrazine it forms an indole *compound*, $C_{17}H_{16}O_2N_5$, in brick-red, soft needles, decomp. 244°, ammonia being eliminated.　　　　J. C. W.

Syntheses in the Group of the Indogenides. ANDRÉ WAHL and P. BAGARD (*Compt. rend.*, 1913, **156**, 1382—1385).—Condensation of oxindole with cyclic aldehydes and isatin or its chloride in acetic acid solution yields, respectively, *iso*indogenides, *iso*indigotin, and indirubin (compare A., 1909, i, 330, 735). This reaction has now been extended, firstly by modifying the conditions of the reaction, and secondly by using substituted isatins.

Oxindole and isatins condense in alcoholic solution under the influence of sodium ethoxide, giving colourless products, constitutions of which have not yet been determined.

In concentrated sulphuric acid the condensation is accompanied by sulphonation, yielding *iso*indigotindisulphonic acid, which is isolated in the form of its *sodium* salt, $C_{16}H_8N_2O_2(SO_3Na)_2,2H_2O$, crystallising in brown leaflets, which become anhydrous at 100°. It is an acid colour, dyeing wool reddish-orange. Other salts have been prepared, namely : the *calcium* salt, red needles, crystallising with $5H_2O$; the *barium* salt, an amorphous, red powder; the *silver* salt, red needles, crystallising with $2H_2O$; the *nickel* salt, reddish-brown crystals, containing $5H_2O$. By decomposing the barium salt with the calculated quantity of sulphuric acid, the free *acid*, "*iso*indigo-carmine," is obtained, which is very soluble in alcohol and water, and yields an equally soluble *ammonium* salt on the addition of ammonia.

If oxindole is condensed with substituted derivatives of isatin in acetic acid solution, unsymmetrically-substituted derivatives of *iso*-indigotin are obtained, thus :

$$C_6H_4 \begin{array}{c} CH_2 \\ NH \end{array} \hspace{-2mm} > \hspace{-2mm} CO + CO \begin{array}{c} CO \\ NH \end{array} \hspace{-2mm} > \hspace{-2mm} C_6H_3X =$$

$$H_2O + NH \begin{array}{c} C_6H_4 \\ CO \end{array} \hspace{-2mm} > \hspace{-2mm} C:C \begin{array}{c} C_6H_3X \\ CO \end{array} \hspace{-2mm} > \hspace{-2mm} NH.$$
By this means *brom*oiso*indigotin*, *dibrom*oiso*indigotin*, *methyl*iso-*indigotin*, and *nitro*iso*indigotin*, all crystalline compounds, have been prepared.

By the interaction of substituted isatin chlorides and oxindole in benzene solution, substituted indirubins of the type

$$NH{<}^{C_6H_4}_{CO}{>}C{:}C{<}^{CO}_{NH}{>}C_6H_3X$$
are obtained, isomeric with those prepared by Baeyer's condensation with indoxyl and isatins (compare A., 1911. i, 164, 577). These new indirubins, thus obtained, have a violet colour and dissolve in sodium hyposulphite, giving yellow dye liquors. The mono-substituted derivatives are only slightly fixed on the fibre. Nitroindirubin dyes a violet-black, due to the reduction of the nitro-group by the hyposulphite.

The Condensation of *para*Quinones with Reduced Heterocyclic Nitrogen Compounds. JULIUS SCHMIDT and AUGUST SIGWART (*Ber.*, 1913, 46, 1491—1497. Compare Möhlau and Redlich, A., 1912, 1, 129).—The observation that hexahydrocarbazole when mixed with *p*-benzoquinone in alcoholic solution yields a violet-red liquid from which brown crystals, m. p. 199—200°, soon separate (A., 1912, i, 616) has now been followed up. The product has the composition $C_6H_2O_2(C_{12}H_{14}N)_2$, that is, bishexahydrocarbazyl-*p*-benzoquinone, analogous to the dianilino-*p*-benzoquinones (Zincke, A., 1883, 1117) and to diethyldiamilino-*p*-benzoquinone (Fischer and Schrader, A., 1910, i, 270). Carbazole and dihydro- and tetrahydro-carbazole do not form such compounds, probably on account of their feebler basic character.

Piperidine and *p*-benzoquinone mixed in cold alcoholic solution give a brownish-violet coloration, followed by a deposit of brownish-violet needles with a steel-blue lustre, m. p. 172°; the substance is *dipiperidyl*-p-*benzoquinone*, $C_5NH_{10}{\cdot}C{<}^{CH\cdot CO}_{CO\cdot CH}{>}C{\cdot}C_5NH_{10}.$

The condensation product of *p*-benzoquinone with tetrahydroquinoline has already been described (Möhlau and Redlich, *loc. cit.*); 1-methyltetrahydroquinoline and 9-methylhexahydrocarbazole gave no condensation products, the crystalline deposit obtained in each case consisting of quinol. Pyrrole reacted with *p*-benzoquinone in alcoholic solution, but the dark crystalline powder, m. p. above 360°, was abnormal in composition, equimolecular quantities of the two substances apparently having entered into reaction. Coniine gave a deep coloration, but no solid product. Pyridine, quinoline, and *iso*quinoline caused only depositions of a nitrogen-free solid, which probably is some polymerisation product of quinone or quinhydrone.

Toluquinone gives rise to condensation products of small crystallising power, for although the expected colorations were obtained with piperidine and hexahydrocarbazole, no crystalline deposits could be obtained; tetrahydroquinoline gives a crystalline compound with toluquinone, but this has already been described (Möhlau and Redlich, *loc. cit.*). Naphthaquinone with hexahydrocarbazole, piperidine, and

tetrahydroquinoline gave deep red alcoholic solutions, but the deposit in each case consisted merely of naphthaquinhydrone.

Tetrachloro-p-benzoquinone (chloranil) behaves like p-benzoquinone with piperidine, producing *dipiperidyldichloro-p benzoquinone*,

$$C_5NH_{10}\cdot C\!\!<^{CCl\cdot CO}_{CO\cdot CCl}\!\!>C\cdot C_5NH_{10},$$
lustrous, bluish-black needles, m. p. 143—144°.　　　　　D. F. T.

Action of isoQuinoline on 1 : 3-Dichloro-4 : 6-dinitrobenzene.

THEODOR ZINCKE and G. WEISSPFENNING (*Annalen*, 1913, **397**, 255—273).—isoQuinoline and 1 : 3-dichloro-4 : 6 dinitrobenzene react in warm ether to form, after fourteen to fifteen days, *dinitrophenyldi-isoquinolinium dichloride*, $C_9H_7NCl\cdot C\!\!<^{C(NO_2)=\!=\!=CH}_{CH\cdot C(C_9H_7NCl)}\!\!>C\cdot NO_2$, and an orange-red, crystalline ψ-*base*, $C_{15}H_{10}O_5N_3Cl$, m. p. 168° (decomp.), blackening at about 100°.

In its behaviour, dinitrophenyldiisoquinolinium dichloride resembles partly dinitrophenyldipyridinium dichloride (A., 1910, i, 585), partly 2-op dinitrophenylisoquinolinium chloride (this vol , i, 389). From it an orange-yellow *dichromate*, yellow *picrate*, m. p. 225°, and *platini-chloride*, m. p. 250°, can be prepared. By treating its aqueous solution with sodium carbonate or ammonia, a ψ-*base* is obtained, a brownish-red powder, which is regarded as a dicarbinol base,

$$^{C_6H_4\cdot OH(OH)}_{OH=\!=\!=CH}\!\!>N\cdot C_6H_2(NO_2)_2\cdot N\!\!<^{CH(OH)\cdot C_6H_4}_{OH=\!=\!=CH}.$$
This ψ-base regenerates salts of dinitrophenyldiisoquinolinium by treatment with acids, is converted into the yellow betaine (see below) by boiling dilute acetic acid, reacts with warm alcohols to form

carbinyl ethers, $^{C_6H_4\cdot CH(OR)}_{CH=\!=\!=CH}\!\!>N\cdot C_6H_2(NO_2)_2\cdot N\!\!<^{CH(OR)\cdot C_6H_4}_{CH=\!=\!=CH}$

(*methyl ether*, decomp. 180 --190°, long, red needles; *ethyl ether*, m p. 172°, red needles), and forms a *dihydrazide*,

$$C_6H_2(NO_2)_2(NH\cdot CH\!:\!CH\cdot C_6H_4\cdot CH\!:\!N\cdot NHPh)_2,$$
almost black crystals, by warming with alcoholic phenylhydrazine. In methyl alcoholic solution the ψ base is converted by nitric acid, D 1·4, into the very characteristic *dinitrophenyldiisoquinolinium dinitrate*, $C_6H_2(NO_2)_2(C_9H_7N\cdot NO_3)_2,H_2O$, decomp. 140—150°, colourless needles.

By long keeping with 10% sodium nitrite, dinitrophenyldiisoquinolinium dichloride is converted into the *betaine*,

$$C_6H_2(NO_2)_2\!\!<^{O}_{C_9NH_7},$$
yellow needles. The constitution of the latter, which is also obtained by treating the ψ-base with boiling 25—30% acetic acid, is proved by the formation of the substance from isoquinoline and 3-chloro-4 : 6-dinitrophenol at 100°. The betaine forms salts (*chloride*, colourless needles, *platinichloride*, *nitrate*) which are hydrolysed by an excess of water. A corresponding *thiobetaine*, $C_6H_2(NO_2)_2\!\!<^{S}_{C_9NH_7}$, dark

crimson powder, is obtained by treating alcoholic dinitrophenyldiisoquinolinium dinitrate with hydrogen sulphide; it forms a very unstable *chloride* and *platinichloride*.

The ψ-base, $C_{15}H_{10}O_5N_3Cl$, behaves similarly to the ψ-base obtained from 2-*op*-dinitrophenyl*iso*quinolinium chloride (*loc. cit.*), and proves to be a chloro-derivative thereof. It has the constitution

$$\begin{matrix} C_6H_4 \cdot CH(OH) \\ CH === CH \end{matrix} > N \cdot C_6H_2Cl(NO_2)_2,$$
forms a *chloride*, $\begin{matrix} C_6H_4 \cdot CH \\ CH == CH \end{matrix} > NCl \cdot C_6H_2Cl(NO_2)_2$, colourless needles,

platinichloride, and *nitrate*, and yields ethers by treatment with alcohols in chloroform; the *methyl ether*, m. p. 164—165° (decomp.), dark red needles, and *ethyl ether*, m. p. 156—157°, red leaflets, are described. By boiling with alcohol and aniline, the ψ-base is converted into 2 - phenyl*iso*quinolinium chloride and 3 - chloro - 4 : 6 - dinitroaniline, the latter being changed to 2 : 4-dinitro-5-aminodiphenylamine by the excess of aniline.

By warming with water, the ψ-base is transformed into an *isomeride*, $C_{15}H_{10}O_5N_3Cl$, m. p. 168° (decomp.), dark violet-red leaflets, which forms salts with acids very slowly, and does not yield ethers or a hydrazide. On the contrary the ψ-base is converted by boiling alcoholic phenylhydrazine into the *hydrazide*,

$$NHPh \cdot N{:}CH \cdot C_6H_4 \cdot CH{:}OH \cdot NH \cdot C_6H_2Cl(NO_2)_2,$$
m. p. 155° (decomp.), blackish-red needles.　　　　　　　　　　　O. S.

Preparation of 5 : 5-Dialkylbarbituric Acids Containing an Unsaturated Hydrocarbon Residue Attached to Nitrogen. EMANUEL MERCK (D.R.-P. 258058. Compare A., 1899, i, 16 ; 1904, i, 380).—5 : 5-*Diethyl-1-allylbarbituric acid*, m. p. 77°, is obtained by heating monoallylcarbamide (20 parts) with diethylmalonyl chloride (40 parts) during fifty hours at 100—120°, whilst the latter compound with diallylcarbamide (sinapoline) furnishes 5 : 5-*diethyl-1 : 3-diallyl barbituric* acid, b. p. 153—157°/9 mm.　　　　　　F. M. G. M.

Pyrimidines. LXII. Syntheses of Pyrimidines Related Structurally to Pyrimidine-Nucleosides. TREAT B. JOHNSON and LEWIS H. CHERNOFF (*J. Amer. Chem. Soc.*, 1913, 35, 585 597 ; *J. Biol. Chem.*, 1913, 14, 307—320).—This work was undertaken with the object of establishing the constitution of the nucleosides. The simplest nucleoside of thymine, namely, 4-hydroxymethyl-5-methyl tetrahydropyrimid-2 : 6-dione, has been synthesised in the following manner.

When thiocarbamide is condensed with ethyl γ-ethoxy-α-methylacetoacetate (Johnson, this vol., i, 588) in presence of sodium ethoxide, 2-*thio-4-ethoxymethyl-5-methyltetrahydropyrimid-2 : 6-dione*,

$$NH < \begin{matrix} CS - NH \\ CO \cdot CMe \end{matrix} > C \cdot CH_2 \cdot OEt,$$
m. p. 191—192°, is obtained, which crystallises in hexagonal tablets. On boiling this substance with chloroacetic acid and water, it is converted into 4-*ethoxymethyl-5-methyltetrahydropyrimid-2 : 6-dione*,

$$NH < \begin{matrix} CO - NH \\ CO \cdot CMe \end{matrix} > C \cdot CH_2 \cdot OEt,$$

m. p. 220°, which forms arborescent crystals, and when heated with concentrated hydrochloric acid at 125—130° in a sealed tube yields 4-*chloromethyl-5-methyltetrahydropyrimid-2*: 6-*dione*,

$$NH<^{CO-NH}_{CO \cdot CMe}>C \cdot CH_2Cl,$$
m. p. 243°, which crystallises in plates. By the action of silver acetate on this chloro-compound, the *acetyl* derivative,

$$NH<^{CO-NH}_{CO \cdot CMe}>C \cdot CH_2 \cdot OAc,$$
m. p. 260 —261° (decomp.), is produced, which is hydrolysed by barium hydroxide with formation of 4-*hydroxymethyl-5-methyltetrahydro-pyrimid-2*: 6-*di-one*, $NH<^{CO-NH}_{CO \cdot CMe}>C \cdot CH_2 \cdot OH$, m. p. 224—225° (decomp.), which crystallises in needles. An attempt to convert this simple nucleoside into thymine and formaldehyde by hydrolysis with 10% sulphuric acid was not successful, but on heating it with hydriodic acid and amorphous phosphorus it was converted into 4:5-dimethyl-tetrahydropyrimid-2: 6-dione (4:5-dimethyluracil). E. G.

Abnormal Solubility of Colloidal Uric Acid. LEOPOLD LIGHTWITZ (*Zeitsch. physiol. Chem.*, 1913, **84**, 416—418).—Polemical. Schade and Boden (this vol., i, 404) have regarded a supersaturated uric acid solution as a colloid gel. Their views are now criticised. The passage from the aggregate of molecules in drops to the amorphous solid phase, and from this to the crystalline form, takes place with very varying velocity, and the amorphous form can remain stable for a considerable time; it is therefore unnecessary to regard it as a colloid. E. F. A.

Purines. IX. 6:8 Dihydroxy-2-thiopurine and 6-Hydroxy-2:8-dithiopurine. The Desulphurisation of Thiopurines. A New Method of Preparing Xanthine. CARL O. JOHNS and ALBERT G. HOGAN (*J. Biol. Chem.*, 1913, **14**, 299—306).—6:8-*Di-hydroxy-2-thiopurine* is easily prepared in quantity by heating a mixture of 4:5-diamino-6-hydroxy-2-thiopyrimidine with carbamide.

6-*Hydroxy-2*:8-*dithiopurine* is obtained by heating a mixture of 4:5-diamino-6 hydroxy-2-thiopyrimidine and thiocarbamide.

Hypoxanthine-2-thiolacetic acid and 6:8-dihydroxypurine-2-thiolacetic acid can be boiled with water for hours without undergoing notable decomposition. When boiled with 20% hydrochloric acid they are hydrolysed to xanthine and uric acid respectively. 6-Hydroxypurine-2:8-dithiolacetic acid is more stable, and it is not desulphurised by boiling for several hours with 20% hydrochloric acid, although a small quantity of a dihydroxypurine monothiolacetic acid is obtained.

6:8-*Dihydroxy-2-thiopurine*, $^{NH-CO \cdot C \cdot NH}_{CS \cdot NH \cdot C \cdot NH}>CO$, forms minute needles, which do not melt at 310°; they give a brilliant murexide reaction. The corresponding 6:8-*dihydroxypurine-2-thiolacetic acid* has decomp. 225°.

Hypoxanthine-2-thiolacetic acid, $^{NH \cdot CO \cdot C \cdot NH}_{CO_2H \cdot CH_2 \cdot S \cdot C=N-C-N}>CH,$
prepared by the action of monochloroacetic acid on thiohypoxanthine, decomposes at 240°, forming a violet-coloured substance. It is decomposed quantitatively on boiling with 20% hydrochloric acid into xanthine. This forms the most convenient procedure of preparing pure xanthine in quantity; it is not necessary to isolate the intermediate thiolacetic acid.   E. F. A.

Considerations and Experiments on the Constitution of the Azoxy-compounds. I. and II. ANGELO ANGELI (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 201—213, 282—293).—A summary and discussion of the work of the author with various collaborators published in recent years.   R. V. S.

Polyazoxy-compounds. ANGELO ANGELI (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 356—360).—The paper deals with the action of hydrogen peroxide in acetic acid solution on bisbenzeneazobenzene (Mills, T., 1895, **67**, 929) and on the new *compound*,

$$NPh{:}N{\cdot}C_6H_4{\cdot}NO{:}N{\cdot}C_6H_4{\cdot}N{:}NPh.$$
This substance is prepared by the action of sodium ethoxide on *p*-nitro-azobenzene ; it crystallises in red laminæ, m. p. about 215°.

Bisbenzeneazobenzene, when treated with hydrogen peroxide and glacial acetic acid, yields *bisbenzeneazoxybenzene*, $C_6H_4(N_2O{\cdot}Ph)_2$, which forms lustrous, yellow laminæ, m. p. 155°. It yields a *dibromo*-derivative, $C_{18}H_{12}O_2N_4Br_2$, which forms yellow crystals, m. p. about 200°. The azoxy-compound has, therefore, probably the formula

$$Ph{\cdot}NO{:}N{\cdot}C_6H_4{\cdot}NO{:}NPh.$$
On treatment with concentrated sulphuric acid for one hour on the water-bath, it yields a product from which a substance, $C_{15}H_{14}ON_4$, can be extracted with benzene ; it forms yellowish-green leaflets, m. p. 185° (yielding a red liquid), and is probably the p-*hydroxyazo*-compound, $Ph{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}OH.$

Azoxybisazoxybenzene, $Ph{\cdot}N_2O{\cdot}C_6H_4{\cdot}N_2O{\cdot}C_6H_4{\cdot}N_2O{\cdot}Ph$, is obtained from the corresponding triazo-derivative above mentioned; it forms lustrous, golden-yellow crystals, m. p. 230°. It yields a *dibromide*,

$$C_{24}H_{16}O_3N_6Br_2,$$
which is a yellow, microcrystalline powder, decomposing about 265°, and in consequence the structural formula of the azoxy-compound is probably $Ph{\cdot}N{:}NO{\cdot}C_6H_4{\cdot}NO{:}N{\cdot}C_6H_4{\cdot}NO{:}N{\cdot}Ph.$ The triazoxy-compound also suffers Wallach's re-arrangement, for on warming with sulphuric acid an intense blue coloration is obtained.   R. V. S.

The Relation between the Metallic Salts and the Soluble Carbonates and its Bearing on the Precipitation of Protein. W. NEVILL HEARD (*J. Physiol.*, 1913, **46**, 104—129).—Since thorough dialysis removes all precipitation of emulsoid protein by salts of the heavy metals, precipitation must be associated with some removable constituent. The experiment of adding salts to such dialysed solutions shows that the production of a substance with a very low solubility product is the necessary condition in causing precipitation. The only salt in the dialysate which is capable of producing this result is a hydrogen carbonate, except in the case of silver. The reaction of the metals with emulsoid protein closely follows the reaction of these

metals with soluble hydrogen carbonates, and the conclusion is therefore drawn that the process depends on this reaction. Probably the precipitation with hydrogen carbonates and carbonates acts mainly by the removal of the hydroxyl ions freed by the hydrolysis of these salts. But the results with silver nitrate and sodium chloride suggest that there are other factors.   W. D. H.

The Soluble Metallic Compounds of Sulphurised Proteins, with Special Reference to Copper. ROBERT UHL (*Zeitsch. physiol. Chem.*, 1913, 84, 478—496).—The preparation is described of sulphur-protein compounds from various proteins by means of carbon disulphide. It is analogous to the preparation of dithiocarbamates from aliphatic amines. These substances are converted by salts of the heavy metals in presence of alkali into metal-sulphur-protein compounds which are soluble in water, and in which the sulphur is united to the metal. The compounds with copper, silver, and mercury have a high content of metal, are resistant to alkali, are not precipitated by protein solutions, are resistant to proteolytic enzymes, and do not diffuse through an animal membrane. Sulphur-peptone given subcutaneously or intravenously is relatively non-toxic. Its copper compound is also relatively non-poisonous, and produces no local reaction; the animal resists doses of copper five times greater than when given in any other way. It is deposited in most of the organs except the brain and heart; most appears in the liver, and is then secreted into the bile. It has but little effect on blood pressure, and inhibits diuresis. It is bactericidal to staphylococci, but has no action on anthrax or trypanosomes.
                                                         W. D. H.

Method of Preparing Ash-free Caseinogen and Casein LUCIUS L. VAN SLYKE and ALFRED W. BOSWORTH (*J. Biol. Chem.*, 1913, 14, 203—206).—The ash-free proteins were prepared by alternate precipitation with dilute acid and solution in dilute ammonia several times, the last portion of calcium being removed by ammonium oxalate; after this the protein is precipitated with dilute acid and purified by treatment with water, alcohol and ether, being finally dried over sulphuric acid under reduced pressure. Elementary analyses are given of both proteins; the figures are very similar.   W. D. H.

Preparation and Composition of Basic Calcium Caseinogenate and Caseinate. LUCIUS L. VAN SLYKE and ALFRED W. BOSWORTH (*J. Biol. Chem.*, 1913, 14, 207--209).—Basic calcium caseinogenate and caseinate were prepared by treating the ash-free protein with calcium carbonate, or by dissolving the protein in lime-water and neutralising with hydrochloric acid. In the first reaction, the amount of carbon dioxide displaced by the protein was estimated, and also the amount of calcium in the resulting product. In the second method the calcium was also estimated. The compound contains 1·78% of calcium.
                                                         W. D. H.

Preparation and Composition of Unsaturated or Acid Caseinogenates and Caseinates. LUCIUS L. VAN SLYKE and ALFRED W. BOSWORTH (*J. Biol. Chem.*, 1913, 14, 211—225).—These were prepared

by dissolving the ash-free protein in $N/50$-sodium, potassium or ammonium hydroxide, and careful neutralisation with hydrochloric acid. The caseinates contain twice the amount of the basic element present in the caseinogenates. Such compounds are monobasic. With calcium, strontium, and barium, monobasic and dibasic compounds were obtained; in the caseinates twice the amount of base combines with the protein molecule as combines in the caseinogenates.   W. D. H.

Valency of Molecules, and Molecular Weights of Caseinogen and Casein. LUCIUS L. VAN SLYKE and ALFRED W. BOSWORTH (*J. Biol. Chem.*, 1913, 14, 227—230).—From the study of the caseinogenates and caseinates, the molecular weight of caseinogen is given as 8888, and of casein as 4444. The valency of the protein molecule in basic caseinogenates is 8, in basic caseinates, 4.   W. D. H.

Composition and Properties of the Brine-soluble Compound in Cheese. LUCIUS L. VAN SLYKE and ALFRED W. BOSWORTH (*J. Biol. Chem.*, 1913, 14, 231—236).—The protein in cheese which dissolves in warm 5% solution of sodium chloride is mono-calcium caseinate, formed from calcium caseinate by removal of part of its calcium by lactic acid produced from lactose in the process of cheese-making.   W. D. H.

Formation of Porphyrin. II. Porphyrinogen and its Relation to the Blood Pigment and its Derivatives. HANS FISCHER, ERICH BARTHOLOMÄUS, and HEINRICH ROSE (*Zeitsch. physiol. Chem.*, 1913, 84, 262—287. Compare this vol., i, 409).—Porphyrinogen, the first crystalline, colourless reduction product of the blood pigment, is obtained by the action at the ordinary temperature of glacial acetic acid and hydrogen iodide, in presence of phosphonium iodide, on hæmin, mesoporphyrin or hæmatoporphyrin. It is also obtained from the last two substances by reducing in alkaline solution with sodium amalgam, or with zinc dust and iron. Porphyrinogen is readily reconverted into mesoporphyrin by means of sodium methoxide, methyl alcoholic potassium hydroxide, alkaline potassium ferricyanide, or by exposure to atmospheric oxidation in neutral or alkaline solution.

Sodium methoxide splits off phyllopyrrole from porphyrinogen. The complete reduction is similar to that of hæmin. On oxidation, methyl ethylmaleinimide and hæmatic acid are obtained. When administered to animals, porphyrinogen has a sensibilising action, whereas mesoporphyrin has no action.

Use is made of the sparingly soluble sodium salt for the purification of mesoporphyrin. On total reduction of mesoporphyrin, phyllopyrrole is obtained with other products.   E. F. A.

Behaviour of the True Nucleic Acids to Dyes. II. R. FEULGEN (*Zeitsch. physiol. Chem.*, 1913, 84, 309—328. Compare A., 1912, i, 926).—Nucleic acid gives precipitates with basic dyes, but none with acid dyes. It is necessary to add the solution of sodium nucleate to the dye, otherwise the formation of colloidal gels prevents precipitation.

Nucleic acid and tetramethyldiaminotriphenylcarbinol give a

precipitate having the composition of a tetrabasic salt,

$$C_{43}H_{57}O_{34}N_{15}P_4,4(C_{21}H_{25}N_9),9H_2O.$$
Treatment with alcohol extracts the dye, leaving a more or less colourless residue. It is considered that an ethyl ether of the dye and nucleic acid are formed.

The compound with hexamethyl-p-rosaniline is also tetrabasic, namely, $C_{41}H_{57}O_{34}N_{15}P_4,4(C_{25}H_{30}N_3),9H_2O.$ It forms a remarkable jelly during the preparation, which can be drawn out into very long threads. It is remarkable in being entirely soluble in methyl alcohol. Some decomposition takes place in alcoholic solution, part of the dye being eliminated.

The substances are considered to be chemical rather than adsorption compounds, and the whole of the phosphorus is shown to be fixed as nucleic acid.

Crystal-violet is a very suitable precipitant for nucleic acid, and may be used to purify it.

Methylene-blue gives a precipitate with nucleic acid, which is readily filtered and washed. It is entirely indifferent towards all solvents, and in no case could the dye be eliminated. E. F. A.

Preparation of an Iron Derivative of Iodoparanucleic Acid. KNOLL & Co. (D.R.-P. 258297. Compare A., 1909, i, 275).—When the iron derivative of paranucleic acid (Salkowski, A., 1901, i, 242, 434) is dissolved in 8% hydrochloric acid, and treated at 50° with a solution of iodine in potassium iodide, it furnishes the *iron* derivative of *iodoparanucleic acid*, a reddish-brown powder which has therapeutic properties and contains : iodine = 8%, iron = 13%, phosphorus = 2%, and nitrogen = 12%.

It can also be prepared from iodocaseinogen, pepsin, and a solution of iron alum ; or by the action of iodine on paranuclein in the presence of iron alum. F. M. G. M.

Action of Quinones on Wool and Other Protein Substances. WASSILI W. SCHARVIN (*Zeitsch. angew. Chem.*, 1913, **26**, 254). - Wool is dyed reddish-brown when acted on by the vapour or solutions of p-benzoquinone. Derivatives of p-benzoquinone act in a similar manner, the rate of reaction and colour depending on the compound employed; anthraquinone and phenanthraquinone are without action on wool.

Silk, leather, casein, egg-albumin, gelatin, etc., are dyed similarly by p-benzoquinone and its derivatives.

The conclusion is drawn that the quinone reacts with the amino-groups in the protein, and in the case of chloro-derivatives it is found that part of the chlorine is eliminated as hydrogen chloride, although chlorine can also be detected in wool dyed with dichloro-benzoquinones. W. H. G.

Preparation of Fibrinogen by Dialysis Against Sucrose Syrup. MAURICE PIETTRE and ANTONY VILA (*Compt. rend.*, 1913, **156**, 1182—1185).—The plasma is demineralised by dialysis against a syrup of sucrose followed by dialysis against distilled water. The

plasma, placed in a collodion bag, is first immersed in the sugar syrup for eight to ten hours, then removed, and the bag and contents placed in distilled water until the contents of the bag have returned to their original volume. By this means practically the whole of the mineral substances are removed, and the fibrinogen is deposited during the second operation, thus being isolated in the minimum of time with the use of but little liquid.   W. G.

β-Glutokyrine Sulphate. MAX SIEGFRIED (*Zeitsch. physiol. Chem.*, 1913, **84**, 288—299).—By the action of silver salts and barium hydroxide on glutokyrine a simplification of the glutokyrine molecule is brought about (compare Levene and Birchard, this vol., i, 109). There is no evidence that the silver and barium hydroxide treatment leads to a separation of the constituents of a mixture of kyrines. The quotient CO_2/N becomes smaller after treatment, but there is no increase in the nitrogen measured by Sörensen's formaldehyde method, indicating that no peptide linkings have been destroyed. On hydrolysis of the various fractions obtained during the treatment, arginine and lysine were obtained.   E. F. A.

The Rate of Destruction of Pepsin by the Direct Electric Current. W. E. BURGE (*Amer. J. Physiol.*, 1913, **32**, 41—43).— The digestive activity of a solution of pepsin is decreased (as is that of ptyalin) by the passage through it of a direct electric current at a uniform rate per unit of current.   W. D. H.

A New Method of Isolating Trypsin. HENRY LEOPOLD HOLZBERG (*J. Biol. Chem.*, 1913, **14**, 335—339).—The addition of safranine to aqueous solutions of Grübler's or Fairchild's trypsin, or to aqueous extracts of the pancreas causes a precipitate which is strongly proteolytic. The precipitate contains safranine, and is sparingly soluble in water. Removal of the safranine, or an increase in water solubility has not yet been accomplished. The precipitates produced by alcohol, or by a mixture of alcohol and ether in the mother liquor are practically devoid of proteolytic activity.   W. D. H.

The Enzymes of the Pancreas. II. The Action of Calcium Salts in the Generation of Trypsin from Trypsinogen. JOHN MELLANBY and V. J. WOOLLEY (*J. Physiol.*, 1913, **46**, 159 -172).— Salts of barium and strontium activate pancreatic juice as effectively as salts of calcium. On the addition of these salts to the juice the carbonate is precipitated, and the inhibiting alkali (sodium carbonate) is thus removed; the enterokinase (which is always present in the juice, although in variable amounts) is then allowed to act and convert trypsinogen into trypsin.   W. D. H.

Action of Ammonia on Invertase. IV. THEODOR PANZER (*Zeitsch. physiol. Chem.*, 1913, **84**, 408—416. Compare this vol., i, 113, 541).—Invertase takes up rather more dry ammonia than diastase. Some of the ammonia is not removed in a vacuum, and nitrogen determinations indicate that part has combined with some constituent

of the enzyme. The treatment does not affect the activity of the enzyme, but after the removal of the ammonia in a vacuum the activity is less, indicating that some such chemical process as the formation of an anhydride is concerned. The conclusion is drawn that the presence of free carboxyl groups is necessary for the enzyme activity. The mere addition of ammonia to form ammonium salts and aldehyde additive compounds has no effect on the specific activity. There is thus a difference in the active chemical groups in diastase and invertase as already indicated in the experiments (*loc. cit.*) with anhydrous hydrogen chloride. E. F. A.

Synthetical Properties of Emulsin. VERNON K. KRIEBLE (*Biochem. Bull.*, 1913, **2**, 227).—An emulsin which produced *l*-mandelonitrile from amygdalin, two years later produced the *d*-variety. This is explained by the supposition that the fresh emulsin contains two enzymes, one of which synthesises the *d*-nitrile from benzaldehyde and hydrocyanic acid, whilst the other, which is less stable, synthesises the *l*-nitrile. Fresh emulsin from sweet almonds produces the *l*-, and from bitter almonds the *d*-nitrile. W. D. H.

The Biochemical Synthesis of β-Methylglucoside in a Neutral Liquid, not Participating in the Reaction. ÉMILE BOURQUELOT and ÉM. VERDON (*Compt. rend.*, 1913, **156**, 1264—1266; *J. Pharm. Chim.*, 1913, [vii], **7**, 482—486).—Emulsin, although insoluble in acetone, will bring about the synthesis of β-methylglucoside by its action on a solution of dextrose and methyl alcohol in acetone containing 20% of water. This synthesis in acetone solution is as complete as in alcoholic solution, but is somewhat slower at first. Thus the ferment is capable of synthesising and hydrolysing glucosides in a neutral liquid, such as acetone, in which it is completely insoluble (compare A., 1912, i, 593). W. G.

The Enzymes of the Character of Emulsin. LEOPOLD ROSENTHALER (*Biochem. Zeitsch.*, 1913, **50**, 486—496).— Adopting Euler's suggestion as to nomenclature, the enzyme which brings about the hydroxynitrile synthesis is termed the *oxynitrilese*, whereas that which causes the scission of the former substance is called the *oxynitrilase*. The conclusion is drawn that oxynitrilese is not identical with δ-emulsin (amygdalase + prunase), because (1) a preparation which has been heated for some time at 40° can still cause the synthesis of an optically active nitrile, whereas it does not lead to the decomposition of amygdalin. (2) A preparation which has been treated successively with acid and then with alkali (to neutralise the acid) behaves in a similar way. (3) Filtrates from the precipitates produced by copper sulphate, by saturation with magnesium sulphate or half-saturation with ammonium sulphate, produce no synthetic action, although they exert the degrading action. The experiments on which these conclusions are founded did not, however, always yield concordant results. The conclusion is also drawn that oxynitrilase and oxynitrilese are different. The grounds are (1) that the latter is more rapidly inactivated by the action of benzaldehyde cyanohydrin,

(2) In several fruits of Umbelliferæ, only the oxynitrilase is present. (3) Preparations can be artifically obtained which contain only the oxynitrilese.   S. B. S.

Reversible Enzyme Action. Hydrolysis and Synthesis of Fats by a Lipase. UGO LOMBROSO (*Chem. Zentr.*, 1913, i, 1043—1044; from *Arch. Farmacol. sperim.*, 1912, **14**, 429—459).— Pancreatic secretion and intestinal juice were used as sources of lipase. At 37° hydrolysis of fats sets in immediately and continues until 80% has been changed. Synthesis is slow, requiring thirty to forty hours before it can be detected, and the amount is extremely small. The addition of bile had not the slightest effect on the synthetic process, but it accelerates the hydrolytic changes. Prolonged heating at 40° damages the hydrolytic enzyme, but does not affect the synthetic. Glycerol lessens the destructive influence of heat, but oleic acid has no such influence. The synthetic enzyme in the pancreas is not favoured by prolonged contact with either glycerol or oleic acid before these are mixed Pancreatic juice preparations which contain the synthetic enzyme have only feeble lipoclastic properties. The addition of fats retards the synthetic changes, but does not stop them. Intestinal secretions which are active hydrolytically have no synthetic activity.
                                                        E. F. A.

Enzyme Action. V. Action of Neutral Salts on the Activity of Castor Bean Lipase. K. GEORGE FALK (*J. Amer. Chem. Soc*, 1913, **35**, 601—616. Compare Falk and Nelson, A., 1912, i, 522, 593 ; Falk and Hamlin, this vol., i, 303 ; Falk, this vol., i, 433)—An account is given of experiments to determine the influence of neutral salts on the activity of a castor bean lipase preparation towards ethyl butyrate. In all cases, the change in the activity was found to be a continuous function of the concentration of the added salt. The activities, as compared with those of pure aqueous solutions, were decreased by the uni-univalent salts, by the chlorides and nitrates of barium and calcium (except for dilute solutions) and magnesium, by sodium oxalate, and by dilute solutions of sodium sulphate. The activities were increased by dilute solutions of the chlorides of barium and calcium, by concentrated solutions of sodium sulphate, by magnesium sulphate, and by manganous chloride and sulphate. Potassium sulphate solutions did not affect the activity.

The retarding action is probably due to coagulation of the enzyme by the salts, the ions of which produce their individual specific effects in each case. The accelerating action cannot be so easily explained, except perhaps for cases in which an increased formation of active lipase may be assumed (compare Falk and Hamlin, *loc. cit.*).   E. G.

Enzyme Action. VI. Specificity of Lipase Action K. GEORGE FALK (*J. Amer. Chem. Soc.*, 1913, **35**, 616—624)—An account is given of the effect of methyl and ethyl alcohols, acetone, glycerol, and dextrose on the activity of a preparation of lipase from the castor bean. Solutions of the alcohols and acetone exerted an inhibiting action on the hydrolysis of ethyl butyrate, the effect increasing with the con-

centration, but solutions of glycerol and dextrose did not produce any inhibiting effect except perhaps in concentrated solutions. It is considered probable that the simpler esters exert a specific inhibiting action on the activity of lipase similar to that exerted by the simpler alcohols, and that higher esters exert a smaller inhibiting action like that exerted by glycerol. This view is in harmony with the results obtained on testing the activity of castor bean lipase with solutions of methyl and ethyl acetates, ethyl butyrate, and glyceryl triacetate. In the light of these results, glyceryl triacetate is regarded as the most suitable ester for testing lipolytic activity.   E. G.

Enzyme Action. VII. Further Study of the Hydrolytic Action of Amino-acids on Esters. MARSTON LOVELL HAMLIN (*J. Amer. Chem. Soc.*, 1913, **35**, 624—632).—In continuation of the study of the hydrolytic action of certain amino-acids on esters (Falk and Nelson, A., 1912, i, 593) it has been found that glycine, glutamic acid, and aspartic acid exert a varying action on methyl and ethyl acetates, glyceryl triacetate, phenyl acetate, ethyl butyrate, and ethyl and phenyl benzoates. If these esters are arranged in the order of decreasing amounts of hydrolysis, the order varies with the hydrolytic agent used, namely, water, glycine, or glutamic or aspartic acid, and this indicates that the action is selective. Solutions containing both glycine and acetic acid exert a smaller hydrolytic action on methyl acetate and ethyl butyrate than do solutions of acetic acid alone.
                                                                      E. G.

Preparation of Thrombokinase from Fibrin. H. L. F. BOSWELL (*Proc. Physiol. Soc.*, 1913, iii; *J. Physiol.*, **46**).—Distilled water extracts thrombokinase from washed fibrin, but not thrombin.
                                                                      W. D. H.

Glyoxylase. HENRY D. DAKIN and HAROLD W. DUDLEY (*J. Biol. Chem.*, 1913, **14**, 423—431).—The catalyst, *glyoxylase*, studied converts methylglyoxal into lactic acid, and phenylglyoxal into mandelic acid. Evidence is presented that the agent is an enzyme; it is contained in aqueous extracts of muscle, liver, blood corpuscles, yeast cells, and the tissues of the oyster, but not in serum, potatoes, or cultures of the *B. bulgaricus*. The acids yielded are mixtures of the lævo- and inactive forms. It is possible that more than one enzyme is concerned.
                                                                      W. D. H.

Compounds of Carboxyarylarsinic Acids with Amino-acids Derived from Proteins. Hippuroarsinic Acid. LOUIS HUGOUNENQ and ALBERT MOREL (*J. Pharm. Chim.*, 1913, [vii], **7**, 383—389).—Hippuroarsinic acid and arsenohippuric acid have been prepared, and their physiological actions compared with those of benzarsinic acid and arsenobenzoic acid.

Dichloroarsinobenzoyl chloride (Fournean and Oechslin, A., 1912, i, 928) reacts with glycine in presence of *N*-sodium hydroxide solution to give a liquid from which, on addition of hydrochloric acid, hippur-

aisine oxide is precipitated along with some benzarsine oxide. This precipitate on solution in sodium hydroxide solution is oxidised by hydrogen peroxide to a mixture of benzarsinic and hippuroarsinic acid and the former is precipitated completely on adding hydrochloric acid in excess. The filtrate is made alkaline and concentrated under reduced pressure. On adding alcohol there separate *trisodium hippurarsinate*, $Na_2AsO_3 \cdot C_6H_4 \cdot CO \cdot NH \cdot CH_2 \cdot CO_2Na,4H_2O$, which crystallises from alcohol in needles, and on treatment with alcohol and hydrochloric acid furnishes crystalline *hippurarsinic acid*,

$$H_2AsO_3 \cdot C_6H_4 \cdot CO \cdot NH \cdot CH_2 \cdot CO_2H,$$
which is very soluble in water, but like the analogous substances decomposes when its aqueous solution is boiled with calcium or barium chloride or magnesia mixture. On reduction by Ehrlich and Bertheim's method, it yields *arsenohippuric acid*,

$$CO_2H \cdot CH_2 \cdot NH \cdot CO \cdot C_6H_4 \cdot As:As \cdot C_6H_4 \cdot CO \cdot NH \cdot CH_2 \cdot CO_2H,$$
a yellow powder, soluble in solutions of alkali carbonates or phosphates, forming unstable solutions, which deposit highly toxic arsine oxides, but gives solutions in alkali hydroxides, which are stable in the absence of air, and have a toxicity similar to those of solutions of arsenobenzoic acid.   T. A. H.

Physiological Chemistry.

Calorimetrical Experiments on Warm-blooded Animals. ARCHIBALD V. HILL and (MISS) A. M. HILL (*J. Physiol.*, 1913, 46, 81—103).—An automatic self-registering respiration calorimeter for small, warm-blooded animals is described; by its use it is possible to estimate within 2% the total heat liberated. In fasting rats at 15°, the heat production per gram is constant if the animals are more than one-third the size of the full-grown animal; for smaller specimens the figure rises rapidly, and may reach 70% greater than for grown animals. If the body surface is S, and the weight H, then in rats, $S = 10 \times W^{2/3}$. The rate of heat production to S during inanition is not constant, being 140 cal. per sq. cm. for small animals, 99 for medium-sized, and 110 for large animals. Any assumption that heat production is determined by heat loss is therefore unjustifiable. The high value in small animals is probably not due to their smallness, but to their youth, and consequently high chemical activity. Rats fed on biscuit at 15° give out 13% more heat than when fasting. If this is due to Rubner's specific dynamic value of foodstuffs, it suggests that the animals, even when fasting, give out more heat than is necessary to keep them warm. If the animals are kept in the calorimeter in groups, the heat production is lessened, because contact prevents heat loss, and especially as company promotes sleep and rest; they certainly grow faster.   W. D. H.

Oxygen Capacity of the Blood Pigment. WILHELM MANCHOT (*Zeitsch. physiol. Chem.*, 1913, **84**, 306—308).—Polemical. A reply to Burn (this vol., i, 306) and to Butterfield (A., 1912, ii, 820).

E. F. A.

The Phosphorus content of the Blood of Normal and Parathyroidectomised Dogs. ISIDOR GREENWALD (*J. Biol. Chem.*, 1913, **14**, 369—379).—After removal of the parathyroid glands, the total phosphorus of the blood and serum is increased, even at a time when the tremors are slight. The increase may be as much as 160 mg. of phosphorus per kilo. of blood. The greater part of this increase is in the fraction which is insoluble in the usual lipoid solvents, but is soluble in a mixture of dilute hydrochloric or acetic and picric acids.

W. D. H.

Formation of Lactic Acid from Dextrose, Glyceraldehyde, and Dihydroxyacetone in the Blood of the Ox and Pig. ADAM LOEB (*Biochem. Zeitsch.*, 1913, **50**, 450--456).—The red corpuscles of the ox and pig, which do not cause glycolysis of either the blood-sugar or added sugar, and only produce a small amount of lactic acid, nevertheless show either as high (pig) or even a higher (ox) capacity for producing lactic acid from glyceraldehyde than the blood of the dog, which has considerable glycolytic action. The red corpuscles of the pig have, furthermore, a considerably greater capacity than those of either the dog or ox of converting dihydroxyacetone into lactic acid.

S. B. S.

The Formation of Lactic Acid from Carbohydrates in Laked Blood. WALTER GRIESBACH (*Biochem. Zeitsch.*, 1913, **50**, 457—466).—From the blood of the ox and dog, cell-free blood solutions can be obtained, which, while they do not act on dextrose, can convert *dl*-glyceraldehyde and dihydroxyacetone into lactic acid as vigorously as the intact corpuscles. A mixture of racemic and *l*-acids is thereby produced, as is the case when the intact corpuscles are employed. The conclusion is drawn that the degradation of sugar into lactic acid takes place in two phases, and by two ferments; in the one phase the conversion of the dextrose into glyceraldehyde takes place, and this action is only possible when the cells are intact; in the second phase, the aldehyde is converted into lactic acid, and for this process the intact cell is not necessary.

S. B. S.

The Estimation of the So-called "Residual Reduction" of the Blood. PAUL MAYER (*Biochem. Zeitsch.*, 1913, **50**, 362--368).—By "residual reduction" is meant the reduction of Fehling's solution after the sugar in the blood has been removed by fermentation with yeast. It is now shown that pure dextrose solutions (0·1%), after treatment with various races of pure yeasts, also show a "residual reduction," after removal of proteins, etc., by colloidal iron hydroxide. This is due to substances derived from the yeast itself, and the concentrated solutions, after treatment, show reactions for amino-acids and, in most cases, also for purine substances.

S. B. S.

The Formaldehyde Titration of Proteins. II. FRIEDRICH OBERMAYER and ROBERT WILLHEIM (*Biochem. Zeitsch.*, 1913, **50**, 369—385. Compare A., 1912, ii, 399).—It is possible, by Sörensen's method, to estimate the reactive amino-groups in a protein, and the ratio of this reactive amino-nitrogen to the total nitrogen is designated the "amino-index." In euglobulin the mean value (21·5) of the index is higher than that of albumin (about 12). In mammals the value for pseudoglobulin is about the same as that for euglobulin, but in birds it does not differ very much from that of albumin (the mean value is about 15). By means of the determination of this index it is possible to show that the various protein fractions of serum are not homogeneous substances. It is also possible to demonstrate differences in the sera of different species, and the fraction salted out by 25—30% ammonium sulphate has a higher "amino-index" in the case of a hen (28·5- -32·5) than in the case of an ox (19—21·5). The serum of the horse is similar to that of the ox, and the serum of the goose is similar to that of the hen; it is therefore possible that the "amino-index" of a definite fraction may be characteristic for definite classes of animals.

S. B. S.

The Specificity of Immunity Reactions, and their Explanation as Colloidal Chemical Phenomena. KURT LANDSTEINER (*Biochem. Zeitsch*, 1913, **50**, 176—184).—The author does not regard the contention of Michaelis and Davidsohn (this vol., i, 121), that certain immunity reactions are not of colloidal chemical character, as justified. The view was arrived at on the ground that certain precipitin reactions are independent to a large extent of the hydrogen ion concentrations. Attention is especially called to the fact that serum, blood corpuscles, etc., of different species exert the maximum action in the presence of different hydrogen ion concentrations. This point is illustrated by the adsorption of ricinus agglutin, by the different strengths of acid or alkali which haemolyse the corpuscles, by the differences in the agglutination of stromata, and the differences in the precipitability of the sera precipitating reagents.

S. B. S.

The Coagulation of the Blood. The Significance of Various Physico-chemical Processes in the Action of Thrombin. M. LANDSBERG (*Biochem. Zeitsch.*, 1913, **50**, 245 272). The temperature curve of reaction velocity of blood coagulation is the result of at least two concurrent processes. The main process is the reaction between the thrombin and fibrinogen, and is apparently of a chemical character. The other reaction, which is antagonistic to the first, is an inhibition of the thrombin action due to its adsorption by the proteins of the serum. Both processes are accelerated by increase of temperature, which exerts therefore a twofold influence on the clot formation. The temperature curve depends to a large extent on the conditions of the experiment. In such combinations, in which the adsorption process is reduced to a minimum, the clotting reaction resembles a fermentative process with an optimal temperature of 35—40°. In the combination,

magnesium sulphate plasma-| Schmidt's thrombin, which is particularly favourable to adsorption processes, there is a diminution of the reaction velocity even at 17– 20°. The adsorption of thrombin by the serum proteins increases with temperature, and is only partly reversible. The conversion of the serum thrombin into its inactive "metathrombin" form is simply due to adsorption; the reactivation by Schmidt's method by means of alkalis being simply the breaking down of the adsorption compound. The general results indicate that there are no facts which are antagonistic to the idea of a fermentative process in clotting.

<div style="text-align: right">S. B. S.</div>

Water Drinking. XIV. The Digestive Efficiency of Saliva as Increased by Dilution with Water. OLAF BERGEIM and PHILIP B. HAWK (*J. Amer. Chem. Soc*, 1913, **35**, 461—476).—Mattill and Hawk (A., 1912, ii, 65) have shown that the drinking of large volumes of water with meals increases the amount of carbohydrate digested. Experiments which have now been made *in vitro* show that the dilution of normal human saliva increases its digestive efficiency. The optimum dilution depends on the nature of the diluent, and is 4 volumes for 0·3% sodium chloride solution and 7 volumes for water. Water, softened by the addition of lime water, exerts an inhibiting effect, due principally to the presence of magnesium hydroxide.

<div style="text-align: right">E. G.</div>

The Action of Sugar on Digestion. ERWIN THOMSEN (*Zeitsch. physiol. Chem.*, 1913, **84**, 425—436) —Sucrose has no direct action on the stomach, or on the secretion of pancreatic juice and bile. Its action on the small intestine is due to prolongation of gastric digestion without altering the secretions. The lengthening of gastric digestion is due to the occurrence of long pauses in the emptying of the stomach. Sucrose is completely or almost completely absorbed in the small intestine in large quantities, but it delays the absorption of the chyme.

<div style="text-align: right">W. D. H.</div>

The Pepsin-Chymosin Question. A. RAKOCZY (*Zeitsch. physiol. Chem.*, 1913, **84**, 329—353. Compare A., 1911, i, 827). The question of the identity of the milk coagulating and protein digesting enzymes is bound up with nature and age of the animal. Hasselt (A., 1911, i, 248), Porter (A., 1911, i, 698), and Burge (A., 1912, i, 148) have all established the presence of a special milk coagulating enzyme in the stomach of the calf. In such infusions where the two enzymes are present they can be separated by Hammarsten's casein method, but with the stomach infusions from other animals which contain no chymosin no such separation could be effected. The power of coagulating milk is inseparably bound up with the peptic enzyme.

In a similar manner elastin may be used to adsorb pepsin, whereas it has no effect on chymosin. This method enables the two enzymes to be separated in the gastric juice of the calf, but not in that of other animals. In slightly acid solution (*N*/200 hydrochloric acid) edestin adsorbs chymosin, but there is no action when the acidity

is increased ($N/80$-acid).   On digestion with water, the adsorbed chymosin is recovered from the edestin.

Pepsin in the ox and in the calf appears to have the same properties, and that derived from the two sources is the same.

Milk is coagulated in the stomach in all mammals from the first day of life onwards.   The ruminants and such animals as the horse and the pig secrete both pepsin and chymosin.   Human beings secrete pepsin only, whilst in dogs and cats neither pepsin nor chymosin is present, and the coagulation is due to other factors which are at present but imperfectly understood.   E. F. A.

Formation of Plastein. I. P. GLAGOLEV (*Biochem. Zeitsch.*, 1913, **50**, 162—175).—Formation of plastein has characteristics of a fermentative character, in that it takes place in the presence of minute quantities of the digestive fluid, requires a certain definite reaction of the medium, and does not take place if the digestive fluid is first boiled.   It appears to be a generative process, in that when produced by rennin powder (Witte's), natural gastric juice, or papayotin, there is a diminution of the reactive amino-groups, as determined by Sörensen's formaldehyde titration.   Plastein formation is a reversible process, and depends on the quantities of ferment, concentration of reacting substances, and reaction of the medium.   The reversibility of the reaction can even be detected in very concentrated syrupy solutions.   S. B. S.

Synthetic Powers of the Organism of the Dog. WILHELM STEPP (*Zeitsch. physiol. Chem.*, 1913, **84**, 359—360.   Compare A., 1911, ii, 1002; this vol., i, 419).—This is a reply to Abderhalden's criticism of the author's work.   The death which follows feeding mice on nutriment boiled in alcohol is attributed to destruction of lipoids, and doubt is expressed whether mice possess the synthetic powers to construct these substances from simple cleavage products.
W. D. H.

Metabolism Experiments on Parathyroidectomised Dogs. ISIDOR GREENWALD (*J. Biol. Chem.*, 1913, **14**, 363—367)—After removal of the parathyroids, the excretion of phosphorus in the urine is lessened; there is no increase of phosphorus in the fæces; apparently it is retained in the body.   This retention appears to be primary, and not secondary to the retention of sodium or potassium, or of both.   In no experiments did the retention of the bases precede that of phosphorus.   Whether the changes are the cause of tetany is questionable.   W. D. H.

The Carbohydrate-sparing Action of Alcohol. O. TUGEL, E. BREZINA, and ARNOLD DUBIG (*Biochem. Zeitsch*, 1913, **50**, 296—345).—The method of experiment was as follows.   A human subject was kept on a carbohydrate-rich diet.   A large quantity of dextrose or lævulose was then ingested, and the respiratory quotient was determined at definite intervals afterwards, while the subject was kept in a state of rest.   The results thus obtained were com-

pared with those where the experiment was carried out in a similar manner, but where alcohol was ingested in addition to a carbohydrate. After ingestion of 100 grams of dextrose, it was found that the respiratory quotient sank at first, but began to rise after half an hour, until after two hours it gradually rose to 1. After an interval, it gradually sank, until after four hours it reached the original value. Repeated doses of 100 grams of dextrose administered to a subject on carbohydrate-rich diet finally caused only a slight rise in the respiratory quotient. The sugar in this case was neither burnt, excreted as such, nor found in the blood-stream. Lævulose acted in a similar manner, but the action was somewhat more marked than that of dextrose. By repeated doses of 30 grams of lævulose, the respiratory quotient could be maintained for a long time at 1. The general effect of the ingestion of alcohol with the sugar was to depress the respiratory quotient as compared with the control experiments without alcohol. The addition caused no change in the calories used up. In the first period, it was calculated that 70—100 mg. of alcohol were burnt per minute. The depression of the respiratory quotient is not due to the narcotic action of the alcohol, as this is uninfluenced by other narcotics, such as opium. The conclusion is therefore drawn that alcohol exerts a carbohydrate-sparing action in the metabolism.

S. B. S.

Nitrogenous Metabolism. EMIL ABDERHALDEN and ARNO E. LAMPÉ (*Zeitsch. physiol. Chem.*, 1913, **84**, 361—362).—Polemical. A reply to Grafe (this vol., i, 547). W. D. H.

Intermediary Metabolism of Amino-acids. HENRY D. DAKIN (*J. Biol. Chem.*, 1913, **14**, 321—333).—Serine, cysteine, proline, ornithine, and arginine all yield large amounts of sugar in glycosuric dogs. Valine, leucine, isoleucine, lysine, histidine, phenylalanine, and tryptophan yield little or no sugar. Arginine is thus the only amino-acid with more than five carbon atoms which yields sugar, and in this case the ornithine moiety is responsible for the action. Amino-acids with branched chains yield little or no sugar. Proline is the only cyclic amino-acid which yields sugar readily; the opening of the ring is the first step in the breakdown. Phenylalanine, tyrosine, and tryptophan all contain an alanine side-chain, but yield no sugar, although alanine itself does; this indicates that the side-chain is broken up.

Ornithine, lysine, arginine, proline, tryptophan, and di-iodo-tyrosine do not yield acetoacetic acid in marked amounts when added to blood perfusing a dog's liver. W. D. H.

The Behaviour of Some Hydantoin Derivatives in Metabolism. II. 2-Thiohydantoins. HOWARD B. LEWIS (*J. Biol. Chem.*, 1913, **14**, 245—256).—2-Thiohydantoin is toxic for rabbits; the toxicity is increased by the substitution of an alkyl group in the 4-position. 2-Thio-4-methylhydantoin is less toxic, and 2-thio-hydantoin-4-acetic acid is not toxic in doses of 2 grams. 2-Thio-

4-methylhydantoin in fatal doses causes albuminuria in rabbits. The sulphur is not oxidised.   W. D. H.

Purine Metabolism. I. Uricolysis in the Human Subject. ALONZO E. TAYLOR and WILLIAM C. ROSE (*J. Biol. Chem.*, 1913, 14, 419—422).—The nitrogen of milk and eggs was replaced by that in sweetbreads. The purine nitrogen of the urine was increased; this increase is due solely to uric acid. More than half the ingested nitrogen was, however, either destroyed in the alimentary tract before absorption, or was converted in metabolism into non-purine substances, presumably urea.   W. D. H.

The Utilisation of Ammonia in Protein Metabolism. ALONZO E. TAYLOR and A. I. RINGER (*J. Biol. Chem*, 1913, 14, 407—418. Compare this vol, i, 548).—In dogs during inanition, and still more in diabetic dogs, ammonium carbonate given by the mouth led to a retention of nitrogen; given under the skin it was promptly eliminated. The administration of urea was followed by complete elimination of all the nitrogen. Ammonia given to man on a protein-free diet was retained to the extent of two-thirds. The presence of carbohydrates in the food is not a necessary factor in the retention of nitrogen from ammonia. It is suggested that the nitrogen is retained because of a reversible reaction that leads to combination with the α-ketonic- or α-hydroxy-acids to form amino-acids, which may be used in the synthesis or sparing of the body proteins.   W. D. H.

The Action of Completely Cleaved Nutriment on the Alimentary Canal. OTTO COHNHEIM (*Zeitsch. physiol. Chem.*, 1913, 84, 419—424).—Although it has been shown that animals can maintain nitrogenous equilibrium on protein food which is broken down to the simplest constituents, no note has hitherto been made on the effect of such diet on the alimentary canal itself. There are other factors, such as taste, consistence, etc., which influence digestion in addition to chemical composition. In the present research, however, in a dog with a duodenal fistula fed on two commercial specimens of such nutriment (erepton and hapan), no effect on the time of digestion in the stomach or on the amount of digestive juices secreted could be found, when compared with what occurs on a usual diet. These preparations were found to be well absorbed when administered by the rectum.   W. D. H.

The Preparation of Dry Animal Organ Material. ALBRECHT KOSSEL (*Zeitsch. physiol. Chem.*, 1913, 84, 354—358).—An elaborate apparatus is described which enables animal organs to be frozen solid by means of carbon dioxide snow, cut into small pieces, and dried below 0°. Colourless or reddish-grey powders are thus obtained from the original organs.   E. F. A.

The Relative Influence of Weak and Strong Bases on the Rate of Oxidations in the Unfertilised Egg of the Sea Urchin. JACQUES LOEB and HARDOLPH WASTENEYS (*J. Biol. Chem.*, 1913, 14, 355—362).—Weak bases, which are more efficient in causing

artificial parthenogenesis, are also more efficient in raising the rate of oxidation in the unfertilised egg-cell. This lends support to the view that bases cause parthenogenesis by accelerating oxidation.

W. D. H.

Chemistry of Embryonic Growth. I. Certain Changes in the Nitrogen Ratios of Developing Trout Eggs. Ross A. GORTNER (*J. Amer. Chem. Soc.*, 1913, **35**, 632—644).—An account is given of a study of the nitrogenous constituents of trout eggs at various stages of development. It is probable that the egg does not lose any nitrogen before hatching, but afterwards it suffers a rapid loss, until in twenty-one days after hatching, 21·96% of the total nitrogen has disappeared. During its development into the fish, the egg loses 25·35% of its weight, of which 37·26% is due to non-protein matter (fats, etc.) and 62·74% to proteins, and simultaneously basic forms of nitrogen increase at the expense of the monoamino-acids. Urea and uric acid are not produced in any considerable quantity. The composition of the nitrogenous substances which disappear indicates that there is a selective utilisation of the nitrogen compounds by the developing fish. It is probable that some of the energy of development is derived from the shifting of the nitrogen ratios, and it is suggested that as the change from monoamino-acids to basic nitrogen compounds proceeds the energy relations may perhaps be changed and heat liberated.

E. G.

Chemical Differentiation of the Central Nervous System. I. Comparison of the Brain of the Albino Rat at Birth with that of the Fœtal Pig. (Miss) MATHILDE L. KOCH (*J. Biol. Chem.*, 1913, **14**, 267—279).—Estimation of the constituents of the brain of the rat at birth shows it to be as chemically undifferentiated as the brain of a 50—100 mm. length fœtal pig. The correspondence is further supported histologically. If the nervous systems are assumed to be in corresponding states when motor control is obtained, and Donaldson's law is correct that the nervous system is in the same state at corresponding physiological ages, then the brain of the rat at birth should correspond chemically with the 100 mm. fœtal pig brain. This was found to be the case. W. D. H.

Chemical Differentiation of the Central Nervous System. II. A Comparison of Two Methods of Preserving Nerve-tissue for Chemical Examination. WALDEMAR KOCH and (Miss) MATHILDE L. KOCH (*J. Biol. Chem.*, 1913, **14**, 281—282).—The material was placed directly in 95% alcohol, and part was dried at 95°. The latter process was found to seriously affect the analyses, the most important change produced being a destruction of phosphatides; this was more marked in brains than in spinal cords. W. D. H.

Distribution of Nerves in the Heart. (Miss) WINIFRED C. CULLIS and (Mrs.) ENID M. TRIBE (*J. Physiol.*, 1913, **46**, 141—150). --After section of the auriculo-ventricular bundle in rabbit and cat,

pilocarpine and muscarine no longer inhibit ventricular activity; they act on the auricles as usual, and are antagonised by atropine; atropine has no effect on the ventricles. Under similar conditions adrenaline produces its normal augmentor effect on the ventricles. From this, it appears that the ventricle does not receive vagus fibres, and that the normal effect of the vagus on the ventricles is therefore indirect through the auricle; further, the ventricle must be supplied with sympathetic fibres, which reach it not only by way of the auriculo-ventricular bundle.   W. D. H.

Action of Certain Drugs on Isolated Strips of Ventricle. (Miss) Constance Leetham (*J. Physiol.*, 1913, **46**, 151—158).— Experiments are recorded with isolated strips of ventricle which confirm the findings of Cullis and Tribe (see preceding abstract).
                                        W. D. H.

Action of Dyes on the Isolated Frog's Auricle. A. J. Clark (*Proc. Physiol. Soc*, 1913, xx; *J. Physiol.*, **46**).—The excised auricle and fibres of the frog's heart beat in Ringer's fluid for some hours. Neutral-red dissolved in the fluid stains the muscular fibres red, but does not injure them. If the alkalinity of the fluid is increased, the fibres remain red as long as they exhibit activity, but when the concentration of alkali is sufficient to arrest activity, they turn yellow. This agrees with Warburg's observations on sea-urchin eggs, and supports the conclusion that normally animal cells are not permeable to hydroxyl ions.   W. D. H.

The Presence of Trimyristin and Cephalin in the Liver. Armando Frank (*Biochem. Zeitsch.*, 1913, **50**, 273—282).—The coagulated and dried ox-liver was extracted by acetone, from which solution, on keeping, a crystalline substance separated, which was identified as trimyristin. The liver powder was then extracted with light petroleum. The extract thus obtained was dissolved in ether and precipitated with acetone. The precipitate was redissolved, filtered, and then reprecipitated with acetone, and this procedure was repeated many times. The substance was, in composition and properties, nearly allied to the cephalin isolated from brain by Thudichum and others. Experiments were carried out which tend to show that the so-called liver jecorin is cephalin contaminated with other substances, such as sugar.   S. B. S.

Estimation of Adrenaline. Thomas R. Elliott (*Proc. Physiol. Soc.*, 1913, xv—xvii; *J. Physiol.*, **46**).—Many workers give adrenaline values which are too low owing to faulty extraction and estimation. At birth nearly all the adrenaline is in the outside paraganglia; in the adult the two suprarenals contain 8—9 mg. In septic conditions it may drop to a quarter of this value. Estimations may be made by the effect on arterial pressure, or by the new colorimetric reaction of Folin and Denis with phosphotungstic acid. The two work out practically the same, but the latter is much the simpler and quicker method.   W. D. H.

The Iodine and Phosphorus Contents, Size, and Physiological Activity of the Fœtal Thyroid Gland. FREDERIC FENGER (*J. Biol. Chem*, 1913, **14**, 397—405).—Functional therapeutic activity and the presence of iodine coincide in the fœtal human thyroid as in extra uterine life. The amount of iodine during the last three months of fœtal life is uniform in the various seasons. The fœtal thyroid is relatively large, and contains more iodine and phosphorus per unit of body weight than those from mature animals. This is especially the case for females. Enlarged thyroid glands were found in small fœtuses. The enlarged glands, as in the adult, contain less iodine and more phosphorus than the normal. Enlargement of the fœtal thyroid is common, and is probably the consequence of insufficient supply or faulty assimilation of iodine on the part of the pregnant animal. W. D. H.

The Changes in Metabolism Produced by the Extirpation of Thyroids and Parathyroids. RAFFAELE PALADINO (*Biochem. Zeitsch.*, 1913, **50**, 497—507).—The experiments were carried out on dogs. The parathyroids and thyroids appear to exert a considerable influence on the phosphorus metabolism, for after extirpation the amount of phosphate excreted (chiefly in the form of phosphates of alkaline earths) increases to three times the normal amount. The amount of calcium excreted diminishes. There is no marked change in the nitrogen excretion. S. B. S.

The Relation of the Corpus Luteum to Lactation. CHARLES H. O'DONOGHUE (*Proc. Physiol. Soc.*, 1913, vi; *J. Physiol.*, **46**).—In rabbits, if the rupture of the Graafian follicles in the ovary is followed by the formation of corpora lutea, there is also growth of the mammary glands, but there is no such growth if corpora lutea do not form. W. D. H.

Biochemistry of the Female Genitalia. III. Enzymes of Ovary, Uterus, and Bladder in Sheep. JACOB ROSENBLOOM and THUISCO A. ERPF-LEFKOVICZ (*Biochem. Bull.*, 1913, **2**, 233—235).—Lipase and amylase are more abundant in the ovary and uterine mucous membrane of pregnant than of non-pregnant sheep. Pregnancy has no effect on the acid-protease of either organ, but increases the alkali-protease. Bladder extracts contained lipase, amylase, and acid-protease, but no alkali-protease. W. D. H.

Biochemistry of the Female Genitalia. IV. Absence of Certain Enzymes from the Human Chorion. JACOB ROSENBLOOM (*Biochem. Bull.*, 1913, **2**, 236—237).—One chorion weighing 10 grams was examined. Extracts made with water and with glycerol were free from amylase, sucrase, maltase, lactase, lipase, peptidase, ereptase, acid-protease, and alkali-protease. The enzymes of the placenta are either developed later, or originate from the maternal moiety (decidua serotina). W. D. H.

The Effect of Small Variations in Concentration of Ringer's Solution on the Response of Isolated Plain Muscle. HENRY H. DALE (*Proc. Physiol. Soc.*, 1913, xix; *J. Physiol.*, **46**).—By adding

salt in small amounts to Ringer's fluid in which plain muscle (uterus) is suspended, the response of the muscle to the anaphylactic reaction and to stimulant drugs is lessened or annulled.   If the tonicity of the fluid is lowered by adding water, the responsiveness is increased.   The effects are not due to specific ionic action, but are due to alterations in osmotic pressure; solutions of non-electrolytes produce the same effects.   W. D. H.

Muscle Chemistry. VI. The Free Amino-acid Nitrogen Titratable by Formaldehyde and the Total Extractive Nitrogen in Muscular Tissue of Animals in a State of Inanition. GIUSEPPE BUGLIA and A. COSTANTINO (*Zeitsch. physiol. Chem.*, 1913, **84**, 243—253).—In dogs to which water only was given for periods varying from twelve to twenty-five days, there was no change in the total nitrogen of the muscles, but there was a small increase in the total extractive nitrogen and in the nitrogen of free amino-acids.   This change is not a progressive one, that is, it does not increase as the period of inanition increases.   Confirmatory experiments on the octopus are also recorded.   W. D. H.

The Lipins (Lipoids) of the Heart Muscle of the Ox. JACOB ROSENBLOOM (*J. Biol. Chem.*, 1913, **14**, 291—294).—Only about 40% of the ether and alcohol extract of heart muscle of the ox is composed of phospholipins (phosphatides), and practically no difference in this percentage was obtained on comparing the extractions carried out in the cold with those carried out at the boiling point of the solvent.   W. D. H.

Origin of Fatigue. GAETANO VIALE (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 253—256).—In prolonged muscular work quantities of water are eliminated in the sweat.   This water comes from the blood, which in turn withdraws water from the tissues   When a certain point is reached, the necessary water is no longer forthcoming.   This is evidenced by decreased secretion of sweat, and by increase in the amount of sodium chloride contained in it.   The origin of fatigue is to be found in this removal of water, which causes accumulation of toxins in the blood and disturbs the heat regulation of the organism.   In agreement with other workers, the author finds a decrease in red blood corpuscles and in hæmoglobin in fatigue, and this is to be explained as being due to an accumulation of them in the organs.   R. V. S.

The Behaviour of the Creatine of Muscle during Fatigue. VITTORIO SCAFFIDI (*Biochem. Zeitsch*, 1913, **50**, 402—417).—In the muscular tissue of the frog and dog (and probably in all muscular tissue) creatinine does not exist as such in a preformed condition. Care must be taken to exclude high temperatures and acids in the process of its extraction from the tissues.   Neither does creatinine appear to be formed in frog's muscle during work; if it is formed, it is either immediately removed or destroyed.   Creatine shows certain variations in the quantity found, both in resting and

fatigued conditions, these variations being of about the same order of magnitude in both cases. It was not possible therefore to draw the conclusion that the creatine is formed as a result of work. It is, however, possible that during work creatine is used up, and new supplies are formed from degradation products of the muscle proteins. The condition of the circulation exerted no influence on the creatine metabolism in the frog during muscular work, as similar results were obtained when the circulation was intact, or entirely excluded.   S. B. S.

The Effect of Adrenal Secretion on Muscular Fatigue. WALTER B. CANNON and L. B. NICE (*Amer. J. Physiol.*, 1913, **32**, 44—60).—The experiments were performed on cats, rabbits, and dogs; a fatigue curve of a voluntary muscle was obtained by stimulating its nerve. Excitation of the splanchnic nerve increased the height of the muscular contraction. The question was whether this was due to the pouring out of adrenaline into the circulation, and this is answered in the affirmative; the adrenaline appears to act, however, not on the muscle directly, but by improving the circulation of blood through it. Previously reported favouring effects of adrenaline on voluntary muscles (mainly studied in cold-blooded animals) are capable of a similar explanation.
                                                                  W. D. H.

The Consumption of Fats in the Animal Organism. G. LAFON (*Compt. rend.*, 1913, **156**, 1248—1250).—In order to determine the consumption of fat by the tissues, the author has estimated the amount of fat in the arterial blood and in the venous blood coming from the muscle, first in a state of repose, and then during activity. This has been done in the case of the horse and the ass, working on the muscle of the upper lip, activity being produced by mastication, and in the case of the dog on the muscle of a hind limb, the muscle being electrically excited. The results show that the fat is consumed directly, and to the same extent as dextrose, during the activity of the tissues, and in particular during muscular work. Muscles fatigued by electrical excitation contain less fat than fresh muscle.   W. G.

Fluorine in the Animal Organism. I. Skin and its Appendages. ARMAND GAUTIER and PAUL CLAUSMANN (*Compt. rend.*, 1913, **156**, 1347—1353).—Fluorine is to be found everywhere in the organs of plants and animals, but is specially concentrated in a few of them. This paper gives an account of the quantitative examination for fluorine of the skin, and such appendages as the hair, epidermis, nails, tooth enamel, etc., in the case of human beings, animals, birds, and fishes. In their fluorine content, the hair, down, fish-scales, nail, and tortoise-shell resemble the epidermic tissue, whilst the enamel of teeth and the horns differ from it widely, the former parts being rich and the latter poor in fluorine. The fluorine in skin itself appears to accompany the phosphorus and increase with it, for the same organs, without being proportional

to it. It is more abundant at the adult age in human than in animal skin, and diminishes in organs which are in process of decay, such as hair, teeth, etc., of old animals.

The method of estimation consists in incinerating the organ under examination, when dried, with 1 to 1·5% of calcium oxide, and the fluorine is estimated in the alkaline non-fused ash by a method already described (compare A., 1912, ii, 681, 805, 806).   W. G.

The Relation of Osmotic Pressure to Absorption Phenomena in the Dog-fish. G. G. SCOTT and WILLEY DENIS (*Amer. J. Physiol.*, 1913, **32**, 1—7).—Dog fishes, of which the spinal cord was largely destroyed, were immersed in various solutions (methylene-blue, boric acid, potassium iodide), and the material being prevented from entering the alimentary canal, the time was noted when they appeared in the blood, urine, etc. The gill membranes appear to be the main channel of absorption, and the physical laws of diffusion suffice to explain the results.   W. D. H.

The Action of Ultra-violet Rays on the Ear of the Rabbit Influence of Intensity. Intermittent Radiations. VENCESLAS MOYCHO (*Compt. rend.*, 1913, **156**, 1268—1271. Compare this vol., i, 424).—As the intensity of the radiation increases, the time necessary for the ear to be subjected to it, to produce visible effect, diminishes. The amount of energy necessary to produce minimum visible reaction is practically constant for intensities varying from 4 to 100. If, instead of continuous radiation, the ear is subjected to intermittent treatment, the visible effect is produced when the sum of the short radiations is equal to the continuous radiation, providing that the intervals between the application of the light do not exceed forty-eight hours.   W. G.

Chemical Studies on Rhizostoma Cuvieri. RICHARD VON ZEYNEK (*Monatsh.*, 1913, **34**, 581—621).—If a jelly-fish of the above type is removed from water, a mucous substance is exuded which contains innumerable stinging threads; it causes an intense burning when cautiously placed on the tip of the tongue. The mucous substance easily undergoes decomposition; when precipitated by ammonium sulphate and redissolved by a very weak potassium hydroxide solution, acetic acid throws down a flocculent precipitate, which dissolves readily in hydrochloric acid; when heated with this acid, a solution is obtained which reduces Fehling's solution and gives an osazone. The precipitate given by acetic acid contains no phosphorus, whilst the potassium hydroxide solution gives the biuret reaction. The stinging threads are very resistant, and contain very appreciable quantities of silicic acid. When the above mucous substance is allowed to dry on the clothes, the dust causes nasal irritation and acute catarrh, which persists for several hours. The substance to which irritation is due appears to be non-volatile; a careful examination of the mucous substance, however, revealed the presence of an alkaloidal substance.

[With F. AMESEDER.]—Specimens of the Rhizostoma were

analysed, also the water in which one had lived and parts of the organism; the results are to be seen in the original

The blue colouring matter (zoocyanin) present in *Rhizostoma Cuvieri* varies slightly in tone with the age of the specimen. The fresh aqueous extract is neutral, and the coloured substance is almost entirely precipitated by a 22—27% solution of ammonium sulphate, when it is obtained as a gelatinous mass; it was purified by washing and fractional precipitation with ammonium sulphate solution. The aqueous solution of the substance is turned brown on warming to 55° or on adding alcohol or acetone. Formaldehyde has no effect, but precipitates are obtained with phosphotungstic acid, phosphomolybdic acid, potassium bismuth iodide, potassium mercuri-iodide, and a solution of iodine in potassium iodide. It thus appears that the colouring matter is a protein substance, and the composition is in confirmation of this view. The colour was examined spectroscopically. D. F. T.

Analysis of Human Bile. JACOB ROSENBLOOM (*J. Biol. Chem*, 1913, **14**, 241—244).—An analysis of a specimen of fistula bile is given, and compared with others previously published. W. D. H.

The Physiology of Secretion in the Kidney. OTTO COHNHEIM (*Zeitsch. physiol. Chem.*, 1913, **84**, 451—467).—Sodium chloride and dextrose are taken up by the surviving kidney at body temperature from solutions, and fixed in loose chemical union, which is dissolved at boiling heat. These combinations, as well as the secretion of these substances by the kidney, have a certain threshold, beneath which the kidney unites with none, and over it with considerable quantities. The chemical combination with the cell-constituents is a preliminary stage in secretion. W. D. H.

The Conditions Affecting the Formation and Excretion of Formic Acid. The Estimation of Formic Acid in Urine HENRY D. DAKIN, N. W. JANNEY, and ALFRED J. WAKEMAN (*J. Biol. Chem.*, 1913, **14**, 341—354).—The formic acid in urine is partly endogenous. The effect of a number of substances on formic acid excretion was investigated, including amino-, hydroxy-, and saturated fatty acids. Special attention is called to the effect of inanition, which greatly reduces the amount excreted. The acid is largely increased when carbohydrates are given by the mouth or subcutaneously. Protein feeding is followed by a similar but smaller increase. Formic acid is regarded as a product of the intermediary metabolism of carbohydrates and proteins.

Formic acid is estimated in urine by saturating the latter with ammonium sulphate, extracting with ether, removing the formic acid from the ether by sodium carbonate, acidifying with phosphoric acid, distilling in a current of steam, adding mercuric chloride to the distillate, and weighing the calomel formed. W. D. H.

The Excretion of Nitrogen Subsequent to Ligature of Successive Branches of the Renal Arteries. J. D. PILCHER (*J. Biol. Chem.*, 1913, **14**, 389—395).—Ligaturing half the blood

supply of both kidneys causes no noticeable disturbance in renal function. Complete ligature of one artery, and one branch of the other (that is, shutting off three-quarters of the arterial supply), results in prostration, loss of weight, and an increase of excretion of nitrogen; the animals, however, recover gradually. One quarter of the kidney tissue is therefore able to do the work of the whole.

W. D. H.

A Differential Chemical Study of Glucoses from a Case of Pancreatic Diabetes. FREDERIC LANDOLPH (*Biochem. Bull.*, 1913, **2**, 217—222).—The sugar is diabetic urine (one specimen examined) is regarded as a complex of many carbohydrates which can be separated by various treatments. Some of these are dextrin-like, and yield with phenylhydrazine "pseudo-osazones," which are resinous and have low melting points. The work is not yet completed.

W. D. H.

A Modification of Diphtheria Antitoxin. A. T. GLENNY (*J. Hygiene*, 1913, **13**, 63—67).—Evidence is adduced that diphtheria antitoxin is of two kinds, which affect two kinds of the toxin, one of which is lethal, and the other of which produces the local reaction.

W. D. H.

Presence of Propionic Acid in the Secretions of Rheumatic Persons. WILLIAM ŒCHSNER DE CONINCK (*Compt. rend.*, 1913, **156**, 1272).—The urine of rheumatic patients, after a severe attack, has an odour recalling at the same time butyric and acetic acids, and from this urine the author has isolated propionic acid. This acid he has also found in the discharge from eczema sores of such patients.

W. G.

The Action of Nitrites on the Body Temperature of Normal Rabbits, and on those Rendered Hyperthermic by Brain Stimulation EMANUEL KRAUSS (*Arch. expt. Path. Pharm.*, 1913, **72**, 97—128).—The experiments show that nitrites, as stated by Jacobj, depress the body temperature. Further observations are necessary to explain this, and also why the inhalation of amyl nitrite acts much more markedly on rabbits in a state of hyperthermia.

W. D. H.

Action of Nitrites on the Body Temperature of Rabbits. CARL JACOBJ (*Arch. expt. Path. Pharm*, 1913, **72**, 129—152).—Nitrites given in various ways (inhalation, subcutaneously, etc.) depress the body temperature of rabbits, especially if they are rendered hyperthermic by stimulation of the brain. These compounds appear to act chiefly on the heat-regulating centres, and secondarily by influencing the calibre of the skin-vessels.

W. D. H.

The Action of Electrolytes on Paramœcium. (Miss) DOROTHY DALE (*J. Physiol.*, 1913, **46**, 130—140).—Experiments were performed to determine the C_H limits fatal to Paramœcium. These for a

given "buffer" are constant for the various cultures used, and are different for different "buffers." The simple tervalent positive ions are more potent than the complex tervalent ions. The action of the former, although similar to that of increased C_H, is not explained by hydrolytic dissociation. The action of various ions on the changes of movement is described. The action of hydrogen and hydroxyl ions and of multivalent cations and anions may possibly be ascribed to the power they possess of conferring electric charges on colloidal materials. W. D. H.

The Mechanism of Histamine Action. C. OEHME (*Arch. expt. Path. Pharm.*, 1913, **72**, 76—96).—Histamine (4 β iminoethylglyoxaline) is a base which Barger and Dale separated from the intestinal mucous membrane (A., 1911, ii, 217), and is also formed by bacterial action from the intestinal contents (Mellanby and Twort, A., 1912, ii, 853). In minute doses it is fatal to rabbits, producing a great fall of blood pressure, and the other symptoms of anaphylactic shock. The lethal dose is larger if the injection is made into the mesenteric vein instead of into the systemic circulation; it is therefore possible that the liver may have some action in destroying the poison. Slow injection into the jugular vein also lessens its toxicity, and the question is discussed whether this is due to its being destroyed in the blood, or to its removal from the blood. No evidence of actual destruction in the blood itself was discovered, and only traces pass into the urine. When tested on the isolated uterus, the same difference as to whether the injection or addition to Locke's fluid is made rapidly or slowly is noticeable, as in the intact animal. The uterine tissues take up the drug, and this can subsequently be washed out. The question of its activity seems to be related mainly to the concentration. W. D. H.

The Urinary Elimination of Morphine Injected into an Unaccustomed Animal. H. DOBLENCOURT (*Compt. rend.*, 1913, **156**, 1338—1340. Compare Totze, A., 1904, ii, 220; Bettink, A., 1905, ii, 546).—In the case of the rabbit the intramuscular injection of morphine hydrochloride to the extent of 0·15 gram per kilo. of body-weight is always followed by urinary elimination of the alkaloid as such. This elimination begins within an hour of injection, is at its maximum from the second to the fourteenth hour, and ends after seventy-two hours. The total elimination amounts to about 4% of the alkaloid injected, and only traces of dioxymorphine could be detected in the urine. The animals employed had never previously had morphine, and received only one injection. W. G.

Influence of Some Derivatives of Quinoline and of Naphthaquinoline on the Elimination of Uric Acid. RICCARDO CIUSA and RICCARDO LUZZATTO (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 305—311).—2-p-Methoxyphenylquinoline-4-carboxylic acid, $C_{17}H_{13}O_3N$, forms yellow scales, m. p. 217°. 2-p-Dimethylamino-

phenylquinoline-4-carboxylic acid, $C_{18}H_{16}O_2N_2$, forms ruby-red crystals, m. p. 192° (decomp.). 6-Amino-2-phenylquinoline-4-carboxylic acid, $C_{16}H_{12}O_2N_2$, has m. p. 160° (decomp.). 2-Phenyl-β-naphthaquinoline-4-carboxylic acid gives a *methyl* ester, m. p. 124°. In the preparation of the acid, a *dihydro*-derivative, $C_{20}H_{15}O_2N$, is also formed; it has m. p. 226°. A yellow *substance* of acid properties and m. p. 275° also occurs in the preparation of 2-*p*-dimethylaminophenyl-β-naphthaquinoline-4-carboxylic acid.

The authors have investigated the influence of these acids and of a number of others on the excretion of uric acid (compare Nicolaier and Dorn, *Arch. klin. Med.*, 1908, **93**, 331). There is no increase of uric acid after administration of 2-*p*-methoxyphenylquinoline-4-carboxylic acid, 2-*p*-dimethylaminophenylquinoline-4-carboxylic acid or 6-amino-2-phenylquinoline-4-carboxylic acid. A small increase (15—18%) occurs with 2-*o*-hydroxyphenyl-β-naphthaquinoline-4-carboxylic acid. A greater increase (18—27%) is observed with 2-*p*-dimethylaminophenyl-β-naphthaquinoline-4-carboxylic acid, 2-phenyldihydro-β-naphthaquinoline-4-carboxylic acid, and with 2-phenyl-β-naphthaquinoline. Great increases occur after administration of 2-phenylquinoline-4-carboxylic acid ("atophan") and 2-phenyl-β-naphthaquinoline-4-carboxylic acid ("diapurine"). The increase is somewhat less with the latter substance, but it is better tolerated.   R. V. S.

Poisoning by Acid. GERTRUDE D. BOSTOCK (*Zeitsch. physiol. Chem*, 1913, **84**, 468—477).—Subcutaneous injection of glycine in rabbits has no protective action against the fatal effect of acids given by the stomach. The simultaneous administration of ammonium acetate with the acid hastens death. In acid poisoning, the ammonia in the urine increases absolutely and relatively; there is also a rise in total urinary nitrogen. The increase in the ammonia is much greater if glycine or ammonium acetate is given at the same time.   W. D. H.

Distribution of Ante-mortem Administered Arsenic in the Human Cadaver. JOHN B. EKELEY (*J. Amer. Chem. Soc.*, 1913, **35**, 483—485).—The analysis of the corpse of a person who had died from arsenical poisoning showed the presence of the following percentages of arsenic (calculated as As_2O_3) in the various parts of the body: Kidneys, 0·02466; stomach walls, 0·02273; liver, 0·00961; intestines, 0·00377; heart, 0·00125; thigh, 0·00039; toes, 0·00031; brain, 0·00012; spinal cord, a trace.   E. G.

The Influence of the Intestinal Poisons (*p*-Cresol and Indole) on the Central Nervous System of Animals. S. WLADYCZKO (*Ann. Inst. Pasteur*, 1913, **27**, 336—340)—Continued ingestion of small quantities of *p*-cresol and indole, which are formed by the action of putrefactive bacteria on protein degradation products in the intestine, have no visible action on the general health of the animal, as compared with control animals, as a result of the regressive changes in the blood-vessels of the brain. These

alterations, which are produced by the substances, are less marked in the case of guinea-pigs than of rabbits. They have also been observed in an experiment on *Macacus cynomolgus*. Small doses of *p*-cresol and indole also produce after repeated ingestion a slight destructive change in the cellular elements of the central nervous system. S. B. S.

Chemistry of Vegetable Physiology and Agriculture.

Tyrosinase from Two Enzymes. MARTINUS W. BEYERINCK (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **15**, 932—937).—By the symbiotic action of *Actinomyces* with a common soil bacterium, tyrosine in an agar plate culture is oxidised to melanin, which appears as black spots on the culture plate. Neither organism alone oxidised tyrosine to the same stage. Other species of *Actinomyces* produce blue, red, or yellow pigments, the simultaneous presence of certain varieties of hay bacteria being favourable in the case of blue and red. Dextrose, malates, and nitrates form the chromogeneous food in this case instead of tyrosine. It is considered that the *Actinomyces* produce homogentisic acid from tyrosine, and that the bacterium oxidises this acid to melanin. Plant tyrosinase (from *Euphorbia lathyis*) is a mixture of these two oxidising enzymes. E. F. A.

The Formation of Lactic Acid by Acetic Acid Bacteria. ALFONS OSTERWALDER (*Centr. Bakt. Par.*, 1913, ii, **37**, 353—364).— When inoculated into sterilised red or white wine, two acetic acid bacteria were found to bring about an increase in the amount of lactic acid. This change was observed in both fresh and fermented wines, and was not affected by the addition of sucrose, lævulose, and malic and tartaric acids. The addition of alcohol was followed by an increase in the amount of lactic acid as well as of acetic acid. Malic acid was decomposed by the organisms, while a reduction in the amount of sucrose was accompanied by an increase in total acids, possibly by the formation of gluconic acid. The fermentation is probably without practical significance, since wines possessing a high acetic acid content are regarded as worthless, and those with little acetic acid would only contain traces of lactic acid as a result of fermentation by these organisms. H. B. H.

Natural Variation of B. acidi lactici with Respect to the Production of Gas from Carbohydrates. J. A. ARKWRIGHT (*J. Hygiene*, 1913, **13**, 68—86).—A bacillus of the *B acidi lactici* group isolated from urine occurred in two varieties, one of which formed gas from sugars and alcohols, and the other of which formed acid, but no gas. Their other characters (serum reactions, etc.) were identical. W. D. H.

Biochemical Activity of Bacillus lactis erythrogenes. MARY LOUISE FOSTER (*J. Amer. Chem. Soc*, 1913, **35**, 597—600).—An investigation of the action of *Bacillus lactis erythrogenes* on milk has shown that it is progressively catabolic, the proteins being ultimately converted into mono- and di-amino-acids. This proteolytic change is probably due to an enzyme. By precipitation with alcohol, a soluble ferment can be obtained, which decomposes the lactose with formation of formic and acetic acids, and this seems to indicate the presence of an intracellular enzyme, which is set free by the alcohol after it has destroyed the organism. These changes in the milk are accompanied by the production of a pigment, which causes a red to dull brown coloration, and can be extracted with amyl alcohol; it is extracellular, since its formation is dependent on the life of the organism.   E. G.

The Inhibitory Selective Action on Bacteria of Substances Related to Monochloroacetic Acid. WILLIAM J. PENFOLD (*J. Hygiene*, 1913, **13**, 35—48).—*B. coli* (Escherlich) when grown on agar to which phenylacetic acid has been added, produces colonies which vary in size, but produce about the same amount of gas from dextrose. When the agar contains monochlorohydrin or sodium monochloroacetate, it throws off variants which ferment alcohol with gas formation, and sugars without gas formation. *B. lactis aërogenes* on monochlorohydrin agar gives rise to variants unable to ferment glycerol. In cases of inhibitory bacterial selection by chemical agents, a comparison of the surviving cells with the original strain indicates what portion or function of the cell is implicated in the cell's intoxication. The cellular enzymes, by virtue of their specific chemical affinities, may play a part in cell intoxication. Phenol, for instance, is rendered more germicidal by the addition of acids; in many media, the cell enzymes produce acids; hence it is probable that phenol selections of bacteria commonly result in the development of new strains with impaired fermenting powers.   W. D. H.

Alcoholic Fermentation. ALEXANDER VON LEBEDEV (*Zeitsch. physiol. Chem.*, 1913, **84**, 308).—Polemical (compare Kostytschev, this vol., i, 323).   E. F. A.

Influence of Respiratory Chromogens on Alcoholic Fermentation. VLADIMIR I. PALLADIN and S. D. LVOV (*Bull. Acad. Sci. St. Pétersbourg*, 1913, 241—252. Compare this vol., i, 430).—The authors have made experiments to ascertain the cause of the influence exerted on the action of zymase by the oxidising processes due to respiratory chromogens. The yeast employed was treated by von Lebedev's method (A., 1911, i, 248), and the chromogens were obtained from turnips, sugar-beets, or mushrooms.

The fermentation of expressed plant juices by killed yeast in a current of air is accompanied by oxidation of the respiratory chromogen of the juice to a pigment, which greatly retards the action of the zymase; the retardation is especially marked when

the juice is oxidised prior to introduction of the yeast. In the case of boiled juice, which is incapable of converting the prochromogen into chromogen and of oxidising the latter to pigment, alcoholic fermentation proceeds readily. Further, no retardation occurs when the unboiled juice is fermented in a stream of hydrogen, which prevents oxidation of the chromogen to pigment.

In cases where the fermentation is delayed, the proportions of alcohol and of carbon dioxide formed are affected to equal extents.

Consideration of these results and of modern views concerning the mechanism of fermentation renders it probable that, in the above experiments, the pigment withdraws the hydrogen liberated in the formation of the intermediate fermentation products and oxidises it, by means of atmospheric oxygen, to water. The absence of the hydrogen necessary for the subsequent synthesis of the alcohol renders the formation of the latter impossible.   T. H. P.

The Use of Ammoniacal Salts in Wine-making. RENÉ MARCILLE (*Compt. rend.*, 1913, **156**, 1336—1338).—An examination of some musts, which took several weeks instead of four or five days for complete fermentation, showed them to be deficient in ammoniacal nitrogen. On the addition of ammonium phosphate to the grape-juice, fermentation proceeded·at the normal rate. Ammonium sulphate gives slightly better results than the phosphate, but care must be taken with respect to plastering. The wine obtained by the slow fermentation was normal in every respect.
                                                                    W. G.

The Action of Cyclamine on Alcoholic Fermentation. JOHAN LUNDBERG (*Arkiv. Kem. Min. Geol.*, 1913, **4**, No. 32, 1—24).—The rate of fermentation at 30° of a sugar solution by means of yeast in the presence of cyclamine was followed by measuring the volume of carbon dioxide evolved (compare Slator, T., 1906, **89**, 128).

Preliminary treatment of the living yeast with a pure solution of cyclamine has no effect on its power of fermentation; in the presence of sugar, however, the activity of the yeast is greatly diminished by the cyclamine. The action of the poison (cyclamine) thus depends on the physiological condition of the cell.

The amount of cyclamine necessary to poison the yeast is proportional to the quantity of the latter. Above a certain limit of concentration of cyclamine a further increase in quantity does not increase the velocity of poisoning.

It is probable that the poisoning is not a simple chemical reaction, but depends on the individual resistance of the cells.

The action of cyclamine on dry yeast depends only on the active yeast present, and not on the total quantity of dry material.

Even in very small concentrations cyclamine has no stimulating action on the yeast fermentation.   T. S. P.

A Ferment of Bitter Wines. E. VOISENET (*Compt. rend.*, 1913, **156**, 1181—1182. Compare A., 1911, ii, 915, 1127).—The ferment from a bitter wine develops in sterile or natural wines, or in wines partly deprived of their alcohol. Thus grown it presents all the

morphological characters of the ferment from the bitter wine. The author names it *Bacillus amaracrylus*. It attacks glycerol, giving acraldehyde, and other products of the fermentation are carbon dioxide, hydrogen, ethyl alcohol, volatile acids, and lactic and succinic acids. It rapidly attacks mannitol and the sugars, acts moderately on dextrin, but does not ferment erythritol, dulcitol, or starch. The fermentation of the sugars, sucrose, lactose, maltose, dextrose, lævulose, and galactose is complete in the presence of calcium carbonate. W. G.

Does the Ferment Causing Bitterness in Wine Consume Cream of Tartar? E. VOISENET (*Compt. rend.*, 1913, **156**, 1410—1412. Compare preceding abstract).—A determination of the tartaric acid in wine before and after it has become bitter shows no difference in the content. Further, if the *B. amaracrylus* is sown on different nutrient solutions containing cream of tartar, no difference can be detected in the tartaric acid content after three months' action. W. G.

Zymase and Reductase in their Mutual Relations. SERGEI LVOV (*Ber. Deut. bot. Ges.*, 1913, **31**, 141—147).—The first or one of the first stages in the alcoholic fermentation of dextrose is the withdrawal of two hydrogen atoms from the dextrose molecule. The hydrogen temporarily attached to the reductase is necessary for the normal course of fermentation.

An exact parallelism exists between the reducing and the fermentative energy of yeast; so that the reducing energy of yeast can be measured by its fermentative energy. The question arises whether reductase exists as a separate, individualised ferment, or whether the reducing properties do not more probably belong to a single, if complicated, fermenting apparatus usually termed zymase? N. H. J. M.

Sugar-free Fermentations of Stereoisomerides. PAUL MAYER (*Biochem. Zeitsch.*, 1913, **50**, 283—287)—Hydroxyfumaric acid, like the corresponding hydroxymaleic acid, undergoes fermentation with yeast, yielding carbon dioxide and acetaldehyde, which was isolated in the form of the *p*-nitrophenylhydrazone. S. B. S.

Replacement of Zinc by Uranium in the Culture of Aspergillus niger. CHARLES LEPIERRE (*Compt. rend.*, 1913, **156**, 1179—1181.* Compare this vol., i, 326, 327).—Uranium, like cadmium and glucinum, can replace zinc in the medium for the culture of *Aspergillus niger*. The weight of crop is normal if the amount of uranium in the form of nitrate is less than 1 in 5000; there is, however, a considerable retardation in attaining the maximum. Sporulation takes place if the amount of uranium is less than 1 in 10,000, but is checked by 1 in 5000. The addition of uranium to media containing zinc produces a marked retardation in growth, but the crop finally attains its normal maximum weight. The uranium is in all cases fixed by the plant. W. G.

* and *Bull. Soc. chim*, 1913, [iv], **13**, 491—498.

Tannic Acid Fermentation. I. Lewis Knudson (*J. Biol. Chem.*, 1913, **14**, 159—184).—Tannic acid is toxic to many fungi in low concentrations. *Aspergillus niger* is a more vigorous fermentative organism than *Penicillium*. Fermentation is more rapid in the gall-nut infusion than in a synthetic solution, in which tannic acid was the only source of carbon. Certain organic compounds in the infusion protect the gallic acid to some extent. The addition of 5% of sugar did not protect the gallic acid, but simply increased the growth; 10% protected the gallic acid entirely. Fermentation can take place under anaerobic conditions, and 1 mg. of mycelium can effect the transformation of 2·7 grams of tannic acid in ten days. The presence of 10% of sugar does not inhibit the secretion of tannase by *Aspergillus niger*, but it does do so to some extent in *Penicillium*. This enzyme is secreted into the culture solution by submersed mycelium as well as by surface growth. There is no evidence that tannic acid is used directly; it is first transformed into gallic acid.   W. D. H.

Tannic Acid Fermentation. II. Effect of Nutrition on the Production of Tannase. Lewis Knudson (*J. Biol. Chem.*, 1913, **14**, 185—202).—There is a progressive increase of tannase in *Aspergillus* and *Penicillium* with increased concentration of tannic acid in Czapek's solution containing 10% sugar. In a full nutrient solution containing 2% tannic acid as a source of carbon, the addition of sucrose decreases the secretion of tannase. *Aspergillus* secretes more tannase (or more active tannase) per unit weight than *Penicillium*. The production of the enzyme is stimulated in both moulds by gallic and especially by tannic acids.   W. D. H.

The Catalytic Action of Light on the Germination of Seeds. Ernst Lehmann (*Biochem. Zeitsch.*, 1913, **50**, 388—392).—Experiments carried out with the seeds of *Epilobium hirsutum* show that in water and in the dark they only germinate very slightly, whereas under otherwise the same conditions 98—100% germinate when exposed to light. The same effect as that produced by light can also be attained by treatment in the dark with solutions of proteoclastic ferments, such as papayotin and trypsin, and by low concentrations of acids (0·05*N*-hydrochloric acid). It appears, therefore, as if light acts catalytically in "mobilising" the proteins of the seeds.   S. B. S.

Influence of Cancer Extracts on the Growth of Lupine Seedlings. Jacob Rosenbloom (*Biochem. Bull.*, 1913, **2**, 229—232). —The extracts had no deleterious effects; but, on the contrary, growth was accelerated; this may be due to inorganic salts.
                                                        W. D. H.

The Action of Poisonous Substances in Different Concentrations on Seeds. The Biochemical Action of Very Concentrated Solutions. V. Arcichovski (*Biochem. Zeitsch.*, 1913, **50**, 233—244).—The action of the following substances was investi-

gated: formalin, sulphuric acid, and silver nitrate. The seeds were soaked in varying concentrations in water of these substances for varying periods, then washed, and allowed to germinate under sterile conditions. The apparatus for carrying out these various operations is described and figured in the text. The number of seeds (pea-seeds) which germinate, and the percentages which start germinating in given times, were ascertained. The toxicity of these substances increases as the concentration is increased up to a certain optimal point. Further increase in the concentration beyond this point diminishes the toxicity. The causes of this phenomenon are discussed by the author.   S. B. S.

Anaerobic Respiration of Various Seed Plants. S. Kos-TYTSCHEV (*Ber. deut. bot. Ges.*, 1913, **31**, 125—129).—Experiments on the amounts of carbon dioxide produced by different plants during anaerobic respiration are described. The ratio $CO_2/EtOH$ varied from $100/100$ to $100/0$.

It seems to be typical of leaves that about half the carbon dioxide is produced by zymase fermentation. Potato tubers produced only traces of alcohol, if any at all, and thus resemble mushrooms, which, however, contain no carbohydrates.

The results obtained support the view that, in most cases, anærobic respiration is not identical with zymase fermentation. As a rule, zymase fermentation takes place at the same time.

N. H. J. M.

The Evolution of Mineral Substances and Nitrogen in Some Annual Plants. GUSTAVE ANDRÉ (*Compt. rend.*, 1913, **156**, 1164—1167. Compare this vol., i, 233).—An extension of the above study to the case of the common flux, spurrey, and *Camelina sativa* shows that, for these three examples of different families of plants, all the mineral elements, as well as the total nitrogen, steadily increase in weight to the time of complete maturity.   W. G.

Experiments with Sterile Cultures of Higher Plants. IVAN SCHULOV (*Ber. Deut. bot. Ges.*, 1913, **31**, 97—121).—The phosphoric acid of lecithin is not assimilated by maize and peas. Phytin is utilised by peas as source of phosphoric acid.

The roots of maize and peas excrete considerable amounts of reducing sugars; maize also excretes malic acid.

Young plants, supplied with ammonium nitrate, take up more ammonia than nitrate; later on the two forms of nitrogen are utilised in about equal amounts, whilst subsequently chiefly nitric nitrogen is taken up by the plant. The physiologically acid reaction initially produced is undoubtedly of importance in the assimilation of phosphates insoluble in water.

The employment of ammonium nitrate causes an increased secretion of organic acids by the roots, and a greater secretion of sugars.   N. H. J. M.

Dry Heating. CARL THOMAE (*J. pr. Chem.*, 1913, [ii], **87**, 423—424. Compare A., 1911, ii, 920; this vol., i, 326, 327).—A

further note on the isolation of the fatty and waxy constituents from plant and animal matters by dry distillation, preferably under diminished pressure. Leaves, pine-needles, blossoms, hay, straw, hair, egg-skins, feathers, wood, and articles manufactured from them, such as cloth, paper, linen, leather, cigars, and wadding, all yield a fat or wax on distillation.

Filter paper and linen gave a white, crystalline wax.   F. B.

Localisation of Betaine in Plants. VLADIMIR STANĚK (*Zeitsch. Zuckerind. Bohm.*, 1913, **37**, 385—390).—The greatest amount of betaine was found in the leaves, especially in young leaves. Leaves of *Amarantus* contained 2·18, and the roots only 0·48% of betaine. The dry matter of sugar beet-roots contained 0·95 to 1·20%, whilst the leaves contained 2·62%. Beet seeds, without husks, contain only traces of betaine; in seeds of *Chenopodium fœtid.*, no betaine was found.   N. H. J. M.

Chemistry of the Floral Pigments. P. Q. KEEGAN (*Chem. News*, 1913, **107**, 181—182).—The colour of blue flowers (gentian, campanula, centaurea, etc.) is attributed to the presence of caffetannin, the only known tannin, except gallotannin, which yields blue oxidation compounds with bases, since it is related to styrene and cinnamic acid. It is doubted whether the presence of an inorganic base is necessary for the production of a blue colour. N. H. J. M.

Chemical Examination of Dicoma anomala. FRANK TUTIN and WILLIAM J. S. NAUNTON (*Pharm. J.*, 1913, [iv], **36**, 694—696).— The material employed for this investigation consisted of the entire air-dried plant of *Decoma anomala*, Sond., which had been specially collected in South Africa.

An alcoholic extract of the plant, when distilled in a current of steam, yielded a small amount of an essential oil, b. p. 130—200°/ ordinary pressure. The portion of the extract which was soluble in water yielded a small amount of a colourless, crystalline *glucoside*, m. p. 243°, which appeared to possess the formula $C_{30}H_{78}O_{17}$, and a large quantity of a yellow, amorphous, deliquescent product, which, when hydrolysed with alkali, gave 3:4-dihydroxycinnamic acid. The aqueous liquid contained, in addition, a quantity of sugar which yielded *d*-phenylglucosazone, m. p. 218°.

The portion of the extract which was insoluble in water formed a dark-coloured, resinous mass. It consisted largely of amorphous products, some of which gave 3:4-dihydroxycinnamic acid on hydrolysis, and a small amount of an amorphous alkaloid was also present. The following definite substances were, however, obtained from the resin: (1) hentriacontane, $C_{31}H_{64}$, m. p. 68°; (2) a *phytosterol*, $C_{28}H_{46}O$, m. p. 159° (*acetyl* derivative, m. p. 133°), which seems to be a lower homologue of stigmasterol; (3) possibly myricyl alcohol; (4) phytosterolin; (5) palmitic, stearic, arachidic, cerotic, and melissic acids, together with some unsaturated acids, which appeared to consist chiefly of a compound, $C_{16}H_{30}O_2$.   H. W.

Occurrence of Gentiopicrin and Gentianose in the Fresh Roots of Gentiana cruciata, L. MARC BRIDEL (*J. Pharm. Chim.*, 1913, [vii], **7**, 392—395).—Gentiopicrin and gentianose have been isolated in a crystalline condition from the roots of this species (compare A., 1913, i, 149, 434).   T. A. H.

Development of Fat in the Black Walnut (Juglans nigra). II. FRANK M. McCLENAHAN (*J. Amer. Chem. Soc.*, 1913, **35**, 485—493).—In continuation of the work on this subject (A., 1909, ii, 924), analyses have been made of the ovule of the black walnut at various stages of its development. The fat accumulates rapidly up to a certain point, and afterwards increases but slowly. During the early period of development, the fat is waxy in character, but subsequently becomes liquid. In the very young ovule, phosphatides are greatly in excess of fat, but later their relative importance becomes insignificant. The young ovule contains a large proportion of potassium, but this decreases as the fruit approaches maturity. High percentages of calcium, magnesium, and phosphorus are also present during the early life of the ovule, but are relatively unimportant in the later stages.   E. G.

The Anti-toxic Rôle of Calcium with Respect to Some Nutritive Salts in the Culture in Liquid Medium of Peas and Lupins. (Mlle.) C. ROBERT (*Compt. rend.*, 1913, **156**, 915—918). —A comparison of the growth of seedlings of peas and lupins grown on: (*a*) distilled water, (*b*) solutions containing 500 mg. of calcium sulphate per litre, (*c*) solutions containing one of the usual nutrient salts in corresponding strength, (*d*) solutions, being a combination of (*b*) and (*c*). The results show that, with the strength used, calcium is not toxic, but very considerably favours the development of the young plants. The salts of magnesium, potassium, and ammonium are toxic at the concentration used, but the addition of a calcium salt suppresses this toxicity. The development in mixtures of salts of potassium, magnesium, or ammonium with the calcium salt is the same as when the calcium salt alone is used; thus, in the early days of its growth, the salts of those three metals do not seem to act as nutrients to the plant. The white lupin is more sensitive to the toxic action than the pea, very small quantities of potassium salts sufficing to arrest all development.   W. G.

Nutritive Value of Maize Proteins. THOMAS B. OSBORNE and LAFAYETTE B. MENDEL (*Proc. Amer. Soc. Biol. Chem.*, 1912–13, xxxi—xxxii; *J. Biol. Chem*, **14**).—About one-third of the proteins in maize consists of glutelin, which yields all the amino-acids found in most proteins. Zein causes rapid decline in weight, but may be made of greater value by adding tryptophan or other proteins. Gliadin suffices for maintenance, but not for growth. Glutelin is adequate for growth also.   W. D. H.

Cotton-seed Meal Intoxication. I. Pyrophosphoric Acid. WILLIAM A. WITHERS and BURTON J. RAY (*J. Biol. Chem.*, 1913, **14**, 53—58).—The results indicate that pyrophosphoric acid is not the cause of the toxicity of cotton-seed meal.   W. D. H.

Accumulation of Nitrogen in the Soil by means of Micro-organisms. JOSEF DVOŘÁK (*Zeitsch. landw. Vers. Wesen. Oesterr.* 1912, **15**, 1077—1121).—A detailed account of numerous experiments based on the observations of Stoklasa (A., 1911, ii, 429) and others on the assimilation of nitrogen (atmospheric or otherwise) by plants, and the micro-organisms of the soil.

The influence of various organic substances is studied, and the conclusions arrived at that the ammonium ion is as readily absorbed as the nitrate ion, and that acid soils exhibit the least, and those with a neutral or alkaline reaction the highest, biological absorption.

F. M. G. M.

Fixation of Nitrogen by So-called Zeolites. GEORG WIEGNER (*J. Landw.*, 1913, **61**, 11—56).—Experiments were made to ascertain whether the ammonium fixed by zeolites in soils, or any portion of the ammonia, is rendered unavailable to plants. With regard to the amount of ammonia fixed by 100 grams of permutite it is shown that this varies according to the concentration of the ammonia in the solution.

Pot experiments are described in which oats followed by buck-wheat were manured with ammonium sulphate, without and with calcium zeolite in different amounts, and with ammonium zeolite both without and with calcium zeolite.

The results showed that addition of calcium zeolite increased the dry produce, and did not diminish the nitrogen. With large amounts of nitrogen applied as manure, the nitrogen was better utilised in presence of zeolites, possibly owing to losses in the pots without zeolites.

There can be no question of the permanent fixation of a definite and constant amount of ammonia by zeolites, as the amount which is fixed depends on the concentrations, which are variable. The changes are sometimes favourable and sometimes unfavourable to the plants.   N. H. J. M.

Action of Histidine and Arginine in Soils. J. J. SKINNER (*Bied. Zentr.*, 1913, **42**, 213—214; from *Proc. 8th Internat. Cong. Appl. Chem.*, 1912).—Histidine and arginine, which are produced in soils as primary cleavage products of proteins, are favourable to the growth of plants except when large amounts of nitrates are present, when they have no appreciable effect. Like creatine and creatinine, both substances can take the place of nitrates.   N. H. J. M.

Influence of Sodium Carbonate and the Imperviousness of the Soil on the Growth of Plants. JOHN W. LEATHES (*Bied. Zentr.*, 1913, **42**, 213; from *Proc. 8th Internat. Cong. Appl. Chem.*, 1912).—The result of pot experiments in which alkali soils received

calcium sulphate in amounts sufficient to reduce the sodium carbonate from 0·06 to 0·01% failed to show any appreciable change in the physical properties of the soil. When the sodium carbonate was partly neutralised with calcium sulphate, 33% of the seeds germinated, the best results being obtained with rice and wheat. When the imperviousness of the soil was removed by addition of sodium chloride, 16% of the seeds germinated, but the plants did not ripen.

N. H. J. M.

The Effect of Ignition on the Solubility of Soil Phosphates. CHARLES B. LIPMAN (*J. Ind. Eng. Chem.*, 1912, **4**, 663).—An account of the analysis of five typical soils, as a result of which the author draws the conclusion that the observation of Fraps (A., 1912, ii, 85), that ignition increases the solubility of the phosphates in minerals, does not apply to soils where ignition appears to definitely decrease the solubility of the phosphates; and it is suggested that the increased solubility noted in minerals may be due to mechanical changes induced by heat, which, in disintegrating the particles, increase the amount of surface available for attack by acids.

F. M. G. M.

Zinc as Catalytic Manure. MAURICE JAVILLIER (*Bied. Zentr.*, 1913, **42**, 215; from *Proc. 8th Internat. Congr. Appl. Chem*, 1912).— Field experiments in which oats, maize, rye, clover, and peas received from 1 to 10 kilos. of crystallised zinc sulphate per hectare. The best results were obtained with maize, which always showed increased production under the influence of zinc sulphate, whilst the other plants gave irregular results.

Laboratory experiments were made with *Aspergillus niger*, showing the effect of zinc on the assimilation of carbohydrates, nitrogen, and minerals, and on the composition of the plant. N. H. J. M.

Aluminium Sulphate as Catalytic Manure. GABRIEL BERTRAND and HENRI AGULHON (*Bied. Zentr.*, 1913, **42**, 215; from *Proc. 8th Internat. Congr. Appl. Chem.*, 1912)—Small amounts of aluminium sulphate (2 mg. per kilo. of soil) increased the yield of barley 18%, or 17% calculated on the dry matter. With 4 mg., the dry produce was not increased, whilst there was a gain in the fresh produce.

N. H. J. M.

Employment of Manganese as Catalytic Manure. GABRIEL BERTRAND (*Bied. Zentr.*, 1913, **42**, 214; from *Proc. 8th Internat. Cong. Appl. Chem.*, 1912).—In pot experiments with peas and barley it was found that addition of manganese sulphate increased the yield by 10—20%. Field experiments gave similar results, oats being increased 9·5% by 60 kilos. of manganese sulphate per acre, peas 20% by 30 kilos., colza 18%, and clover 15% by 40 kilos. of manganese sulphate. The most suitable amounts of manganese sulphate are 30 to 50 kilos. of the anhydrous salt per hectare. N. H. J. M.

Organic Chemistry.

Magnesium in Organic Chemistry. VICTOR GRIGNARD (*Bull. Soc. chim*, 1913, [iv], **13**, i—xxxvii).—An address delivered to the Chemical Society of France on February 13th, 1913. T. A. H.

Synthesis of Methane by Catalysis. VLADIMIR N. IPATIEV (*J. pr. Chem.*, 1913, [ii], **87**, 479—487; *J. Russ. Phys. Chem. Soc.*, 1913, **45**, 433—442).—According to the author the synthesis of methane from its elements in the presence of metals is not a direct combination of the elements, but consists in a catalytic oxidation of the carbon, by means of the metallic oxide contained in the metal, to carbon dioxide, which then undergoes a catalytic reduction to methane, the water formed in the latter reaction being subsequently decomposed by the metal with the regeneration of the metallic oxide.

In support of this view, the author describes a series of experiments showing (1) that methane is formed by heating carbon at $500—520°$ in hydrogen under pressure and in the presence of metallic oxides (nickel, copper, tin, iron); (2) that metallic nickel, containing $98·41\%$ of the metal and not further reducible, brings about the catalytic synthesis of methane from carbon and hydrogen under pressure at $500—510°$, the amount of methane formed being far greater than that corresponding with the carbon dioxide which could be formed from the oxygen in the apparatus or combined with the metal; (3) that methane in the presence of nickel and water is decomposed under pressure at $485—520°$ with the formation of hydrogen and carbon dioxide, and (4) that the latter reaction is reversible, a mixture of carbon dioxide and hydrogen, when heated under pressure in the presence of metallic nickel or copper, or the oxides of these metals, yielding water and methane. F. B.

The Relation between the Crystal-Symmetry of the Simpler Organic Compounds and their Molecular Constitution. I. WALTER WAHL (*Proc. Roy. Soc.*, 1913, *A*, **88**, 354—361).—This paper simply contains the experimental data concerning the aliphatic hydrocarbons; general conclusions will be given later. Methane crystallises in the regular system (compare A., 1912, ii, 1041). The crystallographic systems of other hydrocarbons are as follows: ethane, hexagonal; propane is polymorphic, giving rhombic, prismatic needles which, with rise in temperature, give crystals which are either rhombic or monoclinic; β-methylpropane is possibly rhombic, but the matter is uncertain; $\beta\beta$-dimethylpropane gives cubical crystals, which at low temperature change into crystals which are probably tetragonal; n-butane is hexagonal, changing at a temperature close to that of liquid air to rhombic crystals; n-pentane is rhombic; n-hexane is either monoclinic or triclinic, probably the former; n-heptane and n-octane are either monoclinic or triclinic, it is uncertain which. T. S. P.

Polymerisation of Ethylene at High Temperature and Pressure in the Presence of Catalysts. VLADIMIR N. IPATIEV and O. RUTALA (*Ber.*, 1913, **46**, 1748—1755. Compare A., 1911, i, 937).—In a previous paper (*loc. cit.*), it has been shown that the presence of alumina does not affect the nature of the products formed by the polymerisation of ethylene, but has a marked influence on their relative amounts. The present work was undertaken to test the influence of zinc chloride and aluminium chloride.

Ethylene readily undergoes polymerisation when heated under a pressure of about 70 atmospheres at 275° in the presence of zinc chloride. The residual gas has the composition: C_nH_{2n} 36%, H_2 3%, C_nH_{2n+2} 61%. The liquid products were fractionated, and those boiling below 85% found to consist mainly of pentane and hexane, *iso*pentane being isolated from one of them in an approximately pure state. Methyl*cyclo*butane was not detected. In the fractions of b. p. 50—300°, the proportion of ethylenic hydrocarbons increases regularly with increasing temperature, whilst those boiling below 145° contain only ethylene and saturated hydrocarbons.

The individual fractions were treated with fuming sulphuric acid and the residue again fractionated, all the fractions so obtained being unacted on by nitrating mixture or permanganate. Those boiling below 130° consisted almost entirely of paraffin hydrocarbons; in those of higher b. p. an increasing quantity of polymethylene hydrocarbons was found, so that the fraction b. p. 256—265° contained practically only naphthenes.

The portion of the original product of b. p. above 280° was distilled under diminished pressure. The fractions obtained were uniform in ultimate composition and consisted of a mixture of ethylene hydrocarbons and naphthenes.

Ethylene is scarcely affected by commercial aluminium chloride at 240° and about 70 atmospheres pressure. At 280° it gives a charred residue and a gas having the composition C_nH_{2n} 4·0%, H_2 10·0%, C_nH_{2n+2} 86%. With freshly prepared aluminium chloride at 200°, liquid products were not obtained, and only a charred residue remained in the apparatus; liquid products were, however, prepared at the ordinary temperature. These were fractionated as before, and, after removal of unsaturated hydrocarbons by means of fuming sulphuric acid, again distilled, when the fractions, b. p. below 200°, were found to consist mainly of paraffin hydrocarbons, naphthenes being only present in the portion, b. p. above 200°. The polymerisation of ethylene in the presence of aluminium chloride yields, therefore, considerably less naphthenes than with zinc chloride as catalyst.   H. W.

$\Delta^{\alpha\gamma}$-**Hexatriene.** PIETER VAN ROMBURGH (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **15**, 1184—1187. Compare van Romburgh and Dorssen, A., 1906, i, 130, 722).—A specimen of $\Delta^{\alpha\gamma}$-hexatriene which had been preserved for five years was distilled, when fully 50% passed over below 80° (the hydrocarbon has b. p. 78·5—80°/766 mm.). From the residue a *substance*, b. p. 99·5°/16mm., D^{11} 0·880, n_D^{11} 1·51951, was isolated, which appears to be a dimeride of hexatriene. It readily forms an additive *product* with bromine (1 mol.), whilst, on further

addition of the latter reagent, much hydrogen bromide is evolved. It is rapidly oxidised by potassium permanganate.

[With MULLER.]—$\Delta^{\alpha\gamma\epsilon}$-Hexatriene has been regenerated from its crystalline dibromine additive compound (*loc. cit.*). A solid compound has also been obtained from $\Delta^{\alpha\gamma\epsilon}$-hexatriene and sulphur dioxide, investigation of which is incomplete, but from which the hydrocarbon may also be regenerated. The latter has also been prepared by dehydration of $\Delta^{\alpha\epsilon}$-*hexadiene-δ-ol* by the action of potassium hydrogen sulphate or phthalic anhydride.

[With LE HEUX.]—$\Delta^{\alpha\epsilon}$-Hexadiene-δ-ol has been prepared by the action of allyl bromide, zinc turnings, and absolute ether on acraldehyde. It has b. p. 132·2—132·4°/769 mm., $D_4^{10·5}$ 0·8698, $n_D^{10·5}$ 1·45231. With acetic anhydride and a drop of sulphuric acid, it yields the corresponding *acetate*, b. p. 151·2—152·7°. Phosphorus tribromide converts it into the *bromide*, b. p. 59—63°/35 mm., which very readily absorbs bromine (1 mol.); further quantities of bromine react very slowly without yielding, however, hydrogen bromide.

By reduction of the chloroacetin of s-divinyl glycol with a copper-zinc couple in ethereal solution with addition of hydrochloric acid, a liquid, b. p. 77—81°, has been obtained, which, when strongly cooled, becomes crystalline and consists very probably of $\Delta^{\alpha\gamma\epsilon}$-hexatriene. With bromine it gives a dibromide identical with that obtained from the said hydrocarbon. H. W.

Preparation of Chloro-derivatives of the Amyl Series. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 258555).—When the vapour of β-methyl-Δ^β-butylene and chlorine are allowed to react at the ordinary temperature and under a pressure of about 50 mm., they give rise to tertiary *iso*amyl chloride and other products which can be employed for the preparation of isoprene. F. M. G. M.

Preparation of Dihalogenated Hydrocarbons. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 259192. Compare this vol., i, 583).—Dichloro*iso*hexane (b. p. 155—160°) is obtained when the vapour of tertiary chloro*iso*hexane is treated with chlorine under reduced pressure; dichloro*iso*butane (b. p. 108—109°) is prepared in a similar manner from chloro*iso*butane, whilst if tertiary bromo*iso*butane (b. p. 72°) is employed it furnishes a satisfactory yield of chlorobromo-*iso*butane. F. M. G. M.

Physical Constants of Certain Chlorinated Hydrocarbons Employed as Solvents. II. WALTER HERZ and W. RATHMAN (*Chem. Zeit.*, 1913, 37, 621—622).—The following freezing point and specific heat data are recorded: s-tetrachloroethane $-36°$, 0·268; pentachloroethane $-22°$, 0·266; trichloroethylene $-73°$, 0·223; tetrachloroethylene $-19°$, 0·216. The specific heats refer to 20°.

Commercial dichloroethylene consists of a mixture of the *cis*- and *trans*-forms, which can be separated by fractional distillation. The *cis*-form boils at 48·8°/763 mm.; its density is given by the equation: $D = 1·2908 - 0·00168t$, and its coefficient of expansion is 0·00136. The *trans*-form boils at 59·8°/763 mm.; its density is

given by $D = 1\cdot3144 + 0\cdot001605t$, and its coefficient of expansion is $0\cdot00127$.

The vapour pressures of the two isomerides have also been determined at a series of temperatures. By substitution of the data in Clausius's equation, the latent heat of vaporisation of the *cis*-form is found to be 6930 cal. (43—48·8°), and that of the *trans*-form 7268 cal. (54·8—59·8°).   H. M. D.

Some New Properties of Carbon Tetraiodide and its Estimation in Presence of Iodoform. MARCEL LANTENOIS (*Compt. rend.*, 1913, 156, 1629—1631. Compare this vol., i, 583). —Carbon tetraiodide is attacked by hydrogen at 100°, giving iodoform and hydrogen iodide, and at the same time small amounts of di-iodomethane and methyl iodide are formed. This hydrogenation is readily brought about by alcoholic potassium hydroxide at 30—40°, a small quantity of methane being present in the product. Sodium in liquid ammonia reacts with carbon tetraiodide (3 mols.), giving methane (1 mol.), together with some sodium cyanide, methylamine, and another base, probably guanidine.

Oxygen readily attacks carbon tetraiodide, even in the dark, giving iodine and carbonyl iodide, which is unstable, and yields carbon monoxide with a small proportion of carbon dioxide, the reaction being facilitated by light.

Silver nitrate in aqueous solution (20%) reacts with iodoform, giving carbon monoxide quantitatively. With carbon tetraiodide, it gives both carbon monoxide and carbon dioxide in the proportion of 3 : 1 by volume. One molecule of the tetraiodide gives one molecule of gas, thus giving a means of estimating it alone or in the presence of iodoform.   W. G.

Density and Thermal Expansion of Ethyl Alcohol and its Mixtures with Water. N. S. OSBORNE, E. C. McKELVY, and H. W. BEARCE (*J. Franklin Inst.*, 1913, 175, 165—167. Compare A., 1912, i, 232).—An abstract of, with a short discussion on, a paper by Pulfrich (*Zeit. für Inst. K.*, 13, 456), describing different methods of purifying ethyl alcohol, and the varying physical constants exhibited by different specimens thus obtained with an investigation on the thermal expansion of the same when diluted with varying proportions of water.   F. M. G. M.

Catalytic Hydrogenation of Acetylenic γ-Glycols in the Presence of Palladium-black. GEORGES DUPONT (*Compt. rend.*, 1913, 156, 1623—1625).—The reduction of acetylenic γ-glycols in the presence of platinum-black gives the saturated glycol (formula 1) together with the alcohol (formula II), but never any of the saturated hydrocarbon (formula III) (compare Lespieau, A., 1910, i, 535) :

(I.) $OH\cdot CRR'\cdot[CH_2]_2\cdot CRR'\cdot OH$.   (II.) $OH\cdot CRR'\cdot[CH_2]_2\cdot CHRR'$.
(III.) $CHRR'\cdot[CH_2]_2\cdot CHRR'$.
If for the platinum-black is substituted palladium-black, in most cases the product of hydrogenation contains only traces of the

glycol with a little of the alcohol, and large quantities of the hydrocarbon.

In the case of the aliphatic glycols of the type dimethylbutinenediol, the hydrogenation is limited and the result is a mixture of the three possible products. With the aromatic glycols, whilst platinum-black gives only the saturated glycol (formula I), palladium-black gives only the saturated hydrocarbon (formula III); thus diphenyldimethyl-butinenediol gives quantitatively *βε-diphenylhexane*, a colourless liquid, b. p. 185°/12 mm., D^{15} 0·9634, n_D 1·5440. W. G.

Preparation of Mesityl Oxide from Diacetone Alcohol [*iso*-Hexan-δ-ol-β-one]. MORITZ KOHN (*Monatsh.*, 1913, 34, 779—780).—The conversion of *iso*hexan-δ-ol-β-one,

$$OH·CMe_2·CH_2·COMe,$$
the primary product in the condensation of acetone to mesityl oxide, into mesityl oxide does not require a large quantity of sulphuric acid as previously supposed. When 290 grams of *iso*hexan-δ-ol-β-one to which sixty drops of sulphuric acid have been added are quickly distilled through a fractionating column, the distillate contains about 190 grams of mesityl oxide. D. F. T.

Action of a-Monochlorohydrin and Epichlorohydrin on Monosodium Glyceroxide. JEAN NIVIÈRE (*Compt. rend.*, 1913, 156, 1628—1629).—a-Monochlorohydrin is readily prepared by saturating glycerol at 120—130° with hydrogen chloride, a yield of 66% being obtained. The product reacts with monosodium glyceroxide, glycerol being regenerated and at the same time 2—3% of diglyceryl alcohol is produced. Epichlorohydrin, which is readily obtained (95% yield) by the action of strong aqueous potassium hydroxide on ay-dichlorohydrin under reduced pressure, reacts with monosodium glyceroxide, giving a *polymeride* of the internal anhydride of the diglyceryl alcohol. This is a white, amorphous substance, insoluble in water and the ordinary solvents, and yields a *diacetyl* derivative on boiling with acetic anhydride and anhydrous sodium acetate. Both of these substances decompose without melting. W. G.

Preparation of Diglyceryl Alcohol. JEAN NIVIÈRE (*Compt. rend.*, 1913, 156, 1776—1778. Compare preceding abstract).—In an attempt to prepare diglyceryl alcohol the author has prepared the diacetyl derivative of monochlorohydrin and caused it to react with monosodium glyceroxide, the product being a small quantity of the diacetyl derivative of the required alcohol and a considerable residue analogous to the vegetable mucilages.

By warming the internal anhydride of glycerol with anhydrous glycerol in equimolecular proportions on a water-bath for seven hours and acetylating the crude product with acetic anhydride, the *tetracetyl* derivative of the required alcohol is obtained as an oily liquid, b. p. 196—197°/3 mm., D^{17} 1·1835. On saponification with alcoholic sodium hydroxide it yields *diglyceryl alcohol*, $C_6H_{14}O_5$, a pale yellow, very viscous liquid, b. p. 235—240°/6 mm. W. G.

Efficiency of the Preparation of Ethyl Ether from Alcohol and Sulphuric Acid. Percy N. Evans and Lena M. Sutton (*J. Amer. Chem. Soc.*, 1913, **35**, 794—800).—An account is given of experiments made with a view to determine the efficiency of the reaction between ethyl alcohol and sulphuric acid. It has been found that the degree of completeness of the reaction $2Et \cdot OH = Et_2O + H_2O$ amounts to about 40%. This efficiency was maintained in some experiments until the distillate amounted to as much as one hundred and seventy-six times the original volume of the sulphuric acid, or until the ether produced was forty times the volume, or sixteen times the weight, of the acid used. The efficiency decreased abruptly when there remained in the flask a charred, semi-solid residue of about one-twentieth of the weight of the acid originally present. The decrease in efficiency is not due to accumulation of water, as the reaction proceeds normally with dilute sulphuric acid. From 15—20% of the sulphuric acid is lost as sulphur dioxide.   E. G.

Crystalline Glycerophosphates. Rogier and Fiore (*Chem. Zentr.*, 1913, i, 1330—1332; from *Bull. Sci. Pharmacol.*, 1913, **20**, 7—25, 72—86).—Technical sodium glycerophosphate,
$$Na_2PO_3 \cdot O \cdot C_3H_7O_2,$$
usually forms small needles with $5H_2O$, but sometimes large tablets with $6H_2O$. The concentrated solution at 18° contains 27·38% anhydrous salt, and may be heated to 120° without decomposition. Cryoscopic methods gave one-third of the calculated molecular weight, so a physiological serum should only contain 35 grams. The following salts have been made by double decomposition. *Calcium* salt, $CaPO_3 \cdot O \cdot C_3H_7O_2$, microcrystalline or large crystals by slow evaporation, solubilities, 1% at 0°, 1·63% at 18°, 0·43% at 60°; *barium* salt, with $1H_2O$ which is lost on boiling the solution, solubility 4·50% at 21°; *strontium* salt, leaflets with $2H_2O$, solubility 2·09% at 19°, 0 80% at 60°; *quinine* salt, $B_2PO_3 \cdot O \cdot C_3H_7O_2 + 4H_2O$, white needles, m. p. 180—181°, $[\alpha]_D^{21} - 133°33'$, $[\alpha]_D^{17} - 140°24'$; *acid strychnine* salt, $BPO_3H \cdot O \cdot C_3H_7O_2, H_2O$, m. p. 260°, $[\alpha]_D^{23} - 25°40'$; *brucine* salt, $B_2PO_3 \cdot O \cdot C_3H_7O_2, 11H_2O$, prisms, m. p. 192°, $[\alpha]_D^{13} - 29°35'$; *basic copper* salt, $Cu[(Cu \cdot OH)PO_3 \cdot O \cdot C_3H_7O_2]_2, 6H_2O$, dark blue powder; *copper* salt, $CuPO_3 \cdot O \cdot C_3H_7O_2, H_2O$, pale blue needles.   J. C. W.
Oxidation of Lecithin in Presence of Iron Salts. Otto Warburg and Otto Meyerhof (*Zeitsch. physiol. Chem.*, 1913, **85**, 412—414).—The mixture of substances known as lecithin is very readily oxidised by atmospheric oxygen in aqueous suspension in presence of iron salts, whereas other important cell constituents are stable under similar conditions. There is a close parallelism between the velocity of lecithin oxidation in vitro and the rate of the oxidation processes in the living cell based on the amount of lecithin present.
                                                                E. F. A.

The Action of Alkali Arsenite on Ethyl Disulphide. August Gutmann (*Ber.*, 1913, **46**, 1474—1475).—Weinland and Rumpf (A., 1897, ii, 257) have shown that sodium disulphide acts on trisodium

arsenite with the formation of trisodium monothioarsenate, Na_3AsO_3S, and sodium sulphide. It was to be expected that ethyl disulphide would act similarly to the sodium disulphide, if it entered into reaction at all, but the author finds that this is not the case, the reaction proceeding readily in the cold with the formation of trisodium arsenate and ethyl mercaptan. This reaction is explained by the author by assigning a peroxide character to the ethyl disulphide, which takes hydrogen from the water, leaving oxygen available for oxidising the arsenite. T. S. P.

Hexadecanesulphonic Acid. ALBERT REYCHLER (*Bull. Soc. chim. Belg.*, 1913, **27**, 110—113. Compare A., 1912, i, 600) —Cetyl iodide reacts with sodium hydrogen sulphide in alcoholic solution to give *cetyl mercaptan*, $C_{16}H_{33}\cdot SH$, which is precipitated as a yellow solid on the addition of water, and on warming this with potassium permanganate solution it is oxidised to the sulphonic acid. The manganese dioxide is filtered off, the solution neutralised with acetic acid, and a slight excess of lead acetate added. The precipitated lead salt is collected, washed, dried, suspended in alcohol, and decomposed by hydrogen sulphide. After filtering and evaporating off the alcohol, *cetylsulphonic* [*hexadecanesulphonic*] *acid*, $C_{16}H_{33}\cdot SO_3H$, is obtained, soluble in alcohol, ether, benzene, and acetic acid, crystallising from the latter in microscopic plates. It behaves like a semi-hard soap, and is a comparatively strong acid, yielding *sodium* and *potassium* salts, which are soluble in water, and closely resemble the alkali palmitates in their behaviour. The *barium* and *lead* salts are insoluble in water. W. G.

The Physico-chemical Properties of Hexadecanesulphonic Acid and Sodium Hexadecanesulphonate. ALBERT REYCHLER (*Bull. Soc. chim. Belg.*, 1913, **27**, 113—128. Compare preceding abstract).—Hexadecanesulphonic acid and its sodium salt in aqueous solution possess the property of emulsifying with toluene, but, unlike the oleates, are only very slightly extracted by that solvent. On the other hand, they possess the property of removing fat from, and cleansing wool in the same manner as, an ordinary soap. The elevation of the boiling point of water on solution either of the acid or its salt does not bear any relation to the concentration of the solutions, and this method gives a wide range of values for the molecular weights. The author has made a complete study of the electrical conductivity of the sodium salt and the free acid at different temperatures and varying concentrations. In the case of the sodium salt, the readings give a sharp indication of the temperature, 38—37°, at which crystallisation takes place. The values obtained for the molecular conductivity in solutions from $0.01665N$ to $0.0666N$ are practically independent of the concentration. The free acid furnishes an excellent example of a colloidal substance, and permits of the direct examination of the molecular problem and of an intermolecular liquid. The values obtained for the molecular conductivity diminish steadily as the dilution passes from 15 to 30 litres, remains constant from 30 to 60 litres, and finally increases regularly and proportionately as the dilution increases. W. G.

The Use of Calcium Carbonate as Catalyst for Organic Acids and their Anhydrides. PAUL SABATIER and ALPHONSE MAILHE (*Compt. rend.*, 1913, **156**, 1730—1734)—Precipitated calcium carbonate can be employed as a catalyst at 450—500° for the conversion of acids into the ketones, but in the acetic acid series the yield diminishes as the molecular weight increases. Whilst acetic acid gives a theoretical yield of propanone, valeric acid only gives a yield of 32% of dibutyl ketone. Despite blackening due to deposition of carbonaceous products, the calcium carbonate retains its activity and can be employed a great number of times, but its use is not so advantageous as that of thorium oxide (compare Senderens, A., 1912, i, 537) for the higher ketones. Benzoic acid mixed with the aliphatic acids yields mixed ketones under the above conditions. The acids can be replaced by their anhydrides in every case, and whilst benzoic acid alone cannot be converted into benzophenone by this method, a certain amount of this ketone can be obtained by the use of benzoic anhydride.

W. G.

Esters Derived from Octanol by the Author's Method; Observations on the Principle of this Method. JEAN B. SENDERENS and J. ABOULENC (*Compt. rend.*, 1913, **156**, 1620—1623 ; *Bull. Soc. chim.*, 1913, [iv], **13**, 586—591).—By their method using sulphuric acid (2—3%) as catalyst (compare A., 1911, i, 600, 637 ; ii, 1080 ; 1912, i, 694 ; this vol., i, 42) the authors have prepared the following esters of octanol, of which only the acetate was previously known (compare Bouis, this Journ., 1854, **7**, 280) :

Ester.	B. p./74·4 mm.	D_4^{14}.
Formate	184·0°	0·8642
Acetate	194·5	0·8626
Propionate	211·5	0·8611
Butyrate	227·5	0·8592
*iso*Butyrate	220·0	0·8554
*iso*Valerate	236·5	0·8540

The *phenylacetate*, b. p. 195°/35 mm., D_4^{14} 0·9503, is decomposed on distilling at the ordinary pressure.

The authors claim that their method is entirely distinct from that of Fischer and Speier (A., 1896, i, 201), where a large excess of alcohol is used and stronger acid, which merely acts as a dehydrating agent. The organic acids are capable of division into two classes. The first contains the aromatic acids with the carboxyl group attached to the nucleus, in which case their method is useless. The second class contains the fatty acids and aromatic acids with the carboxyl group in a side-chain, and here their dilute acid acts as a true catalyst and an excess of alcohol is unnecessary. A compound of the type $RH \cdot SO_4$ is first formed, and then a cycle of reactions goes on :

$$R \cdot HSO_4 + R \cdot OH = R_2SO_4 + H_2O$$
$$R_2SO_4 + R'CO_2H = R'CO_2R + RHSO_4.$$
W. G.

Graded Degradation of Different Saturated Mono- and Di-basic Acids. PHILIPPE BARBIER and RENÉ LOCQUIN (*Compt. rend.*, 1913, **156**, 1443—1446).—The transformation of a saturated acid of the

type $R \cdot CH_2 \cdot CO_2H$ into its next lower homologue can be brought about by first converting the acid into the corresponding tertiary alcohol, $R \cdot CH_2 \cdot CMe_2 \cdot OH$, by the action of magnesium methyl iodide, and then submitting this to oxidation :

$$R \cdot CH_2 \cdot CMe_2 \cdot OH + 3O = R \cdot CO_2H + CH_3 \cdot CO \cdot CH_3 + H_2O.$$
Thus *iso*valeric acid is first converted into $\beta\delta$-dimethylpentan-δ-ol, which on oxidation with chromic acid yields *iso*butyric acid. Decanoic acid is similarly converted into pelargonic acid.

By the interaction of *iso*amyl bromide and ethyl methylmalonate, *aδ-dimethylhexoic acid*, $CHMe_2 \cdot CH_2 \cdot CH_2 \cdot CHMe \cdot CO_2H$, b. p. 228—230°/ 760 mm. and 127—130°/18 mm., is obtained, giving a *methyl* ester, b. p. 172—173°, an *acid chloride*, b. p. 69°/16 mm., an *amide*, m. p 99—100°, and a p-*toluidide*, m. p. 75°. With magnesium methyl iodide it yields $\beta\gamma\zeta$-*trimethylheptan-β-ol*, b. p. 92—95°/18 mm., which on oxidation with dilute nitric acid gives a neutral and an acid product. The acid product is a mixture of acetic, *iso*valeric, and *iso*hexoic acids, whilst the neutral product consists principally of methyl *iso*amyl ketone, together with a small quantity of an unsaturated hydrocarbon, b. p. 160—165°. β-Methyladipic acid on treatment with magnesium methyl iodide and subsequent oxidation yields a certain amount of methylsuccinic acid and some diethylenic hydrocarbon.

With the monobasic acids where the $\cdot CO_2H$ group is attached to a $\cdot CH_2$ group, they are simply converted into their next lower homologue. With an a-substituted acid the principal product is a ketone. The dibasic acids behave in the same way as the monobasic acids, the degradation proceeding simultaneously on the two terminal carboxyl groups.   W. G.

Synthesis of the Glycerides of Lauric Acid. B. W. VAN ELDIK THIEME (*Ber.*, 1913, 46, 1653—1657. Compare A., 1912, i, 333). —A reply to Grün (this vol., i, 157), criticising the latter's experimental results. The author re-affirms that even under the modified conditions stated by Grün (*loc. cit.*) the so-called synthesis of a-dilaurin yields a mixture of trilaurin, crystalline dilaurin, liquid dilaurin, and monolaurin.   D. F. T.

Nickel Oxides as Reduction Catalysts in the Addition of Molecular Hydrogen to Unsaturated Fats and Fatty Acids. FRED BEDFORD and ERNST ERDMANN (*J. pr. Chem.*, 1913, [ii], 87, 425—455 ; *J. Russ. Phys. Chem. Soc.*, 1913, 45, 616—643).— Unsaturated fats and fatty acids undergo catalytic reduction at the ordinary pressure in the presence of nickel oxide, the rate of reduction being much greater than when metallic nickel is employed. In addition to its greater activity, the oxide possesses the advantage over the metal in that it is far less sensitive to hydrogen sulphide and other substances which exert a deleterious effect on the activity of the metal. All three oxides of nickel may be used as catalysts, nickelous and nickelic oxides requiring a temperature of 250°, whilst in the presence of the suboxide the reduction proceeds readily at 180—200°.

During the reduction, the higher oxides become converted into the suboxide, which forms a deep black, colloidal solution with the oil or fat.

Nickel suboxide may be distinguished from metallic nickel by its inability to form nickel carbonyl with carbon monoxide, and by its much smaller electric conductivity.

A nickelic oxide, which has already been used in the catalytic reduction, possesses a greater activity than a fresh specimen on account of the presence of suboxide.

The velocity of hydrogenation is increased by employing a voluminous oxide, prepared by gentle ignition of the nitrate, and also by the addition of small quantities of other metallic oxides (Al, Ag, Zr, Ti, Ce, La, Mg).

Nickel salts of organic acids (formic, acetic, oleic, and linolenic) in the presence of unsaturated fats are reduced at 200—250° to the oxide or to metallic nickel, and may therefore be used as catalysts; thus, nickel formate is reduced at 210° to the suboxide and at 250° to metallic nickel. F. B.

Ricinoleic Acid. BERTHOLD RASSOW [with J. RUBINSKY] (*Zeitsch. angew. Chem.*, 1913, **26**, 316—320).—The authors have investigated the action of heat on ricinoleic acid. Since the products formed are amorphous, yield amorphous salts, and have very similar solubilities, their isolation in the pure state has not been accomplished. Their chemical nature is deduced from observations of acid number, saponification number, acetyl number, iodine number, and molecular weight. The following are the main results obtained.

Ricinoleic acid is decomposed at temperatures below 150°, water being the only volatile product formed. At the same time, the acidity sinks to half the original value; in the presence of a trace of sulphuric acid, the acidity can be reduced to one-quarter of the original value, but completely neutral products are never obtained.

Polyricinoleic acids (ester-acids in which the alcoholic hydroxyl group of one molecule is esterified by the carboxyl group of a second molecule) are the sole products of the action of heat on ricinoleic acid. Such products are not uniform, but contain a mixture of difficultly or non-separable polyricinoleic acids with more or less of the original acid. Polyricinoleic acids of high molecular weight are insoluble in alcohol, whilst their barium salts resemble amber and are soluble in ether; those of lower molecular weight are soluble in alcohol, whilst their barium salts dissolve sparingly in ether. A complete separation of the individual polyricinoleic acids was not achieved.

The effect of a variety of substances on the course of the reaction has been investigated. Chlorides of organic acids and neutral salts which do not yield free acid under the conditions of the experiments have but little effect. Traces of strong acids, particularly sulphuric acid, act as positive catalysts, whilst organic bases have the opposite action.

Ricinelaidic acid behaves in the same manner as ricinoleic acid except that it is more readily decomposed by heat. H. W.

Neodymium Oxalate and Some New Compounds of Europium. CHARLES JAMES and J. E. ROBINSON (*J. Amer. Chem. Soc.*, 1913, **35**, 754—759).—A study of the solubility of neodymium

oxalate in solutions of neodymium nitrate of various concentrations at 25° has shown that only one hydrate of neodymium oxalate,

$$Nd_2(C_2O_4)_3,11H_2O,$$
is stable under these conditions. Evidence was obtained of the formation of an oxalonitrate.

Europium *formate*, $Eu_2(CO_2H)_6$, *quinate*,

$$Eu_2[C_6H_7(OH)_4 \cdot CO_2]_6,12H_2O,$$

pyromucate, $Eu_2(C_4H_3O \cdot CO_2)_6,2H_2O$, and m-*nitrobenzenesulphonate*,

$$Eu_2(NO_2 \cdot C_6H_4 \cdot SO_3)_6,6H_2O,$$

are described.   E. G.

The Action of Ultraviolet Rays on Aldehydes. ADOLF FRANKE and ERNST POLLITZER (*Monatsh.*, 1913, 34, 797—809).—When exposed to the radiation from a quartz-mercury lamp, formaldehyde solutions undergo partial decomposition into carbon monoxide, carbon dioxide, hydrogen and methane, and partial polymerisation to glycollaldehyde and higher products (Pribram and Franke, A., 1912, i, 412); the higher aldehydes have been observed to form carbon monoxide, hydrogen, and the hydrocarbon corresponding with the radicle to which the aldehyde group was previously attached (Berthelot and Gaudechon, A., 1910, ii, 814). A re-investigation of the behaviour of the homologues of formaldehyde indicates that they decompose mainly according to the equation $R \cdot CHO = RH + CO$; at the same time condensation takes place to some extent accompanied by polymerisation to resinous substances ; no pure condensation product could be isolated. Under the conditions of the experiments, in which moisture and atmospheric oxygen were excluded, no formation of acids or of esters could be dectected, so that the earlier suggestion of Pribram and Franke (*loc. cit.*) that the formic acid obtained in the illumination of formaldehyde solution is produced by the hydrolysis of previously formed methyl formate is hardly probable. From the behaviour of crotonaldehyde, which like benzaldehyde and cinnamaldehyde gives practically no liberation of gas, it appears that the decomposition expressed by the above equation is characteristic of the saturated aliphatic aldehydes.

The aldehyde under examination was contained in a quartz flask of approximately 100 c.c. capacity which was filled to the neck, any evolved gas being collected over water or mercury ; the mercury lamp was at a distance of 2 to 3 mm. from the flask, but the temperature of the aldehyde never exceeded 50°.

The substances examined were heptaldehyde, *iso*butaldehyde, propaldehyde, acetaldehyde, crotonaldehyde, benzaldehyde, and cinnamaldehyde. Crotonaldehyde gave only the formation of a resinous substance, whilst the two aromatic aldehydes gave merely red, non-volatile products. The illumination ranged from one to ten days in various cases ; only a relatively small proportion of each aldehyde underwent conversion.   D. F. T.

Action of Hydrazine and Hydrazine Derivatives on Molten Chloral Hydrate. GUSTAV KNOPFER (*Monatsh.*, 1913, 34, 769—777). —Hydrazine reacts with solutions of chloral hydrate, giving an additive product, $CCl_3 \cdot CH(OH) \cdot NH \cdot NH_2$, chloralhydrazine (compare A., 1911,

i, 1033); it is now found that if hydrazine sulphate or hydrochloride is dissolved in an excess of molten chloral hydrate, needles of a *substance*, m. p. 187° (decomp.), separate, but the composition is $C_4H_7ON_2Cl_6$, instead of $C_4H_4ON_2Cl_6$, which would be expected from a simple condensation such as that producing anhydrochloralurethane (Feist, A., 1912, i, 566).

The reaction product of benzalazine and chloral hydrate, obtained in a manner similar to the above, has the composition $C_9H_7ON_2Cl_3$, which is again two hydrogen atoms short of the formula for a substance produced by mere condensation; the *substance*, leaflets, m. p. 185°, when heated with potassium hydroxide solution loses a molecule of hydrogen chloride, giving a *substance*, $C_9H_6ON_2Cl_2$, needles, m. p. 86°. The former of these substances is not identical with the isomeric chloralbenzoylhydrazone, $CCl_3 \cdot CH:N \cdot NHBz$ (Stollé, A., 1905, i, 94), and, as it does not yield chloroform when treated with alkali, it is not likely to be the trichloroacetylhydrazone of benzaldehyde,

$$CCl_3 \cdot CO \cdot NH \cdot N:CHPh.$$

The loss of the two hydrogen atoms in each case is possibly due to a similar cause to the loss observed by Pinner (A., 1894, i, 385) where the continued action of hydrazine on the imino-ester of benzoic acid gives rise to $NH:CPh \cdot NH_2$, $NH:CPh \cdot NH \cdot NH \cdot CPh:NH$, and

$$CPh\underset{NH \cdot NH}{\overset{N \longrightarrow N}{<\quad>}}CPh$$
successively. The structure of the above products, however, remains for the present unsettled.   D. F. T.

Keto-enolic Tautomerism. VIII. Formation of Derivatives of Tautomeric Compounds. KURT H. MEYER (*Annalen*, 1913, 398, 49—65. Compare A., 1912, i, 940, 941).—To the terms "tautomerism," introduced by Laar in connexion with his oscillation theory, and "desmotropy" some confusion has become attached in the course of time and with the increase in the number of examples. The author proposes the following definitions. A substance exhibits tautomerism when it yields two series of derivatives obtained from two isomeric forms differing in the position of a hydrogen atom, and of one or more double linkings. According to the nature of the two isomeric forms, special cases of tautomerism are : (i) desmotropy—the free compounds corresponding with both forms are capable of separate existence or can be separately detected; (ii) pseudomerism—the tautomeric substance is known in only one form, the constitution of which can be determined by methods independent of tautomerism, and which can yield by addition or substitution derivatives of both forms ; the other form is unknown and its existence cannot be detected by any method ; (iii) cryptomerism—the substance is known in only one form, the constitution of which cannot be definitely determined (by methods independent of tautomerism).

Many reactions of desmotropic substances are explained readily by the desmotropy ; each form yields derivatives of its own type by ordinary double decomposition and usually one form reacts, the other being changed to the first by the reagent present. In other reactions the explanation is not so simple ; the tautomeric

substance yields a mixture of derivatives of both forms or only one substance, which is generally a derivative of the non-reacting form, for example, the formation of a brominated ketone by the bromination of an enol. Two theories are existent to explain such cases. The substitution theory claims that a substance can only yield derivatives of its own peculiar constitution, and that the production of a derivative of the other form must be due to a transformation of the tautomeride which precedes the substitution. The addition theory of Michael and of Nef assumes that by the direct addition of a reagent and subsequent elimination of a different molecule, a tautomeride of one form can yield derivatives of the other type.

Evidently the test of the two theories lies in the answer to the question, which of the two forms reacts? This answer can only be obtained by an examination of the behaviour of separately stable desmotropic substances. The author quotes numerous examples from his own work, and from that of Dimroth, Hinsberg, Hantzsch, and Herzig and Wenzel to show that the enolic modification is the reactive form, and that, therefore, the additive theory is probably correct.

[With S. LENHARDT.]—Keto-enolic desmotropes and also tautomerides which are known only in the ketonic or the enolic modifications condense with aldehydes (1 or 2 mols.), the resulting compounds losing water in various ways. In order to ascertain whether the ketonic or the enolic modification reacts with the aldehyde, the two desmotropic modifications of methyl mesityl oxide oxalate have been treated with benzaldehyde in the presence of a little piperidine. The ketonic modification, methyl $\alpha\gamma$-diketo-ϵ-methyl-Δ^δ-hexene-α-carboxylate, m. p. 67°, is unchanged, but the enolic modification, methyl α-hydroxy-γ-keto-ϵ-methyl-$\Delta^{\alpha\delta}$-hexadiene-α-carboxylate, is converted into the *lactone*,

$$\begin{array}{c} O \cdot CHPh \\ CO\text{---}CO \end{array}\!\!\!>\!\!CH \cdot CO \cdot CH\!:\!CMe_2,$$ m. p. 160°, colourless needles, which

does not react with ferric chloride or with alcoholic bromine, and is only slowly attacked by potassium permanganate, and is, therefore, the ketonic modification; the enolic form,

$$\begin{array}{c} O \cdot CHPh \\ CO\text{---}CO \end{array}\!\!\!>\!\!C\!:\!C(OH) \cdot CH\!:\!CMe_2,$$
obtained by dissolving the ketonic modification in cold alcoholic sodium ethoxide, diluting with water, and acidifying, has m. p. 144°, then solidifies and has m. p. 160°, reacts with alcoholic bromine or ferric chloride, and is soluble in alkalis. By prolonged boiling with alcohol and a little piperidine, the enol is converted into the ketonic form; the same change occurs when the fused enol solidifies.

The authors believe that in all desmotropic and tautomeric compounds, condensation occurs by means of the enolic modification.

The Characterisation of Chloro-ketones. EDMOND E. BLAISE (*Compt. rend.*, 1913, **156**, 1549—1551).—The most suitable method of characterising the chloro-ketones is to convert them into their semicarbazones under definite conditions, the ordinary methods being unsatisfactory. Semicarbazide hydrochloride (1 to 1·5 mols.) is dis-

solved in water and the chloro-ketone added, when the semicarbazone is rapidly formed, the only exception being methyl trichloromethyl ketone, which requires a cold alcoholic solution of free semicarbazide. Care must be taken in purification. After filtering and washing with water the semicarbazone is heated with an excess of benzene to below 50°, a little anhydrous sodium sulphate is added, the liquid filtered and left for crystallisation. The semicarbazones of the α-chloro-ketones are readily converted into those of the α-hydroxy-ketones by contact with aqueous potassium carbonate for a few hours, and into those of the α-acetoxy-ketones by warming for a few minutes with an alcoholic solution of anhydrous sodium acetate, thus giving three means of identification of the original ketone.

Dichloro-ketones of the type $CHCl_2 \cdot CO \cdot R$ give a normal semicarbazone, but those of the type $CRCl_2 \cdot CO \cdot R'$ give disemicarbazones, $R \cdot C(N \cdot CH_8ON_2) \cdot C(N \cdot CH_8ON_2)R'$, which are insoluble in organic solvents, except formic and acetic acids.

The following semicarbazones and disemicarbazones have been prepared :

Methyl trichloromethyl ketone semicarbazone, $CCl_8 \cdot CMe \colon N \cdot CH_8ON_2$, fine needles, m. p. 140°.

Dichloromethyl ethyl ketone semicarbazone, m. p. 142°.

Ethylglyoxaldisemicarbazone, $CH \colon (N \cdot CH_8ON_2) \cdot CEt \colon (N \cdot CH_8ON_2)$, m. p. above 230°.

Dimethyldiketone disemicarbazone,
$$CMe \colon (N \cdot CH_8ON_2) \cdot CMe \colon (N \cdot CH_8ON_2),$$
a white, crystalline powder, m. p. above 230°, soluble only in formic acid.
Chloromethyl chloroethyl ketone semicarbazone,
$$CH_2Cl \cdot C \colon (N \cdot CH_8ON_2) \cdot CHClMe,$$
m. p. 140°.
Methyl chloroethyl ketone semicarbazone, micaceous plates, m. p. 148°, which with carbonic acid gives the *semicarbazone*, m. p. 202°, of the corresponding hydroxy-ketone, and with sodium acetate gives *methyl acetoxyethyl ketone semicarbazone*, $CMe \cdot C \colon (N \cdot CH_8ON_2) \cdot CHAcMe$, m. p. 161°.

Chloromethyl propyl ketone semicarbazone, m. p. 157°.   W. G.

Mannitol Esters of Sulphuric Acid. W. R. BLOOR (*J. Amer. Chem. Soc.*, 1913, 35, 784—794).—In preparing certain mannitol esters of the higher fatty acids by heating the substance with sulphuric acid at 70° (A., 1910, i, 538 ; 1912, i, 532 ; ii, 365) unsatisfactory results were obtained, and for this reason a study has been made of the action of concentrated sulphuric acid on mannitol at 39°, 49°, 56°, and 65°.

When mannitol is dissolved in concentrated sulphuric acid, the disulphate is the principal compound produced, but a portion of the mannitol is dehydrated to the form $C_6H_6O(OH)_2$. At low temperatures a lævorotatory ester is produced, but at higher temperatures dextrorotatory compounds are formed together with derivatives which have lost part of their capacity to combine with acid groups. In the presence of the higher fatty acids, esters are produced, presumably

with the mannitol anhydride, but during the processes of separation they are hydrated to mannide and mannitan forms. E. G.

Acetyl-Halogen Sugar Derivatives. W. SLOAN MILLS (*Rep. Brit. Assoc.*, 1912, 444—445).—β-Iodoacetodextrose (E. and H. Fischer, A., 1910, i, 716) may be prepared by the action of dry hydrogen iodide on β-penta-acetyldextrose dissolved in dichloromethane. It is recrystallised rapidly from alcohol. Copper hydride reduces it, yielding a compound $C_{26}H_{44}O_{19}$

β-*Acetyliodogalactose* is prepared in the same manner from β-penta-acetylgalactose, and has m. p. 93—94°. Octoacetylmaltose yields an iodo-derivative, m. p. 62—66°. Acetyliodolactose, from acetyl-lactose, has m. p. 142°. C. H. D.

Gentiobiose. GÉZA ZEMPLÉN (*Zeitsch. physiol. Chem.*, 1913, 85, 399—407).—Octa-acetylgentiobiose crystallises well and is relatively easily isolated from highly impure crude products. Acetylation may thus be used to obtain gentiobiose from plant products, and its preparation from gentian roots is described. *Octa-acetylgentiobiose* sinters at 192°, m. p. 195°, $[a]_D^{20}$ − 5 6°. Gentiobiose is equivalent to 130 c.c. of Fehling's solution, maltose reducing 128·5 c.c. The phenylosazone crystallises in citron-yellow, stellate needles, or from hot water in short, pointed prisms, m. p. 160—170° (decomp.), $[a]_D^{20}$ − 76·1° in pyridine and alcohol. E. F. A.

Deflocculation of Starch and Solution of Dextrose. GIOVANNI MALFITANO and (Mlle.) A. MOSCHKOV (*Compt. rend.*, 1913, 156, 1681—1684. Compare this vol., i, 593).—A further discussion of the difference between the phenomenon of deflocculation of starch and that of the solution of dextrose and a description of the difference in behaviour of solutions of these pseudo-crystals of starch and crystals of dextrose under different conditions. W. G.

Diastatic Degradation of Starch. WILHELM BILTZ (*Ber.*, 1913, 46, 1532—1536).—The degradation of potato starch under the influence of enzymes has been studied, the course of the reaction being followed qualitatively by the iodine reaction and quantitatively by the withdrawal of portions of the solution at definite intervals, addition of boiling water, and precipitation of the dextrins by the addition of so much alcohol that the mixture contained 80—90% of the latter, the treatment being repeated until the product was free from sugar. The approximate mean molecular weight of the dextrins was then determined by measurement of the viscosity of their aqueous solution (compare this vol., i, 593).

The following are the main results obtained :

The diastatic degradation of starch to sugar takes place with intermediate formation of erythrodextrins and achroodextrins which are themselves ultimately transformed into sugar. The velocity of saccharification of the achroodextrins is smaller than that of the erythrodextrins, and this is again smaller than that of the amylodextrins.

The existence of erythrodextrins is established.

The mean molecular weights for the achroodextrins is about 3700 ; for the erythrodextrins, 6200—7000 ; for the amylodextrins, above 10,000. Since purified specimens of achroodextrin I, achroodextrin II, and erythrodextrin IIα have molecular weights 1800, 1200 and 3000 respectively, it would appear that, besides these and the amylodextrins, other dextrins of high molecular weight must exist which are indifferent towards iodine and belong to the class of achroodextrins.

Philoche's determinations of the velocity of the conversion of starch into sugar (A., 1908, i, 712 ; ii, 470) show that this rapidly diminishes at first, but then becomes constant when the reaction appears to be unimolecular. The author's experiments show that the first phase of the reaction is complicated by the presence of amylo- and erythro-dextrins in the mixture, and that reaction only follows a simple law when only one type of substances, namely, the achroodextrins, are undergoing saccharification.　　　　　　　　　　　　　　　H. W.

Partial Hydrolysis of Cellulose. GÉZA ZEMPLÉN (*Zeitsch. physiol. Chem.*, 1913, **85**, 180—191).—On treatment of cellulose with strong sulphuric acid a mixture of various depolymerised products is obtained. Even after prolonged treatment, cellobiose acetate is obtained on acetolysis and not dextrose pentacetate. Crystalline products were not obtained on acetolysis of xylan and mannan preparations or of chitin.

　　　　　　　　　　　　　　　　　　　　　　　　　E. F. A.

Chemical Composition of Cork Substance. GÉZA ZEMPLÉN (*Zeitsch. physiol. Chem.*, 1913, **85**, 173—179).—Cork when treated by Cross and Bevan's method with chlorine yields a product, which in its external properties and solubility resembles cellulose, but on treatment with acetic anhydride and sulphuric acid by Skraup's method gave no cellobioseocta-acetate. One hundred grams of cork meal contained about 4 grams of this cellulose-like product.　　　　　E. F. A.

Betonicine and Turicine. ALBERT KUNG and GEORG TRIER (*Zeitsch. physiol. Chem.*, 1913, **85**, 209—216).—The mixture of betaines in *Betonica officinalis* has been resolved into two isomerides, a lævorotatory base betonicine, and a dextrorotatory base turicine. Both are betaines of the natural hydroxyproline, and on exhaustive methylation of this compound the same mixture of the two betaines is obtained as exists in *Betonica officinalis*, *Stachys silvatica*, etc. According to the method of isolation sometimes one and sometimes the other isomeride has been isolated, in reality both are present.

Betonicine crystallises in four-sided, stunted pyramids, m. p. 243—244° (decomp.). It reacts neutral, tastes sweet, and has $[α]_D^{15} - 36.6°$. The *hydrochloride* crystallises in lustrous prisms, m. p. 222—223° (decomp.), $[α]_D^{15} - 24.79°$. The *aurichloride* separates in dull yellow-coloured plates aggregated in fan-shaped clusters, m. p. 242°. The *platinichloride* forms short prisms, m. p. 226°.

Turicine crystallises in long, transparent, lustrous, flat prisms, or in slender, glistening needles, m. p. 249° (decomp.), $[α]_D + 36.26°$. It tastes sweet and is not hydroscopic. The *hydrochloride* crystallises in slender, lustrous needles, m. p. 223°, and reacts acid, $[α]_D + 24.65°$.

The *aurichloride* is a yellow powder crystallising in obliquely-cut, lustrous prisms, m. p. 232°. The crystalline *platinichloride* has m. p. 223°.   E. F. A.

Synthesis of Betonicine and Turicine. ALBERT KUNG (*Zeitsch. physiol. Chem.*, 1913, 85, 217—224. Compare preceding abstract).— γ-Hydroxyproline prepared by E. Fischer's method from gelatin can be methylated by means of potassium hydroxide in methyl alcohol and methyl iodide. The product, hydroxyprolinebetaine,

$$\mathrm{HO\cdot CH}\Big\langle {}^{CH_2\cdot CH—CO}_{CH_2\cdot NMe_2\cdot O} \text{ ,}$$
is a mixture of betonicine and turicine in equal quantities. The nature of the isomerism between these two betaines has not been established.
                                                                      E. F. A.

Compounds of Hexamethylenetetramine with Various Silver Salts. LUDWIG VANINO and PAULA SACHS (*Arch. Pharm.*, 1913, 251, 290—293. Compare Grützner, A., 1899, i, 6).—The authors have prepared the compound of hexamethylenetetramine with silver nitrate, obtained by Grützner (*loc. cit.*), and also *compounds* with the following silver salts: silver fluoride, $C_6H_{12}N_4,AgF,3H_2O$, slender needles; silver chloride, B,4AgCl, prismatic crystals (compare Délepine, A., 1895, i, 261); silver bromide, B,3AgBr, microscopic crystals; silver iodide, B,3AgI, amorphous; silver chlorate, $B,AgClO_3,H_2O$, amorphous, explodes on warming; silver oxalate, $B,Ag_2C_2O_4$; globular masses of slender needles.   T. A. H.

The Methylation of Glycine by means of Formaldehyde. WALTHER LÖB (*Biochem. Zeitsch.*, 1913, 51, 116—127).—If formaldehyde is allowed to act on glycine in neutral solution in the cold, a compound, $CH_2:N\cdot CH_2\cdot CO_2H$, is formed, with separation of the elements of water, which under the influence of acids or alkalis readily undergoes scission again into formaldehyde and glycine. If, however, the substances are allowed to act on one another in hot acid solution, a stable *methylenediglycine*, $CH_2(NH\cdot CH_2\cdot CO_2H)_2$, is formed, which can be readily isolated in the form of a dihydrochloride, from which, by means of silver oxide, the free base can be obtained in platelets, melting about 199°. In alkaline solution, formaldehyde does not act on glycine. If formaldehyde in the presence of acid and zinc is allowed to act on glycine (at 100°), a mixture of sarcosine and dimethylaminoacetic acid is produced. The mechanism of this reaction is explained by assuming that methylenediglycine is reduced to a mixture of an equal number of molecules of methylglycine and glycine. By the action of formaldehyde on the former, methylenedi(methylglycine) can be produced, which, on reduction, yields an equal number of molecules of dimethyl- and monomethyl-glycines.   S. B. S.

Behaviour of α-Amino-acids and Polypeptides to Neutral Salts. PAUL PFEIFFER and J. VON MODELSKI (*Zeitsch. physiol. Chem.*, 1913, 85, 1—34. Compare A., 1912, i, 949).—The compounds of lithium chloride or bromide with glycine of the composition
$$LiX,NH_2\cdot CH_2\cdot CO_2H,H_2O$$

are readily prepared by evaporating an aqueous solution of the components until crystallisation begins. They form colourless needles, m. p. 136° (the chloride) and 175—176° (the bromide) respectively.

The compounds of the type $LiX,2NH_2\cdot CH_2\cdot CO_2H,H_2O$ are obtained by crystallising rapidly at room temperature from strong solutions after inoculation. They crystallise in colourless, transparent plates, m. p. 186—190° (the chloride) and 223° (the bromide).

The compound of lithium chloride and alanine,
$$LiCl,NH_2\cdot CHMe\cdot CO_2H,H_2O,$$
has m. p. 128—129°.

Monoglycine calcium chloride, $CaCl_2,NH_2\cdot CH_2\cdot CO_2H,3H_2O$, forms tiny, lustrous plates, which do not melt. *Diglycine calcium chloride*, $4H_2O$, crystallises in long, colourless needles. *Triglycine calcium chloride* separates in lustrous, transparent platelets which do not melt at 250°. *Triglycine lanthanum chloride*,
$$LaCl_3,3NH_2\cdot CH_2\cdot CO_2H,3H_2O,$$
forms colourless, transparent, prismatic needles.
Monoalanine lithium chloride, $LiCl,NH_2\cdot CHMe\cdot CO_2H,H_2O$, crystallises in colourless, lustrous platelets, m. p. 127—128°. *Dialanine calcium chloride*, $3H_2O$, yields colourless, transparent needles, m. p. 77° to a viscid, clear liquid.

Monodiglycylglycine calcium chloride,
$$CaCl_2,NH_2\cdot CH_2\cdot CO\cdot NH\cdot CH_2\cdot CO\cdot NH\cdot CH_2\cdot CO_2H,3H_2O,$$
separates in well-formed, colourless, transparent platelets.
Monobetaine potassium bromide, $KBr,C_5H_{11}O_2N,2H_2O$, crystallises in transparent, tabular plates, which soften completely at 90—93°, m. p. about 110°. *Monobetaine potassium iodide* forms long, thin, colourless plates consisting in part of parallel, intergrown, flat needles, which sinter at 100°, begin to melt at 115°, and form a clear liquid at 140°. *Dibetaine potassium iodide* $KI,2C_5H_{11}O_2N,2H_2O$, forms colourless, tabular crystals with oblique faces, m. p. 148°. *Monobetaine barium chloride*, $4H_2O$, crystallises in long, thin, colourless, prismatic needles. *Monobetaine barium bromide*, $4H_2O$, also separates in similar needles.

The constitution of the salts described is discussed; they are regarded as amphi-salts in which both the basic and acid groups of the amino-acid are neutralised.   E. F. A.

Methyl Derivatives of δ-Aminovaleric Acid and *dl*-Ornithine. EMIL FISCHER and MAX BERGMANN (*Annalen*, 1913, **398**, 96—124).— By hydrolysis with hydrochloric acid, D 1·19, in a sealed tube in the water-bath, δ-*m*-nitrobenzoylamino-α-methylaminovaleric acid (A., 1909, i, 793) readily yields δ-*amino-α-methylaminovaleric acid dihydrochloride*, $NH_2\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH(NHMe)\cdot CO_2H,2HCl$, m. p. 207—210° (decomp., corr.), colourless plates or prisms, which forms a precipitate with phosphotungstic acid, but not with potassium bismuth iodide even in considerably concentrated solutions. From the dihydrochloride, the *picrate*, $C_6H_{14}O_2N_2,2C_6H_3O_7N_3$, m. p. 205—206° (decomp., corr.), and the *platinichloride*, $C_6H_{14}O_2N_2,H_2PtCl_6,H_2O$ (or $4H_2O$), decomp. 218° (corr.), when anhydrous, have been prepared.

By treating an aqueous solution of the dihydrochloride with silver

sulphate, removing the excess of silver by hydrochloric acid and the sulphuric acid by barium hydroxide, and evaporating the filtrate at 10—20 mm., all the operations being performed in an atmosphere of carbon dioxide, δ-*amino-a-methylaminovaleric acid*, m. p. 82—100°, is obtained as a crystalline mass. Its aqueous solution reacts strongly alkaline, precipitates ferric hydroxide, and dissolves precipitated copper hydroxide.

By hydrolysing *dl*-benzoylornithine with boiling hydrochloric acid (D 1·19) and treating the resulting *dl*-ornithine with 2N-sodium hydroxide and benzenesulphonyl chloride (3 mols.) at 46—48°, and acidifying, aδ-*dibenzenesulphonyldiaminovaleric acid* (dl-*dibenzenesulphonylorni-thine*), $C_{17}H_{20}O_6N_2S_2,H_2O$, m. p. 155—157° (corr., anhydrous), micro-scopic needles, is obtained. By treatment with 2N-sodium hydroxide and methyl iodide at 65°, it yields, after acidification, aδ-*dibenzenesul-phonyldimethyldiaminovaleric acid*,

$$SO_2Ph\cdot NMe\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH(NMe\cdot SO_2Ph)\cdot CO_2H,$$
m. p. 141—142° (corr.), microscopic plates, by the hydrolysis of which by hydrochloric acid (D 1·19) at 100° is obtained N-*dimethylornithine-*aδ-*dimethyldiaminovaleric acid*), $NHMe\cdot[CH_2]_3\cdot CH(NHMe)\cdot CO_2H$, which is isolated by precipitation with phosphotungstic acid; the *hydro-chloride*, $C_7H_{16}O_2N_2,2HCl$, and *platinichloride*, $C_7H_{16}O_2N_2,H_2PtCl_6$, m. p. 220° (decomp., corr.), are described, and the *aurichloride* and *picrate* are mentioned. A 0·5% aqueous solution of dimethylornithine dihydrochloride and aqueous potassium bismuth iodide yield a brick-red precipitate after a few hours.

dl-Ornithine, obtained by the hydrolysis of δ-benzoylornithine, has been isolated in a crystalline state.

δ-Benzenesulphonylaminovaleric acid, 2N-sodium hydroxide, and methyl iodide at 63—65° yield, after acidification, δ-*benzenesulphonyl-methylaminovaleric acid*, $SO_2Ph\cdot NMe\cdot[CH_2]_4\cdot CO_2H$, m. p. 70—71° (corr.), colourless needles or prisms, by the hydrolysis of which by hydrochloric acid (D 1·19) is obtained δ-*methylaminovaleric acid*, m. p. 121—122° (corr.), needles or prisms, which is isolated by means of phosphotungstic acid. The acid is very hygroscopic, and its aqueous solution gives immediately a brick-red precipitate with potassium bismuth iodide; the *picrate*, $C_6H_{13}O_2N,C_6H_3O_7N_3,H_2O$, has m. p. 70—71° (corr.). At 130—160°, δ-methylaminovaleric acid loses water and is converted into

1-*methyl-2-piperidone*, $NMe\!\!<\!\!^{CO-CH_2}_{CH_2\cdot CH_2}\!\!>\!\!CH_2$, b. p. 94—95° (corr.)/ 9 mm.

3-Amino-2-piperidone, prepared from ornithine, reacts readily with benzaldehyde to form the *benzylidene* compound,

$$CHPh\!:\!N\cdot CH\!\!<\!\!^{CO-NH}_{CH_2\cdot CH_2}\!\!>\!\!CH_2,$$
m. p. 140—142° (corr.), almost colourless crystals.

Glycine, *p*-toluenesulphonyl chloride, and 2N-sodium hydroxide at 67—70° yield, after acidification, p-*toluenesulphonylglycine*, $C_9H_{11}O_4NS$, m. p. 149—150° (corr.), slender needles, which is converted by 3N-sodium hydroxide and methyl iodide at 67° and subsequent

acidification into p-*toluenesulphonylsarcosine*, $C_{10}H_{13}O_4NS$, m. p. 150—152° (corr.), by the hydrolysis of which sarcosine is obtained.

The reaction of alcoholic sodium ethoxide, α-chloro-γ-bromopropane, and ethyl malonate in the presence of ether leads to the production of *ethyl γ-chloropropylmalonate*, $CH_2Cl \cdot CH_2 \cdot CH_2 \cdot CH(CO_2Et)_2$, b. p. 154—155° (corr.)/17 mm., which reacts with bromine in chloroform to form *ethyl bromo-γ-chloropropylmalonate*

$$CH_2Cl \cdot CH_2 \cdot CH_2 \cdot CBr(CO_2Et)_2,$$
b. p. 175—176° (corr.)/17 mm. Ethyl γ-chloropropylmalonate and 33% aqueous methylamine react at the ordinary temperature to form *γ-chloropropylmalonmethylamide*, $CH_2Cl \cdot CH_2 \cdot CH_2 \cdot CH(CO \cdot NHMe)_2$, m. p. 158—162° (corr.), leaflets or needles.

A by-product in the preparation of ethyl γ-chloropropylmalonate under certain conditions is *ethyl di-γ-chloropropylmalonate*,

$$C(CH_2 \cdot CH_2 \cdot CH_2Cl)_2(CO_2Et)_2,$$
m. p. 51—52°, b. p. 195—197° (corr.)/14 mm., flattened crystals, which is converted by methyl alcoholic ammonia at 100° into a *substance*, $C_9H_{14}O_2N_2$, m. p. 330° (decomp., corr.), colourless, microscopic prisms, which is probably *bis-2-piperidone*-3 : 3'-*spiran*,

$$CH_2 \underset{NH-CO}{\overset{CH_2 \cdot CH_2}{<}} C \underset{CO-NH}{\overset{CH_2 \cdot CH_2}{<}} CH_2.$$
O. S.

The Oxidative Degradation of a Synthetic Tripeptide. OTTO EISLER (*Biochem. Zeitsch.*, 1913, 51, 45—52).—By the oxidation of alanylglycylglycine with calcium permanganate, using as much of the latter as is equivalent to 8—10 atoms of oxygen to one molecule of the peptide, an acid in the form of a crystalline calcium salt was isolated, the formula of which corresponded approximately with

$$C_6H_5O_7N_3Ca,6H_2O.$$
On hydrolysis by acids, one molecule gives rise to two molecules of oxalic acid. Two alternative formulæ are suggested by the author.

S. B. S.

Anhydride Formation with a Diaminohydroxy-acid. MORITZ KOHN and ALFONS OSTERSETZER (*Monatsh.*, 1913, 34, 781—786). —It has been shown (Kohn, A., 1908, i, 819; Kohn and Bum, A., 1910, i, 136) that *iso*hexan-δ-ol-β-one on treatment with potassium cyanide and ammonium chloride, or the hydrochloride of an amine, gives rise to an aminolactone. When equimolecular quantities of *iso*hexan-δ-ol-β-one, ethylenediamine dihydrochloride, potassium cyanide, and potassium hydroxide are heated together with a little water at 60° for five to six hours, and the resulting nitrile hydrolysed by treatment with concentrated hydrochloric acid, a *substance*, $C_9H_{18}O_2N_2$, prismatic crystals, m. p. 174°, is obtained, which gives a crystalline *picrate*,

$$C_9H_{18}O_2N_2,C_6H_3O_7N_3,$$
m. p. 154°, and an *oxalate*, $C_9H_{18}O_2N_2,2C_2H_2O_4,\tfrac{1}{2}H_2O$, tablets, m. p. 160° (decomp.).

The structure of the substance is probably that of a diaminolactone or of a hydroxylactam, but the point is at present undecided.

D. F. T.

The Electrolytic Formation of Carbamide and Acetamidine Nitrate. FRITZ FICHTER, KARL STUTZ, and FRITZ GRIESHABER (*Verhand. Naturfors. Ges. Basel*, 1912, **23**, 222—263).—It is shown that small quantities of carbamide are produced by the electrolysis of solutions of ammonium carbamate. The best yields, which are nevertheless very small, are obtained when the anode current density (C_a) lies between 0·130 and 0·555 ampere per sq. cm. Between these values the yield is practically constant and amounts to about 0·60 gram per 100 ampere-hours. It is shown that the yield is increased if the concentration of the carbamate is increased, and also increase of free ammonia increases the yield, the latter factor being of much more importance than the former. The best yield is obtained with a solution containing 12 gram-equivalents of ammonia and 8 gram-equivalents of ammonium carbamate. It is also shown that carbamide is decomposed by the oxidising action of the current and converted into ammonium nitrate, and that the amount of decomposition is greatest when there is no free ammonia present and that it decreases, rapidly as the concentration of ammonia is increased. The gases evolved at the anode were collected and analysed, and the relationship between their composition and the temperature and excess ammonia concentration determined. It is shown that at 18° with $C_a = 0·014$ ampere per sq. cm., the percentage of oxygen slowly decreases, whilst the nitrogen increases with the concentration of free ammonia up to 7 gram-equivalents per litre, and that on further increasing the free ammonia concentration the nitrogen increases rapidly until at 12 gram-equivalents per litre it has reached 100%. From a solution containing 9 gram-equivalents of ammonia the percentage of nitrogen in the gas was 24·8% at 6°, whilst at 18° it had increased to 99·1%. A theory is put forward to represent the electrolytic oxidation of ammonia which can be shortly represented by the scheme:

$$NH_3 \longrightarrow NH_2 \cdot OH \longrightarrow H_2N_2O_2$$
$$\downarrow$$
$$N_2O + H_2O$$

and

$$NH_4 \cdot ON:N \cdot OH \longrightarrow NH_4NO_3 \dashrightarrow NH_4NO_3$$
$$\downarrow$$
$$N_2 + H_2O$$
Nitrous oxide is found in the gases collected at the anode, and the other steps in the process are generally confirmed by the observations. The formation of carbamide by the electrolysis of ammonium carbamate is explained by the following scheme:

$$O:C(NH_2) \cdot ONH_4 + 2NH_2 \cdot OH = 2 \cdot O:CH \cdot NH_2 + H_2N_2O_2 + 2NH_3 + 2H_2O$$
$$O + NH_3 + O:CH \cdot NH_2 = NH_4 \cdot CO(NH_2) + H_2O$$
According to this, formamide is produced by the interaction of hydroxylamine, produced as above, and ammonium carbamate, and this is then electrolytically oxidised in the presence of ammonia to carbamide. In proof of this theory the authors quote the work of Jouve (A., 1899, i, 420), who showed that when carbon monoxide is heated with ammoniacal cuprous chloride, carbamide is produced. Further, Hofmeister and Halsey (A., 1898, ii, 529) have shown that a large number

of organic substances when treated with potassium permanganate in ammoniacal solution yield carbamide. These substances are all oxy-acids, ketones, and ketonic acids, that is, substances which give carbon monoxide on oxidation. Carbamide was next obtained by electrolysing a solution of ammonium acetate containing methyl alcohol; this is represented by

$$CH_3 \cdot OH \longrightarrow CO \longrightarrow H \cdot CO \cdot NH_2 \longrightarrow NH_2 \cdot CO \cdot NH_2.$$

When ethyl alcohol was electrolysed in ammoniacal solution a small quantity of acetamidine nitrate was obtained. It was found that the addition of ammonium nitrate increased the yield of the amidine nitrate, and that if no ammonium nitrate had been added, often there was no yield at all. The formation is represented by the scheme:

$$CH_3 \cdot CH_2 \cdot OH \longrightarrow CH_3 \cdot CHO + NH_3 \longrightarrow$$
$$CH_3 \cdot CH(OH) \cdot NH_2 + O + NH_3 \longrightarrow CH_3 \cdot C(NH)NH_2$$
The authors show in confirmation of the above that aldehyde ammonia can be oxidised to the amidine by calcium permanganate, ammonium persulphate and hydrogen peroxide, and isolated provided that excess of ammonia and some ammonium nitrate are present. The corresponding propionamidine nitrate and butyramidine nitrate were obtained by the electrolysis of ammoniacal solutions of propyl and butyl alcohols respectively. In the case of butyl alcohol only the smallest yield was obtained, and with higher alcohols amidine nitrates could not be obtained in any case. J. F. S.

The Fixation of Nitrogen by Mixtures of Barium Oxide and Charcoal. THOMAS EWAN and THOMAS NAPIER (*J. Soc. Chem. Ind.*, 1913, **32**, 467—474).—The first set of experiments were carried out by heating a mixture of two parts of barium carbonate and one part of well-burned wood charcoal, contained in an iron boat, in a porcelain tube in a current of nitrogen. The results obtained were as follows (compare Kühling and Berkhold, A., 1908, i, 143): the absorption of nitrogen begins between 900° and 930°. The amount absorbed under the same conditions increases very rapidly with the temperature, for example, if 4 mols. of nitrogen are passed over 1 mol. of $BaCO_3$ in two hours, about 1% of the barium will combine with it at 930°, about 14% at 960°, and about 40% at 1000°. The greater part of the nitrogen fixed is in the form of cyanide. Under the conditions used by the authors, about 2·5% of the nitrogen used is fixed at 960° and about 10% at 1000°. The addition of quantities of potassium carbonate up to 11% seems to improve the results, but the improvement is no more than would be produced by a difference of 10—20° in temperature.

No cyanide is formed until some 30% of the barium carbonate has been converted into oxide, and the quantity of carbon monoxide in the gas has fallen to about 30%; the percentage of carbon monoxide falls steadily as the formation of cyanide progresses.

The authors draw the conclusion that the fixation of nitrogen is due to one or both of the reversible reactions: $BaO + 2C + N_2 \rightleftharpoons BaCN_2 + CO$, $BaO + 3C + N_2 \rightleftharpoons Ba(CN)_2 + CO$; and further experiments indicate that the barium compounds mix in the solid (or fused) mixture, so that the ratio of the partial pressures of carbon monoxide and nitrogen in

the gas when equilibrium is attained at any given temperature depends on the relative quantities of cyanide, cyanamide, and oxide in the mixture. The reaction appears to be arrested at half-conversion of the barium oxide, which may be explained by assuming the formation of a compound $BaO,Ba(CN)_2$, in which the barium oxide is much less active than in the free state.

Pure barium cyanide is readily obtained by suspending anhydrous barium hydroxide, in the form of a fine powder, in light petroleum, and adding an emulsion of the theoretical quantity of anhydrous hydrocyanic acid in light petroleum. It fuses at 600° and is distinctly volatile even at its melting point. The fused product contains barium cyanamide, the amount of which depends, among other things, on the temperature and the length of time the fusion is heated; the presence of finely divided iron in the cyanide increases the amount of cyanamide formed.

When barium ferrocyanide is heated in a vacuum or in an atmosphere of nitrogen, decomposition begins at about 500°, nitrogen is evolved, and a mixture of carbon, iron, and barium cyanide and cyanamide remains behind.

When mixtures of barium oxide, cyanide, and cyanamide are heated in nitrogen, the combined nitrogen passes more and more into the form of cyanide as the mixture is more and more diluted with barium oxide.

T. S. P.

Some Aliphatic Cyanoacetylamines. MARIA CLOTILDE BIANCHI (*Atti R. Accad. Sci. Torino*, 1912–1913, **48**, 654—659).—*Cyanoacetomethylamide*, $CN \cdot CH_2 \cdot CO \cdot NHMe$, is prepared with almost the theoretical yield by passing gaseous methylamine into an alcoholic solution of ethyl cyanoacetate; it crystallises in prisms, m. p. about 104—105°. *Cyanoacetoethylamide*, $CN \cdot CH_2 \cdot CO \cdot NHEt$, is similarly prepared and forms prismatic laminæ, m. p. 74—75°; it is oxidised by potassium permanganate at the ordinary temperature.

Dicyanoacetopropylenediamide, $(CN \cdot CH_2 \cdot CO \cdot NH)_2C_3H_6$, obtained by keeping a mixture of ethyl cyanoacetate and propylenediamine for twenty-four hours, crystallises in colourless needles, m. p. 161—162°.

Dicyanoacetotrimethylenediamide, $CH_2(CH_2 \cdot NH \cdot CO \cdot CH_2 \cdot CN)_2$, prepared by mixing ethyl cyanoacetate and trimethylenediamine, crystallises in slightly yellow needles, m. p. 163—165°.

Cyanoacetamide, after recrystallisation from ether, has m. p. 124—125°, which is higher than the m. p. given in the literature.

R. V. S.

Photochemical Synthesis of a New Compound, Carbonyl Cyanide, by means of Ultra-violet Rays. DANIEL BERTHELOT and HENRY GAUDECHON (*Compt. rend.*, 1913, **156**, 1766—1768).—Carbon monoxide and cyanogen when mixed and subjected to the ultra-violet rays ($\lambda < 0.25\ \mu$) from a mercury-quartz lamp combine to form *carbonyl cyanide*, $CO(CN)_2$, a yellow, amorphous compound, which does not volatilise at 200°, but gives off small quantities of nitrogen. It is soluble in alkalis, giving a yellow solution, and slowly

undergoes hydrolysis on the addition of acid, giving carbon dioxide and hydrogen cyanide. It burns only very slowly in oxygen at a red heat.

[Potassium Manganicyanide.] JULIUS MEYER (*Zeitsch. anorg. Chem.*, 1913, **81**, 385—405).—See this vol., ii, 599.

Some Azides of Carbamic Acid. VI. E. OLIVERI-MANDALÀ and F. NOTO (*Gazzetta*, 1913, **43**, i, 514—520).—The azides described in this paper were prepared by the action of azoimide on carbimides. Methylcarbamazide can be obtained in this way. *Chloromethylcarbamazide* (from chloromethylcarbimide in benzene solution) decomposes rapidly on exposure to the air. Alcoholic ammonia converts it into a substance, $(C_2H_5ON_2Cl)_3$, having the composition of a *trimeride* of the *chloromethylcarbamide* to be expected; it decomposes above 300°, evolving hydrogen chloride.

Bromomethylcarbamazide is similarly obtained from *bromomethylcarbimide*, which can be prepared by Schroeter's method (A., 1909, i, 773); this azide is also very unstable. When it is treated with alcoholic ammonia, a *trimeric bromomethylcarbamide*, $(C_2H_5ON_2Br)_3$, is produced; it decomposes above 300°.

Propylcarbimide, prepared from silver cyanate and propyl iodide, has b. p. 82—85°. The *azide*, $C_4H_8ON_4$, has b. p. 85—86°/28 mm. When heated for two hours with aniline in alcoholic solution, it yields s-*phenylpropylcarbamide*, $C_{10}H_{14}ON_2$, m. p. 114—116°.

iso*Propylcarbamazide*, $C_4H_8ON_4$, crystallises in long needles, m. p. 44°. s-*Phenyl*isopropylcarbamide, $C_{10}H_{14}ON_2$, obtained from this azide, forms needles, m. p. 142—143°.

iso*Butylcarbamazide*, $C_5H_{10}ON_4$, has b. p. 94°/22 mm. s-*Phenyl*-isobutylcarbamide, $C_{11}H_{16}ON_2$, crystallises in small needles, m. p. 158°.

A New Class of Lipoid Arsenic Compounds. EMIL FISCHER and GEORG KLEMPERER (*Therapie der Gegenwart*, Jan., 1913; Reprint 8 pp.).—When behenolic acid is heated with arsenic trichloride and the product of action is afterwards treated with bases, an acid containing arsenic and chlorine in approximately equivalent quantities is formed. It has been obtained so far as a coloured oil, which is not sufficiently pure for analysis. The strontium salt, containing about 13% arsenic and 6% chlorine, has been employed under the name of elarson as a medicament containing arsenic in a relatively non-toxic form, and satisfactory therapeutic results are claimed for it in cases requiring treatment by arsenic.

Preparation of Several Dicyclohexylbutanes. PAUL SABATIER and MARCEL MURAT (*Compt. rend.*, 1913, **156**, 1430—1434. Compare A., 1912, i, 547, 617, 757).—By direct hydrogenation with reduced

nickel the authors have prepared five of the nine possible dicyclo-hexylbutanes, three being derivatives of *n*-butane and two of *iso*-butane; *aδ-dicyclohexylbutane*, $C_6H_{11}\cdot[CH_2]_4\cdot C_6H_{11}$, colourless crystals, m. p. 9°, b. p. 304—306° (corr.), D_0^{21} 0·8772, n_D^{21} 1·475, is obtained by the reduction of aδ-diphenylbutane.

Phenyl ethyl ketone reacts with magnesium benzyl chloride at 450° in the presence of thorium oxide to give phenylbenzylethylcarbinol, which by distillation under reduced pressure yields diphenyl-Δ^a-butylere, b. p. 296° (corr.), D_0^{18} 1·0124, n_D^{15} 1·593 (compare Klages and Heilmann, A., 1904, i, 487). This hydrocarbon on hydrogenation in the presence of slightly active nickel gives *aβ-diphenylbutane*, a colourless liquid, b. p. 285—287° (corr.), D_0^{18} 1·0092, n_D^{19} 1·587, which on further hydrogenation over very active nickel at 170° yields *aβ-dicyclohexylbutane*, a colourless liquid, b. p. 276—278° (corr.), D_0^0 0·9104, D_0^{18} 0·9084, n_D^{15} 1·500.

aa-Diphenyl - Δ^a - *butylene*, b. p. 295—297° (corr.), D_0^{16} 1·0039, n_D^{16} 1·595, obtained by the interaction of magnesium phenyl bromide and ethyl butyrate and subsequent dehydration, on hydrogenation at 150° with slightly active nickel yields *aa-diphenylbutane*, b. p. 286—288° (corr.), D_0^{18} 0·9748, n_D^{16} 1 554. If this hydrogenation is carried out at 250° the product is diphenylmethane, m. p. 27°, b. p. 262°, described by Klages and Heilmann (*loc. cit.*) as aa-diphenylbutane. The aa-diphenylbutane, now described, on hydrogenation at 170° with very active nickel yields *aa-dicyclohexylbutane*, b. p. 280—282° (corr.), D_0^0 0·8922, D_0^{16} 0·8842, n_D^{16} 1·485.

By the interaction of benzophenone and magnesium *iso*propyl iodide or by the action of magnesium phenyl bromide on ethyl *iso*butyrate, and subsequent dehydration of the carbinol formed, *aa-diphenyl-β-methylpropylene*, b. p. 293°, D_0^{16} 1·0240, n_D^{16} 1·596, is obtained, and this on gentle hydrogenation at 180° yields *aa-diphenyl-β-methylpropane*, b. p. 285—286° (corr.), D_0^{16} 0·978, n_D^{16} 1·560. This hydrocarbon by more active hydrogenation at 170° gives *aa-dicyclohexyl-β-methyl-propane*, b. p. 278—279° (corr.), D_0^0 0·9017, D_0^{16} 0·8906, n_D^{15} 1·492.

aγ-Diphenyl-β-methylpropylene, b. p. 304° (corr.), D_0^{16} 1 0181, n_D^{16} 1·593, obtained in the usual way from magnesium methyl iodide and dibenzyl ketone, on hydrogenation at 170° with very active nickel yields *aγ-dicyclohexyl-β-methylpropane*, b. p. 290—292° (corr.), D_0^0 0·8916, D_0^{19} 0·8840, n_D^{19} 1·484. W. G.

Partial Reduction of Aromatic Polynitro-compounds by Electrochemical Methods. III. Kurt Brand and Th. Eisen-menger (*J. pr. Chem.*, 1913, [ii], 87, 487—507. Compare A., 1906, i, 80 ; 1907, i, 755).—The present paper deals with the electrolytic reduction of 2 : 4 : 6-trinitrotoluene, 2 : 4-dinitroanisole, and 4-chloro-*m*-dinitrobenzene in alkaline, acid and almost neutral solution.

On reduction in alkaline solution at a mercury cathode, 4-chloro-*m*-dinitrobenzene yields 4-chloro-*m*-nitroaniline and 6-chloro-*m*-nitro-aniline, together with 2 : 4-dinitrophenol ; under the same conditions, 2 : 4-dinitroanisole is reduced to 5 : 5'-*dinitro-o-azoxyanisole*, which separates from benzene in slender, almost colourless leaflets, m. p. 209°.

The constitution of the azoxy-compound has been established by its

preparation from 5-nitro-2-methoxyphenylhydroxylamine by the action
of sodium hydroxide in alcoholic solution. The reduction of 2 : 4 : 6-
trinitrotoluene in alkaline solution yielded no definite product. In
hydrochloric acid solution and in the presence of cupric chloride,
2 : 4 : 6-trinitrotoluene is reduced at a copper cathode to 2 : 6-dinitro-p-
toluidine and 4 : 6-dinitro-o-toluidine.

The last-named compound forms orange-yellow crystals, which have
m. p. 135° and not 155° as given by Holleman and Böeseken (A., 1898, i,
303). It yields an *acetyl* derivative, crystallises in white needles,
m. p. 224°, and when diazotised and boiled with alcohol is converted
into 2 : 4-dinitrotoluene and 2 : 4-*dinitroindazole*,

$$C_6H_2(NO_2)_2 <^{CH}_{N}>NH,$$
which crystallises in almost white needles, m. p. 203°, and dissolves in
aqueous alkalis, yielding yellow solutions.

On reduction in acid solution under the same conditions as given
above for 2 : 4 : 6-trinitrotoluene, 2 : 4-dinitroanisole yields 4-nitro-
o-anisidine (Meldola, Woolcott, and Wray, T., 1896, **69**, 1321), whilst
4-chloro-m-dinitrobenzene gives rise to 4-chloro-m-nitroaniline and
6-chloro-m-nitroaniline, which are separated by crystallisation of their
acetyl derivatives from alcohol.

In almost neutral solution, 2 : 4 : 6-trinitrotoluene is reduced at a
silver cathode to 2 : 6-dinitro-p-tolylhydroxylamine (Cohen and Dakin,
T., 1902, **81**, 27) and 4 : 6-*dinitro-o-tolylhydroxylamine*, which forms
light yellow crystals, m. p. 109°.

The constitution of 2 : 6-dinitro-p-tolylhydroxylamine has been
confirmed by its reduction with copper powder and hydrochloric acid
to 2 : 6-dinitro-p-toluidine, and conversion of the latter compound by
diazotisation and boiling with alcohol into 2 : 6-dinitrotoluene. When
boiled with strong hydrochloric acid, 2 : 6-dinitro-p-tolylhydroxylamine
yields 3 : 5 : 3′ : 5′-*tetranitro*-p-*azoxytoluene*, colourless needles, m. p.
216°; on treatment with phosphorus pentachloride in ethereal solution
it gives rise to 3 : 5 : 3′ : 5′-*tetranitro*-p-*azotoluene*, which crystallises in
orange needles, m. p. 248—250°.

Reduction of 4-chloro-m-dinitrobenzene in almost neutral solution
yields a small amount of 2 : 2′(or 4 : 4′)-*dichloro*-5 : 5′-*dinitroazobenzene*,
m. p. 164°, together with a brown oil, containing 4- and 6-chloro-m-
nitrophenylhydroxylamines, which, however, could not be isolated from
the product, and were therefore identified by oxidation of the cathode
liquid with ferric chloride to the corresponding nitroso-compounds.

1-*Chloro-4-nitro-2-nitrosobenzene* forms white needles, m. p. 95°, and
has also been prepared by the oxidation of 6-chloro-m-nitroaniline with
Caro's acid.

1-*Chloro-2-nitro-4-nitrosobenzene*, prepared from 4-chloro-m-nitro-
aniline in a similar manner, forms white needles, m. p. 120°.

In neutral solution, 2 : 4-dinitroanisole is reduced at a silver cathode
to the above-mentioned 5 : 5′-dinitro-o-azoxyanisole and 5-*nitro-2-methoxy-
phenylhydroxylamine*, which forms a brownish-red, sandy, crystalline
powder, m. p. 129°, is reduced by copper powder and hydrochloric acid
to 4-nitro-o-anisidine, and on oxidation with ferric chloride yields a

compound, $C_{16}H_{16}O_8N_4$, m. p. 121°, the constitution of which has not yet been determined. F. B.

The Transformation of Aromatic Nitroamines and Allied Substances, and its Relation to Substitution in Benzene Derivatives. FREDERICK S. KIPPING, KENNEDY J. P. ORTON, SIEGFRIED RUHEMANN, and JOHN T. HEWITT (*Rep. Brit. Assoc.*, 1912, 116—123).—See Orton and Jones, T, 1912, **101**, 1708, 1720.

C. H. D.

A Photochemical Reaction. FRÉDÉRIC REVERDIN (*Bull. Soc. chim.*, 1913, [IV], **13**, 485—486 *).—A solution of 3 : 5-dinitro 4-nitromethylaminotoluene in alcohol on exposure to sunlight slowly undergoes partial transformation into 3 : 5-dinitro-4-methylaminotoluene.

T. A. H.

Hexylenic Ethers. R. DIONNEAU (*Bull. Soc. chim.*, 1913, [iv], **13**, 519—525).—A more detailed account, with some new data, of work already recorded (A, 1910, i, 353). Phenoxyhexylene, D_4^0 0·9553, reacts with bromine in chloroform to give a *dibromide*, D_4^0 1·5415, b. p. 208°/35 mm. (decomp.), and with excess of hydriodic acid to form di-iodohexane, D_4^0 2·047, whilst with 1 mol. of the acid it gives iodophenoxyhexane, D_4^0 1·4385, b. p. 205°/33 mm., and a *substance*, D_4^0 1·516, b. p. 84°/33 mm. or 183°/760 mm., which may be iodohexylene. Iodophenoxyhexane through its magnesium derivative yields phenoxyhexane, from which Franchimont and Zincke's hexyl iodide is obtainable by heating with hydriodic acid; thus showing that in phenoxyhexylene the radicle C_6H_{11} is linear and carries the phenoxy-group on the first carbon atom. On oxidation with permanganate or ozone, phenoxyhexylene yields phenoxyvaleric and formic acids. These observations indicate that it has the formula $OPh\cdot[CH_2]_4\cdot CH{:}CH_2$.

Ethoxyhexylene (*loc. cit.*) has been prepared by the action of allyl iodide on the magnesium derivative of iodoethoxypropane.

T. A. H.

Aliphatic Dihalogen Compounds. JULIUS VON BRAUN (*Ber.*, 1913, **46**, 1782—1792).—A series of experiments is described on (1) the synthesis of brominated esters, (2) the preparation of polymethylene dibromides in which one $-CH_2-$ group is replaced by $-N(CN)-$, (3) ring-formations with sodium cyanamide, and (4) certain other ring-formations.

(1) Diprimary chloro-, bromo-, and iodo-compounds react readily with alkali phenoxides and alkoxides with the formation of halogenated ethers (for example, $Br[CH_2]_x\cdot OPh$), the use of which in synthetic operations is greatly limited by the difficulty of removing the phenoxy-radicle without completely decomposing the molecule. The author has, therefore, examined the halogen derivatives of alkyl carboxylates (compare A., 1909, i, 419) in this respect. When dry sodium benzoate (1 mol.) is heated with 1·5 mols. of various dibromides, the nature of the product formed depends greatly on the distance of the bromine atoms

from one another. Ethylene dibromide yields almost exclusively ethylene dibenzoate, bromoethyl benzoate, $CH_2Br\cdot CH_2\cdot O\cdot COPh$, not being detectable ; in the trimethylene series, the yield of brominated ester is 30%, in the tetramethylene series 45%, in the pentamethylene series above 60%, and in the heptamethylene series nearly 75%. These esters are readily saponifiable by acid or alkali, or even by protracted action of water and alcohol.

Trimethylene bromide and sodium benzoate yield trimethylene dibenzoate, m. p. 57°, and γ-bromopropyl benzoate, b. p. 162—164°/14 mm. When warmed with sodium iodide in alcoholic solution, the latter yields γ-iodopropyl benzoate, pale yellow oil, b. p. 175—178°/12 mm. δ-Bromobutyl benzoate, b. p. 176—178°/14 mm., together with tetramethylene dibenzoate, is similarly obtained from tetramethylene bromide. ε-Bromoamyl benzoate, b. p. 188—190°/12 mm., is most readily obtained from α : ε-dibromopentane and sodium benzoate at 200—210°. The corresponding pentamethylene dibenzoate is a liquid. ε-Bromoamyl benzoate is readily saponified by aqueous alcoholic potassium hydroxide with formation of pentamethylene oxide (compare Clarke, T , 1912, 101, 1802). η-Bromoheptyl benzoate is an oil, b. p. 205—210°/11 mm., which does not solidify. With sodium iodide it yields η-iodoheptyl benzoate, pale yellow oil, b. p. 220—224°/11 mm.

(2) The observation that in phenoxypropylbromoamylcyanamide (A., 1909, i, 507) the phenoxy-group is replaced by bromine more readily than the nitrile group is saponified under the action of hydrobromic acid has led the author to examine the possibility of introducing two phenoxy-alkyl residues into sodium cyanamide (compare Traube and Engelhardt, A., 1911, i, 955) with the ultimate object of replacing the phenoxy-groups by bromine,

$$N(CN)[(CH_2)_x OPh]_2 \longrightarrow N(CN)[(CH_2)_x Br]_2,$$

and thus obtaining polymethylene dibromides in which one –CH_2– group is replaced by $CN\cdot N<$.

γ-Phenoxypropyl iodide in alcoholic solution reacts readily with commercial sodium cyanide, yielding allyl phenyl ether and diphenoxypropylcyanamide, b. p. 295—300°/13 mm. The yield of the latter is nearly 60% of that theoretically possible. Fuming hydrobromic acid converts it into dibromopropylcyanamide, $CN\cdot N([CH_2]_3\cdot Br)_2$, a pale brown, heavy oil which is not volatile with steam, and cannot be distilled without decomposition. When dissolved in dry ether, it reacts readily with metallic sodium, yielding a product which is only partly volatile in a vacuum. The volatile portion, b. p. 110—120°/11 mm., was hydrolysed with hydrochloric acid, and identified as hexamethyleneimine ; the non-volatile portion was not identified. Phenoxyethyl bromide scarcely reacts with sodium cyanamide, but the corresponding iodide, m. p. 31—32°, yields phenylvinyl ether and diphenoxyethylcyanamide, white leaflets, m. p. 96°. In this compound the cyano- and phenoxy-groups are more simultaneously affected by hydrobromic acid than is the case with diphenoxypropylcyanamide, so that an approximately pure dibromide could only be obtained in small quantity. From β-iodoethyl ethyl ether, $I\cdot[CH_2]_2\cdot O\cdot C_2H_5$, and sodium cyanamide, the corresponding unsaturated ether is produced, whilst

ε-iodoamyl phenyl ether gives a product which is decomposed during distillation into amylene phenyl ether, CH_2·CH·$[CH_2]$,·O·Ph.

(3) When sodium cyanamide is boiled with an alcoholic solution of a : ε-pentamethylene dibromide, and the product treated with water, an oil is obtained which below 100°/12 mm. yields a small unsaturated fraction, at 110°/12 mm. gives a trace of 1-cyanopiperidino, and leaves a viscous, non-volatile oil. Similar results are obtained with a : ε-di-iodopentane and a : δ-di-iodobutane. From o-xylylene bromide and sodium cyanamide, a viscous product is obtained from which a small amount of a crystalline *product*, m. p. 235—236°, can be separated by methyl alcohol ; the substance appears to be a polymeride of cyanodihydroisoindole.

(4) a : η-Dibromoheptane forms with ethyl sodioacetoacetate an *oil*, which is decomposed on distillation, and on saponification yields β : μ-*diketotridecane*, $COMe$·$[CH_2]_9$·$COMe$, m. p. 72° (*semicarbazone*, m. p. 184°), together with nonanedicarboxylic acid and small quantities of the *keto-acid*, $COMe$·$[CH_2]_9$·CO_2H, m. p. 59—62°. The latter was not obtained in the pure state.

An attempt was made to synthesise suberone from a : δ-dibromo-butane and ethyl acetonedicarboxylate. The desired substance was only obtained in very small quantity.

Attempts were further made to form cyclic compounds containing mercury, by the action of sodium amalgam on a : δ-di-iodobutane and a : ε-di-iodopentane respectively. The substances obtained were only partly volatile in a vacuum, and probably consisted of polymerides of the substances required. H. W.

Amino-alcohols. Derivatives of Phenyl Glyceryl Ethers. P. BRENANS (*Bull. Soc. chim.*, 1913, [iv], 13, 525—535).—In continuation of the work of Fourneau (A., 1910, i, 246, 822), a number of new amino-alcohols of these types have been prepared with a view to the investigation of their therapeutic properties.

o-*Nitrophenoxypropanediol*, NO_2·C_6H_4·O·CH_2·$CH(OH)$·CH_2·OH, m. p. 45°, results from the action of monochlorohydrin on o-nitrophenol in presence of potassium hydroxide ; it crystallises in yellow spangles, and on reduction with tin and hydrochloric acid yields o-*aminophenoxypropanediol hydrochloride*, m. p. 170°, crystallising in silky needles ; the free *base* is very soluble in water. o-*Nitrophenyl glycide ether*,

$$NO_2\cdot C_6H_4\cdot O\cdot CH_2\cdot CH{<}^{CH_2}_{O},$$ m. p. 51—52°, formed by the action of

dichlorohydrin on o-nitrophenol in presence of alkali, crystallises in pale yellow needles. In this reaction some dinitrodiphenoxypropanol, m. p. 122° (compare Fourneau, *loc. cit.*), is formed.

p-*Nitrophenoxypropanediol*, m. p. 58°, prepared by the general method (above and *loc. cit.*), crystallises in slender, colourless needles, and on reduction furnishes the corresponding *amino*-compound, m. p. 133°, crystallising in ragged tablets and becoming brown in the light; the *hydrochloride*, m. p. 166°, forms colourless scales.

Tetranitrodiphenoxypropanol, OH·$CH[$·CH_2·O·$C_6H_3(NO_2)_2]_2$, m. p.

79°, obtained by the action of epichlorohydrin on the potassium derivative of 2:4-dinitrophenol, in presence of excess of alkali, or, better, on the silver derivative of the phenol, forms large, yellow-tinted crystals. On reduction with tin and hydrochloric acid, it yields the corresponding *tetra-amino*-compound *hydrochloride*, crystallising from methyl alcohol in small, yellow prisms and decomposing below 200° when heated.

o-*Nitro*-p-*tolyl glycide ether*, $NO_2 \cdot C_7H_6O \cdot CH_2 \cdot CH \underset{O}{\overset{CH_2}{<}}$, m. p.

66—67°, prepared by the action of dichlorohydrin on 2-nitro-p-cresol in presence of alkali, crystallises in bright yellow prisms. When heated with dimethylamine at 100° during ten hours, it yields *γ-dimethylamino-a-2-nitro-*p-*tolyloxypropanol*,

$$NO_2 \cdot C_7H_6O \cdot CH_2 \cdot CH(OH) \cdot CH_2 \cdot NMe_2,$$

as a thick, yellow oil, giving a crystalline *benzoyl* derivative, m. p. 179°.

o-*Iodophenoxypropanediol*, m. p. 95°, prepared from o-iodophenol by the general method, crystallises in silky, colourless needles. o-*Iodophenyl glycide ether*, b. p. 200—202°/20 mm., is a colourless liquid, which, with dimethylamine, yields *γ-dimethylamino-a-o-iodophenoxypropanol*, b. p. 210°/20 mm. (decomp.), as a colourless syrup from which the *benzoylated hydrochloride*, m. p. 169—170°, may be obtained as slender, prismatic needles.

5-*Iodoguaiacyloxypropanediol*, $OMe \cdot C_6H_3I \cdot O \cdot CH_2 \cdot CH(OH) \cdot CH_2 \cdot OH$, m. p. 109°, crystallises in slender, colourless, odourless needles.

γ-Dimethylamino-a o-tolyloxypropanol, b. p. 175—178°/28 mm., gives a benzoyl derivative, the *hydrochloride* of which has m. p. 138° and crystallises in colourless, silky needles.

p-*Nitrobenzoyl-γ-dimethylamino-a-thymoxypropanol hydrochloride*, m. p. 161°, crystallises in large, yellow, octahedra from a mixture of alcohol and ether; the meta *isomeride*, m. p. 187°, forms small, hard prisms from alcohol.

m-*Tolyl glycide ether*, b. p. 136·5°/14 mm., on treatment with dimethylamine gives *γ-dimethylamino-a-*m-*tolyloxypropanol*, b. p. 178—180°/14 mm., as a colourless syrup; the *benzoylated hydrochloride*, m. p. 138—139°, crystallises in rectangular tablets from acetone.

T. A. H.

Preparation of Derivatives of Aldehydo- and Keto-cyano-hydrins containing Sulphur. August Albert (D.R.-P. 259502). —The crystalline *compound* (annexed formula), decomp. 145°, is obtained when a benzene solution of methylenedioxyacetylmandelo-nitrile, $CH_2 \overset{O}{\underset{O}{<}} C_6H_3 \cdot CH(CN) \cdot OAc$, is treated with alcoholic ammonia and the solution saturated at 0° with hydrogen sulphide; after some time the product separates in crystalline form.
The *compound* from benzoyl-o-nitromandelonitrile crystallises with 1 mol. of ethyl alcohol and decomposes at 160°. F. M. G. M.

Chloroquinolsulphonic Acids and Their Conversion into Chloro-*p*-benzoquinonesulphonic Acids. ALPHONSE SEYEWETZ and J. PARIS (*Bull. Soc. chim.*, 1913, [iv], **13**, 486—491. Compare A., 1911, i, 360; this vol., i, 492).—Part of this work has been described already (*loc. cit.*). Chloroquinol on sulphonation by the method already described (*loc. cit.*) yields *sodium chloroquinolsulphonate*,

$$C_6H_2Cl(OH)_2 \cdot SO_3Na,$$
colourless leaflets, soluble in water, but not in alcohol, which acts as a photographic developer in presence of alkalis, and on oxidation by sodium dichromate and sulphuric acid yields *sodium chloro-*p-benzo-*quinonesulphonate*, bright yellow needles, soluble in water but not in alcohol, which has oxidising properties, and in aqueous solution liberates iodine from iodides in presence of acids. T. A. H.

Unsaturated Compounds. Method of Reaction of Enols and Phenols. KURT H. MEYER and S. LENHARDT (*Annalen*, 1913, **398**, 66—82).—It has been shown (this vol., i, 704) that the enolic grouping represents one of the most reactive states in organic chemistry. The additive capacity of the double linking is enormously increased by the presence of the hydroxyl group, as is proved by comparative experiments on the rate of addition, of alcoholic bromine and of *p*-nitro-benzenediazonium hydroxide, to pairs of substances differing only by the one containing a hydroxyl group where the other contains a hydrogen atom, as, for example, styryl methyl ketone and benzoyl-acetone. The reactivity of the enolic grouping is not connected, as Hinsberg supposes, with the dissociability of the hydrogen atom, because alkyl ethers of enols, which do not contain the mobile hydrogen atom, are also extremely reactive.

Recent researches on the action of ozone, potassium permanganate, and hydrogen on benzene have shown that the latter behaves like a substance containing very slowly reacting ethylenic linkings. The comparatively great reactivity of phenol, therefore, is explicable as being due to the activating influence of the hydroxyl group on the double linking. This view is supported by the fact that phenolic ethers are almost as reactive as phenol itself. Phenol, anisole, resorcinol, resorcinol dimethyl ether, α-naphthol, α-naphthyl methyl ether, β-naphthol, β-naphthyl methyl ether, and anthranol each reacts instantly with alcoholic bromine at 0°. The preceding ethers with the exception of anisole react as readily as phenol with diazo-hydroxides; *benzeneazophloroglucinol trimethyl ether*, m. p. 82·5°, garnet-red crystals, easily soluble in dilute mineral acids, p-*nitrobenzeneazophloroglucinol trimethyl ether*, m. p. 150·5°, brown needles with violet lustre, p-*nitrobenzeneazoresorcinyl dimethyl ether*, m. p. 152°, red needles, and p-*nitrobenzeneazo-α-naphthyl methyl ether*, m. p. 169°, red needles, are described. α-Naphthyl methyl ether in glacial acetic acid reacts readily with nitrous acid, yielding nitroso-α-naphthol, methyl alcohol being eliminated.

It is probable that all substances containing the groups ·CH:C·OR or ·CH:C·NR contain an activated ethylenic linking. Examples of the latter kind are found in the reactivity of pyrroles with aldehydes, halogens, and diazo-compounds; 1 : 2-dimethylindole condenses with

p-nitrobenzenediazonium hydroxide in glacial acetic acid to form a *substance*, $C_{10}H_{14}O_2N_4$, m. p. 204—205°, dark red crystals.   C. S.

Aromatic Telluretine Compounds. II. KARL LEDERER (*Ber.*, 1913, **46**, 1810—1812. Compare this vol., i, 615).—The methyl, ethyl, and propyl esters of α-bromopropionic acid have been heated to 50° with diphenyl telluride and the telluretine compounds isolated with difficulty and in poor yields. *Methyl diphenyl-α-propionyltelluretine bromide* [α-*bromodiphenyltelluripropionate*], $TePh_2Br \cdot CHMe \cdot CO_2Me$, and the *ethyl* and *propyl* esters, and also *methyl diphenyl-α-isobutyryltelluretine bromide* [α-*bromodiphenyltelluriisobutyrate*],

$$TePh_2Br \cdot CMe_2 \cdot CO_2Me,$$
are white, amorphous substances with indefinite melting points.

J. C. W.

1-Benzoyl-2-phenyl-Δ²-*cyclo*pentene. ÉDOUARD BAUER (*Compt. rend.*, 1913, **156**, 1470—1472).—The conversion of αδ dibenzoylbutane into the two cyclic compounds 1-benzoyl-2-phenyl-Δ¹-and-Δ²-*cyclo*pentenes by the action of sodium ethoxide (compare A., 1912, i, 777) is equally well brought about by sodamide. 1-Benzoyl-2-phenyl-Δ²-*cyclo*pentene, thus constituted, should behave as a dialkylacetophenone (compare Haller and Bauer, A., 1909, i, 108), and the author has now proved this to be the case. It reacts with sodamide in anhydrous benzene, giving a sodium derivative which, on the addition of methyl iodide, is converted into the the corresponding 1-*benzoyl-2-phenyl-1-methyl-Δ²-cyclopentene* (formula II), b. p. 223—224°/23 mm., a viscid oil instantly decolorising potassium permanganate solution in the cold. This

(I.)   (II.)   (III.)   (IV.)
methyl derivative reacts further with sodamide (compare Haller and Bauer, *loc. cit.*) and is decomposed, giving a mixture of 2-*phenyl-1-methyl-Δ²-cyclopentene* (formula III), b. p. 116—117°/20 mm., and benzamide on the one hand, and benzene and 2-*phenyl-1-methyl-Δ²-cyclopentene-1-carboxylamide* (formula IV), m. p. 165°, on the other.

W. G.

1-Benzoyl-2-phenyl-Δ¹-*cyclo*pentene. ÉDOUARD BAUER (*Compt. rend.*, 1913, **156**, 1684—1686. Compare A., 1912, i, 777; preceding abstract).—Sodamide acts on 1-benzoyl-2-phenyl-Δ¹-*cyclo*pentene in the same manner as on benzophenone (compare A., 1908, i, 987), giving 2-phenyl-Δ¹-*cyclo*pentene-1-carboxylamide and benzene and 1-phenyl-Δ¹-*cyclo*pentene and benzamide.

On boiling 1-benzoyl-2-phenyl-Δ¹-*cyclo*pentene with sodamide in benzene a brick-red precipitate is obtained, which is decolorised on treatment with water. This product is separable by crystallisation from ether into benzamide and 2-*phenyl-Δ¹-cyclopentene-1-carboxylamide*, needles, m. p. 135—136°, which rapidly reduces alkaline permanganate

and decolorises bromine in chloroform. On hydrolysis with alcoholic potassium hydroxide it yields a mixture of two isomeric acids,

$$C_{12}H_{12}O_2,$$

separable by crystallisation from ether into 2-*phenyl*-Δ^1-*cyclopentene-carboxylic acid*, m. p. 157°, and an *acid*, m. p. 124—125°, differing from the other only in the position of the ethenoid linking in the nucleus, and which gives the corresponding *amide*, m. p. 178—179°.

From the original benzene solution, after distilling off the solvent, there is obtained 1-*phenyl*-Δ^1-*cyclopentene*, m. p. 23°, b. p. 120—121°/ 20 mm., D_1^{21} 0 98617, n_α^{21} 1·56723, n_D^{25} 1·5734, n_β^{21} 1·59017, which yields a *picrate*, m. p. 64·5°. On reduction by sodium in absolute alcohol it gives phenyl*cyclo*pentane. W. G.

Preparation of Nitriles from Thiocarbamides [and from Thiocarbimides]. FARBENFABRIKEN VORM. FRIEDR. BAYER & Co. (D.R.-P. 259363, 259364).—It has been shown by Weith (A., 1875, 901, 908, 1241) that nitriles (in very small yield) can be obtained by the action of copper powder on thiocarbamides, and this reaction has now been carried out with cheaper material, such as iron, in the presence of machine or paraffin oils or anthracene.

o-Toluonitrile is obtained in 64% yield when a mixture of iron (20 parts) and paraffin (100 parts) is slowly treated at 280° with 10 parts of *o*-ditolylthiocarbamide. The preparation of the following compounds is also described : *m*-toluonitrile in 62% yield, *p*-toluonitrile in 75% yield, β-naphthonitrile in 75% yield, *m*-xylonitrile in 65% yield, *p*-methoxybenzonitrile in 67% yield, *p*-chlorobenzonitrile in 51% yield from *p*-dichlorophenylthiocarbamide, *p*-cyanoquinoline in 21% yield from *p*-diquinolylthiocarbamide, octonitrile in 61% yield from diheptylthiocarbamide, and phenylacetonitrile in 20% yield from dibenzylthiocarbamide.

The second patent describes the preparation of many of the preceding compounds by substituting the corresponding thiocarbimides for the thiocarbamides, the average yield of product being about the same. F. M. G. M.

Polymerisation. ABRAHAM KRONSTEIN (*Ber.*, 1913, **46**, 1812—1814).—A claim for priority in the study of polymerisation from the chemical, physical, technical, and also physiological points of view (compare Liebermann and Kardos, this vol., i, 476). J. C. W.

Preparation of Diphenyleneacetic Acid (9-Fluorenecarboxylic Acid) from Benzilic Acid and Aluminium Chloride. DANIEL VORLÄNDER and ALFRED PRITZSCHE (*Ber.*, 1913, **46**, 1793—1796).—The fact that Vorländer and Huth assumed the formation of the unknown nitrile of benzilic acid as an intermediate stage in the condensation of benzoyl cyanide to 9-cyanofluorene (A., 1911, i, 867) has led to the study of benzilic acid itself, with the result that a good method for the preparation of 9-fluorenecarboxylic acid has been discovered. Triphenylacetic acid could not be detected in the product, and therefore diphenylchloroacetic acid cannot represent an intermediate stage. Carbon disulphide, or preferably benzene, may be used as a solvent, but they do not enter into the reaction. The fluorene-

carboxylic acid was characterised by conversion into the unstable chloride with thionyl chloride, then into the *amide*,

$$\begin{matrix} C_6H_4 \\ C_6H_4 \end{matrix}\!\!>\!\!CH\cdot CO\cdot NH_2,$$
microscopic needles, m. p. 250°, and finally into the nitrile (Wislicenus and Russ, A., 1910, i, 840).

Phenylglyoxylic acid also condenses with benzene in presence of aluminium chloride, forming benzilic acid, and subsequently the above 9-fluorenecarboxylic acid. Ethyl phenylglyoxylate gives the same result, whereas the action of magnesium phenyl bromide leads to the formation of ethyl benzilate and, with an excess, benzopinacone. In toluene solution, phenylglyoxylic acid condenses to p-*methylfluorenecarboxylic acid*, $C_{15}H_{12}O_2$, which has m. p. 210°, and yields p-*methylfluorene* in leaflets, m. p. 88°, on distillation with soda-lime.

The alkaline solution of the condensation product of diphenylene-glycollic acid and benzene has a violet fluorescence and contains a little 9-*phenylfluorenecarboxylic acid*, $C_{20}H_{14}O_2$, which crystallises in white needles, m. p. 183°, and is easily transformed into 9-phenylfluorene (Kliegl, A., 1905, i, 187). J. C. W.

Pimaric Acid. LEO A. TSCHUGAEV and P. TEEARU (*Ber.*, 1913, 46, 1769—1774. Compare Vesterberg, A., 1886, 365, 1038; 1888, 249; 1906, i, 92; 1907, i, 213).—The authors confirm Vesterberg's conclusion that galipot must contain at least three acids. *d*-Pimaric acid has m. p. 211—212°, $[\alpha]_C + 55\cdot40°$, $[\alpha]_D + 72\cdot52°$, $[\alpha]_E + 97\cdot20°$, $[\alpha]_F^- + 123\cdot0°$, $[\alpha]_F/[\alpha]_C$ 2·20°. 2·129 Grams of acid are soluble in 100 grams of absolute methyl alcohol at 25°. The acid is monobasic. The sodium salt has $[\alpha]_C + 30\cdot12°$, $[\alpha]_D + 38\cdot86°$, $[\alpha]_E + 52\cdot42°$, $[\alpha]_F + 67\cdot37°$, $[\alpha]_F/[\alpha]_C$ 2·23° in methyl-alcoholic solution ($c = 2\cdot174$). Methyl pimarate, m. p. 69°, obtained by the action of methyl sulphate on an aqueous alcoholic solution of sodium pimarate in the presence of an excess of sodium hydroxide or carbonate, has $[\alpha]_C + 46\cdot30°$, $[\alpha]_D + 60\cdot45°$, $[\alpha]_E + 81\cdot36°$, $[\alpha]_F + 102\cdot7°$, $[\alpha]_F/[\alpha]_C$ 2·22.

In the presence of spongy platinum, hydrogen converts *d*-pimaric acid into *dihydropimaric acid*, m. p. 240—241°; 100 grams of absolute methyl alcohol dissolve 0·478 gram acid. In ethyl alcoholic solution ($c = 0\cdot566$) at 20° the latter has $[\alpha]_C + 14\cdot57°$, $[\alpha]_D + 19\cdot43°$, $[\alpha]_E + 26\cdot05°$, $[\alpha]_F + 37\cdot53°$, $[\alpha]_F/[\alpha]_C$ 2·57. It is monobasic, and forms salts closely resembling those of pimaric acid. The *sodium* salt has in methyl alcoholic solution ($c = 3\cdot568$) at 20°, $[\alpha]_C + 4\cdot41°$, $[\alpha]_D + 5\cdot46°$, $[\alpha]_E + 7\cdot84°$, $[\alpha]_F + 11\cdot14°$, $[\alpha]_F/[\alpha]_C$ 2·56. The *ammonium* salt crystallises in long, thin needles.

The authors consider that pimaric acid is probably a tetracyclic compound with one double bond. H. W.

Preparation of Phenolcarboxylic Acids. JOSEPH ZELTNER and MAX LANDAU (D.R.-P. 258887. Compare A., 1876, ii, 632; 1877, i, 77; ii, 415).—The action of chloroform or carbon tetrachloride on phenols has been studied (*loc. cit.*), and the reaction is now found to proceed smoothly under atmospheric pressure in the presence of copper powder, or a salt of copper.

When phenol (9·4 parts), a 40% solution containing potassium hydroxide (39·2 parts), carbon tetrachloride (16 parts), and 0·3 part of copper, are boiled together during eight hours under reflux, it gives rise to a mixture of salicylic acid (25%) and *p*-hydroxybenzoic acid (30%).

The preparation of the following compounds is also described: 4-hydroxy-*m*-toluic acid, m. p. 146—147°, in 60% yield from *p*-cresol; an 80—80% yield of a mixture of 6- and 4-hydroxy-*m*-toluic acids from *o*-cresol. A 45% yield of 3-nitrosalicylic acid (compare Hasse, *loc. cit.*) from *o*-nitrophenol; and of 5-chlorosalicylic acid (in 75% yield) from *p*-chlorophenol. Guaiacol furnished vanillic acid, m. p. 207°, and quinol gave rise to gentisic acid. Salicylic acid gave a 70—75° yield of a mixture of phenol-2 : 4· and 2 : 6-dicarboxylic acids separable by means of their barium salts, whilst *m*-cresotic acid furnished *a*-coccinic acid (A., 1897, i, 539), and *o*-cresotic acid yielded 1-hydroxy-2-methyl-benzene-4 : 6-dicarboxylic acid (*a*-hydroxyuvitic acid), m. p. 294—295°.

F. M. G. M.

Preparation of Acetylcarbinyl *o*-Thymotate. ADOLF DIEFEN-BACH and RICHARD ZAHN (D.R.-P. 258936).—The methyl and ethyl esters of *o*-thymotic acid are known (A., 1910, i, 38), and *acetylcarbinyl o-thymotate*, m. p. 75° (annexed formula), has now been prepared by the action of monochloroacetone on sodium *o*-thymotate.

$$CH_3$$
$$CO_2 \cdot CH_2Ac$$
$$OH$$
$$C_3H_7$$

F. M. G. M.

a-Hydroxy-γ-phenylcrotonic Acid; its Preparation; New Isomerisation. J. BOUGAULT (*Compt. rend.*, 1913, 156, 1468—1470. Compare A., 1912, i, 770; this vol., i, 269).—*a*-Hydroxy-γ-phenylcrotonic acid is most readily prepared from its amide by choice of suitable hydrolysing agents, which will not bring about its isomerisation into benzylpyruvic or benzoylpropionic acids. Aqueous solutions of alkali carbonates or hydrogen carbonates boiled for thirty to forty minutes with the amide convert 30—40% into the acid required, with only a small admixture of its isomerides. As acid hydrolysing agents, the best are aqueous solutions of oxalic or phosphoric acids, oxalic acid (7½%) giving a yield of 80% of the acid required.

The author has isolated a new isomeride, m. p. 91°, which appears to be the *enolic* form of benzoylpropionic acid, and to have the constitution $C_6H_5 \cdot C(OH){:}CH \cdot CH_2 \cdot CO_2H$. It is readily converted by alkalis and strong acids into the ketonic form.   W. G.

Preparation of Halogen Alkyl Esters of *o*-Acetoxybenzoic Acid. RICHARD WOLFFENSTEIN (D.R. P. 258888. Compare A., 1912, i, 556, 768).—The crystalline *ester*, $OAc \cdot C_6H_4 \cdot CO \cdot O \cdot CHMe \cdot CCl_3$, m. p. 52°, is obtained when *o*-acetoxybenzoyl chloride is heated with trichloro*iso*propyl alcohol in the presence of dimethylaniline, whilst the tribromo-*tert.*-butyl *o*-acetoxybenzoate, m. p. 90°, is prepared by the action of *o*-acetoxybenzoyl chloride on acetonebromoform [tribromo-*tert.*-butyl alcohol], $OH \cdot CMe_2 \cdot CBr_3$, and the *compound* formed when the latter constituent is replaced by dichloro*iso*butyl alcohol is also mentioned.   F. M. G. M.

Benzoylcyanohydrins of Ketones, and Amides, and Hydroxy-acids Derived from Them. JULES ALOY and CHARLES RABAUT (*Compt. rend.*, 1913, **156**, 1547—1549. Compare A., 1912, i, 462).— Benzoylcyanohydrins can be readily obtained from ketones by the gradual addition of benzoyl chloride (1/10th mol.) to a solution of potassium cyanide (1/10th mol.) in 100 c.c. of water containing the ketone (1/10th mol.). The mixture is shaken for three hours and then extracted with ether, from which the cyanohydrin crystallises. They are, in general, quite crystalline and stable, and are hydrolysed by sulphuric acid, giving the corresponding benzoylamide, which is further hydrolysed by sodium hydroxide to benzoic acid and the hydroxy-acid.

Thus acetone gives *propylidenebenzoylcyanohydrin*, OBz·CMe₂·CN, m. p. 36—37°, yielding the *amide*, OBz·CMe₂·CO·NH₂, m. p. 142—143°, which is hydrolysed to α-*hydroxy-α-methylpropionic acid*, m. p. 79°.

Methyl propyl ketone yields β-*amylidenebenzoylcyanohydrin*, a syrupy liquid, hydrolysing to the *benzoylamide*, m. p. 126°, which on further hydrolysis yields α-*hydroxy-α-methylvaleric acid*, OH·CPrMe·CO₂H, m. p. 46—47°.

Diethyl ketone gives a small yield of γ-*amylidenebenzoylcyanohydrin*, a liquid, which furnishes an *amide*, OBz·CEt₂·CO·NH₂, m. p. 149—150°.

*cyclo*Hexanone gives *cyclohexylidenebenzoylcyanohydrin*,

$$OBz·C_6H_{10}·CN,$$
m. p. 71°, yielding an *amide*, m. p. 118°, which is hydrolysed to *cyclo*hexanol-1-carboxylic acid.

3-Methyl*cyclo*hexanone gives a *benzoylcyanohydrin*, m. p. 125—126°, yielding the *amide*, m. p. 135—136°, which on hydrolysis gives 3-methyl*cyclo*hexanol-1-carboxylic acid.

4-Methyl*cyclo*hexanone is converted into the *benzoylcyanohydrin*, m. p. 86°, this giving an *amide*, m. p. 122°, which finally yields 4-*methyl*cyclohexanol-1-*carboxylic acid*, m. p. 80—81°.   W. G.

The Action of Nitric Acid on the Dihydroxybenzoic Acids. FRANZ VON HEMMELMAYR (*Monatsh.*, 1913, **34**, 811—820).—Of the dihydroxybenzoic acids it is not the compound in which the carboxyl group is most firmly attached which can be nitrated most satisfactorily, but the important condition apparently is resistance to oxidation by the nitric acid ; for example, β-resorcylic acid can be nitrated successfully, whilst gentisic acid, the nitro-derivative of which is much more stable, is for the greater part oxidised to oxalic acid. The author has therefore compared the behaviour of these acids towards nitric acid (D 1·4), and finds that the acids derived from catechol and quinol are oxidised almost entirely to oxalic acid. It is an interesting fact that those acids in which the meta-positions are unoccupied and in which at least one of these vacant positions is in a para-position to a hydroxy-group, more readily undergo nitration (compare von Hemmelmayr, this vol., i, 468).

3 : 4-Dihydroxybenzoic (protocatechuic) acid with the nitric acid alone or in acetic acid solution gave much oxalic acid, together with orange-red needles of a *substance*, $C_6O_{10}N_4$, possibly tetranitro-o-benzoquinone.

2 : 3-Dihydroxybenzoic acid gave a vigorous reaction with production of oxalic acid.

3 : 5-Dihydroxybenzoic (α-resorcylic) acid reacted vigorously, giving mainly oxalic acid together with a small quantity of an impure yellow, crystalline *substance*. By allowing the nitration to proceed in ethereal solution, the oxidising effect of nitric acid is diminished, and a *nitro-3 : 5-dihydroxybenzoic* acid, deep red needles, m. p. 210° (decomp.), could be isolated in small quantity.

2 : 6-Dihydroxybenzoic (γ-resorcylic) acid gave a vigorous reaction from the product of which a *trinitrohydroxybenzoic acid*, brownish-red, microscopic needles, decomp. at 240°, could be isolated.

2 : 5-Dihydroxybenzoic (gentisic) acid, when nitrated in cold ethereal solution, gave an approximately 30% yield of nitrogentisic acid (compare Klemenc, this vol., i, 49), which crystallises with $2H_2O$.

<div align="right">D. F. T.</div>

Preparation of Anthraquinone-α-carboxylic Acids. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 259365. Compare A., 1911, i, 279 ; 1912, i, 979 ; this vol., i, 49).—1-*Chloroanthraquinone-4-carboxylic acid*, m. p. 229—230°, is prepared by heating together phthalic anhydride and p-chlorotoluene in nitrobenzene solution, and introducing chlorine at a temperature of 160—170°.

When phthalic anhydride and m-xylene are condensed in the presence of chlorine, they furnish 3-methylanthraquinone-1-carboxylic acid, m. p. 246—247°, and apparently identical with that previously prepared by Wachendorff and Zincke (A., 1878, 232), whilst oxidation of the sodium salt with potassium permanganate furnishes *anthraquinone-1 : 3-dicarboxylic acid*, m. p. above 300°. F. M. G. M.

Preparation of Phenylmethylphthalide. ALFONS OSTERSETZER (*Monatsh.*, 1913, 34, 795—796).—From analogy to the behaviour of the o-aldehydic acids which yield alkyl substituted phthalides (Mermod and Simonis, 1908, i, 342 ; Simonis, Marben and Mermod, 1906, i, 32), it might be expected that o-ketonic acids when treated with a Grignard reagent should yield dialkyl substituted phthalides.

The reaction product of o-benzoylbenzoic acid and magnesium phenyl bromide is an oil, but magnesium methyl iodide gave phenylmethyl-phthalide, $C_6H_4{<}^{CMePh}_{CO}{>}O$, leaflets, m. p. 76°; the intermediate hydroxy-acid could not be isolated.

<div align="right">D. F. T.</div>

The Action of Phthalylacyl Chlorides on Benzene and Aluminium Chloride. ERNST PFAEHLER (*Ber.*, 1913, 46, 1700—1702).—Although phthalylphenylglycyl chloride (Pfaehler, this vol., i, 751) behaves similarly to phthalylglycyl chloride and the aliphatic homologues of this substance towards benzene and aluminium chloride, some of its higher homologues, such as phthaliminophenyl-propionyl chloride, act in a different manner.

Phthaliminophenylpropionyl chloride,

$$C_6H_4{<}^{CO}_{CO}{>}N{\cdot}CH(CH_2Ph){\cdot}COCl,$$
m. p. 131—132°, was obtained from the corresponding *acid*, m. p. 176—177°, which is produced when phthalaminobenzylmalonic acid, m.p. 160—170° (compare Sörensen, A., 1903, i, 834), is heated. When warmed with an equimolecular quantity of aluminium chloride in benzene solution, 2-phthalimino-1-hydrindone,

$$C_6H_4{<}^{CO}_{CO}{>}N{\cdot}CH{<}^{CH_2}_{CO}{>}C_6H_4,$$
m. p. 191°, is obtained by intramolecular elimination of hydrogen chloride; it was not found possible to produce this substance by direct dehydration of the free acid. By heating the phthaliminohydrindone in acetic acid solution with fuming nitric acid at first in the open and afterwards in a sealed tube at 135°, the phthalyl nucleus is oxidised with the production of 2-amino 1-hydrindone hydrochloride,

$$C_6H_4{<}^{CH_2}_{CO}{>}CH{\cdot}NH_2,HCl$$
(compare Gabriel and Stelzner, A., 1897, i, 61).   D. F. T.

Hydrogenation of Santonic Acid. GUIDO CUSMANO (*Atti R. Accad. Lincei*, 1913, [v], 22, i, 507—510).—When sodium santonate is treated with hydrogen in presence of platinum-black until no more gas is absorbed, a *tetrahydrosantonic acid*, $C_{15}H_{24}O_4$, is formed; it crystallises in prisms or in leaflets, m. p. 190° (decomp.). The same tetrahydro-derivative was obtained in an experiment in which only one-fourth of the requisite amount of hydrogen was employed, and a corresponding quantity of santonate remained unaltered. In this experiment was also isolated a small quantity of a *substance*, which formed acicular prisms, m. p. about 99°, and gave a green fluorescence with alcoholic potassium hydroxide. This compound of m. p. 99° gives an *oxime*, which crystallises in lustrous needles, m. p. about 235°. Tetrahydrosantonic acid dissolves in carbonates in the cold, gives no coloration with alcoholic potassium hydroxide, and has no bitter taste. When treated with acids it loses water. It dissolves readily in concentrated hydrochloric acid; the solution becomes greenish-brown, and if left exposed to the air deposits a *substance*, which after recrystallisation forms large, colourless, prismatic crystals, m. p. 88°. This compound does not dissolve in carbonates in the cold, but when its alkaline solution (obtained in the warm) is acidified, an *acid* separates in laminar crystals, which at first have m. p. about 130°, but after exposure to the air acquire the m. p. of tetrahydrosantonic acid. The substance of m. p. 88° crystallises from light petroleum in laminæ or in prisms of m. p. 102°, and these are converted into tetrahydrosantonic acid by boiling with potassium hydroxide. Conversely, if tetrahydrosantonic acid is boiled with *N*-sulphuric acid the substance of m. p. 102° is obtained. Tetrahydrosantonic acid yields an *oxime*, which crystallises in colourless prisms, m. p. 222° (decomp.), and on boiling with dilute sulphuric acid yields the above-mentioned compound of m. p. 102°. When an acetic acid solution of the oxime is treated with nitrous acid, a crystalline *compound* of m. p. 130° is formed; it yields a blue coloration with a sulphuric acid solution of diphenylamine. On treatment with concentrated sulphuric acid the oxime is converted into a *substance* which crystallises in rectangular tablets,

m. p. 235° (not sharply); this compound does not dissolve in carbonates in the cold, and it reduces Fehling solution after hydrolysis with acid. The two oximes which have been mentioned can be obtained directly from the raw product of the hydrogenation, but together with them there is then observed a third *oxime*, which forms small, colourless needles, m. p. 240° (decomp.). From alkali solutions of this substance sulphuric acid precipitates a *compound*, crystallising in regular, hexagonal laminæ, m. p. 160—162°. R. V. S.

Hydrogenation of Santonin. YASUHIKO ASAHINA (*Ber.*, 1913, **46**, 1775—1777).—*Tetrahydrosantonin*, $C_{15}H_{22}O_3$, is formed by the action of hydrogen on a solution of santonin in glacial acetic acid in the presence of platinum-black. It consists of thin, white leaflets, m. p. 155—156°, $[a]_D^{23}$ +60·56°, in chloroform solution. It yields a clear solution after protracted boiling with saturated aqueous barium hydroxide, from which the original substance is reprecipitated on acidification, and thus contains the lactonic group intact. In glacial acetic acid solution, it is stable towards permanganate. It yields an *oxime*, $C_{15}H_{23}NO_3$, m. p. 225°, $[a]_D^{20}$ −17·78°, in chloroform solution.

The author is led to the conclusion that the annexed formula for santonin most readily harmonises with the above data. H. W.

Methylcarbonato-derivatives of Phenolcarboxylic Acids and their Use for Synthetic Operations. IX. Derivatives of Pyrogallolcarboxylic Acid. EMIL FISCHER and MAX RAPAPORT (*Sitzungsber. K. Akad. Wiss. Berlin*, 1913, 493—506).—When an excess of methyl chloro-formate is allowed to act on pyrogallolcarboxylic acid the trimethylcarbonato-compound is obtained. Phosphorus pentachloride converts it into the corresponding chloride, which crystallises from ether and has been used for the following synthetic operations.

Benzene and aluminium chloride convert it into a product yielding 2 : 3 : 4-trihydroxybenzophenone on hydrolysis, which is identical with the dye alizarin-yellow-A; the structure of this is thus established.

By interaction of the chloride in alkaline solution with *p*-hydroxybenzoic acid and subsequent elimination of the methylcarbonato-groups the didepside, *pyrogallolcarboyl-p-hydroxybenzoic acid*,

$$C_6H_2(OH)_3 \cdot CO \cdot O \cdot C_6H_4 \cdot CO_2H,$$
isomeric with galloyl-*p*-hydroxybenzoic acid is obtained.

The new term, carboyl, denoting the carboxylic acid radicle is derived in a similar way to benzoyl from benzoic acid—the radicle of pyrogallolcarboxylic acid is thus pyrogallolcarboyl.

When dextrose is shaken with the chloride and quinoline in chloroform solution, five trimethylcarbonatopyrogallolcarboyl residues are introduced into the sugar. On cautious hydrolysis a tannin is obtained isomeric with pentagalloyldextrose.

Trimethylcarbonatopyrogallolcarboxylic acid, $C_6H_2(O \cdot CO_2Me)_3 \cdot CO_2H,$

crystallises in tiny, colourless platelets, m. p. 122—124° (corr.). The pure acid gives hardly any coloration with ferric chloride.

The corresponding *chloride* crystallises in colourless, lancet-shaped needles, m. p. 67—68° (corr.).

The *methyl* ester, $C_6H_4(O \cdot CO_2Me)_3 \cdot CO_2Me$, crystallises in microscopic, stout double pyramids, m. p. 82—84°, the homologous *ethyl* ester crystallises in tiny, oblique plates, m. p. 91—94° (corr.).

Trimethylcarbonatopyrogallolcarboyloxybenzoic acid,
$$C_6H_2(O \cdot CO_2Me)_3 \cdot CO \cdot O \cdot C_6H_4 \cdot CO_2H,$$
crystallises in slender, microscopic platelets, m. p. 198—199° (corr.). Ammonia converts it into *pyrogallolcarboyl-p-hydroxybenzoic acid*, $C_6H_2(OH)_3 \cdot CO \cdot O \cdot C_6H_4 \cdot CO_2H$. The didepside crystallises in very small, lustrous crystals aggregated in bunches, m. p. 235—238° (corr., decomp.). With ferric chloride a blue or bluish-violet coloration is produced.

Penta-[trimethylcarbonatopyrogallolcarboyl]-dextrose,
$$C_6H_7O_6[CO \cdot C_6H_2(O \cdot CO_2Me)_3]_5,$$
forms a colourless, amorphous powder which sinters at 100°, m. p. about 130°, $[\alpha]_D^{18}$ +27°.

Pentapyrogallolcarboylglucose forms also a colourless, amorphous powder, which sinters about 160°, m. p. 200° (decomp.), $[\alpha]_D^{18}$ +69·1°. It differs from tannic acid and pentagalloylglucose in being sparingly soluble in water.   E. F. A.

Synthesis of *o*-Diorsellinic Acid. EMIL FISCHER and HERMANN O. L. FISCHER (*Sitzungsber. K. Akad. Wiss. Berlin*, 1913, 507—512).— Two didepsides are derived from orsellinic acid according as coupling takes place in the ortho- or para-positions. The product previously obtained (this vol., i, 477), identical with the natural lecanorcic acid, was considered to be the *p*-diorsellinic acid, and this is now confirmed by the synthesis of the ortho-isomeride.

Methylcarbonato-orcylaldehyde (Hoesch, this vol., i, 474) is readily coupled with dimethylcarbonato-orsellinyl chloride in alkaline solution, yielding the following compound (I). The corresponding acid is
obtained on oxidation with permanganate, and it is converted into the *o*-diorsellinic acid on elimination of the methyl carbonato-groups by means of dilute ammonia. The *o*-diorsellinic acid (II) differs from lecanoric acid in solubility, melting point, and in its behaviour towards ferric chloride. It differs also from the gyrophoric acid described by Hesse (A., 1901, i, 151).

Trimethylcarbonato-orsellinoylorcylaldehyde crystallises in slender, pliable needles, m. p. 112—113° (corr.).

Trimethylcarbonato o-diorsellinic acid separates in tiny, six-sided

platelets which sinter at 150°, m. p. 158° (corr., decomp.). With ferric chloride only a yellow coloration is obtained.

o-*Diorsellinic acid* (formula II) forms colourless, tiny needles much intergrown, but appears somewhat yellow in bulk. It has m. p. 120—125°, becomes solid, and melts again at 180—185°. E. F. A.

Angeli-Rimini Reaction of the Aldehydes. LUIGI BALBIANO (*Atti R. Accad. Lincei*, 1913, [v], 22, i, 575—579).—Polemical. A reply to Angeli (A., 1912, i, 626). R. V. S.

Quantitative Investigation of the Photochemical Transformation of o-Nitrobenzaldehyde into o-Nitrosobenzoic Acid. ANTON KAILAN (*Ber.*, 1913, 46, 1628—1634) —Polemical. The author maintains the sufficiency of his methods and the accuracy of the results obtained by him (this vol., i, 51) against the criticism of Weigert and Kummerer (this vol., ii, 370). R. V. S.

Some Derivatives of Methyl*cyclo*pentan-3-one. MARCEL GODCHOT and FÉLIX TABOURY (*Compt. rend.*, 1913, 156, 1779—1781. Compare this vol., i, 278).—By the action of dry chlorine on methyl-*cyclo*pentan-3-one in diffused light at a temperature below 25°, 2-*chloro-methyl*cyclopentan-3-one, C_6H_9OCl, is obtained as a colourless oil, b. p. 80—82°/8 mm., D^{22} 1·128, n_D^{22} 1·465. On boiling this chloro-derivative with water it yields a mixture of *methyl*cyclopentan-2-ol-3-one, b. p. 83—85°/12 mm., and 2-*methyl*-Δ^1-cyclopenten-5-one, b. p. 50°/12 mm. The former of these compounds is a pale yellow, syrupy liquid, giving a violet coloration with ferric chloride, and yielding an unstable *phenyl-hydrazone*. On oxidation the ketone-alcohol is converted into a-methyl-glutaric acid. 2-Methyl-Δ^1-cyclopenten-5-one is a colourless liquid, having b. p. 157—158°, D^{-6} 0·9712, n_D^{26} 1·4714. It is very soluble in water, and gives a *semicarbazone*, m. p. 230°, and an *oxime*, m. p. 127°. W. G.

Reduction of Ketones and Aldehydes to the Corresponding Hydrocarbons by means of Amalgamated Zinc and Hydrochloric Acid. ERIK CLEMMENSEN (*Ber.*, 1913, 46, 1837—1843).—The application of amalgamated zinc has led to very good results in the reduction of fatty-aromatic ketones, and of aliphatic ketones and aldehydes to the corresponding hydrocarbons. In practice, an excess of granulated zinc is left for an hour with 5% mercuric chloride, drained, and then heated with the substance and concentrated hydrochloric acid under reflux, care being taken that the evolution of hydrogen is brisk enough to keep the two liquids well mixed.

By this means acetophenone gives ethylbenzene, or by using only the theoretical amount of acid, styrene. Propiophenone or phenyl-acetone give 90% yields of *n*-propylbenzene; butyrophenone or benzyl-acetone give 88—100% yields of *n*-butylbenzene, and methyl a-naphthyl ketone is reduced to a-ethylnaphthalene. Aromatic aldehydes are too susceptible to the action of mineral acids, but, notwithstanding, a 46%

yield of toluene was obtained from benzaldehyde. Heptaldehyde, however, gives a good yield of *n*-heptane. The following reductions of aliphatic ketones give almost theoretical yields; methyl *n*-nonyl ketone to *n*-undecane, methyl *n*-heptadecyl ketone to *n*-nonadecane, di-*n*-heptadecyl ketone (stearone) to *n*-pentatriacontane. The method is being extended to other classes of compounds.   J. C. W.

Dynamic Isomerism. HENRY E. ARMSTRONG, THOMAS M. LOWRY, SIDNEY YOUNG, CECIL H. DESCH, JAMES J. DOBBIE, MARTIN O. FORSTER, and ARTHUR LAPWORTH (*Rep. Brit. Assoc.*, 1912, 115—116).—See Lowry and Glover, T., 1913, **103**, 913.   C. H. D.

Synthesis of Violanthrone. CHRISTIAN SEER and ROLAND SCHOLL (*Annalen*, 1913, **398**, 82—96).—The constitution of violanthrone has been now proved, since the orientation of the benzoyl groups in the dibenzoyl-*aa*-dinaphthyl used in its synthesis (this vol., i, 59) has now been definitely settled.

aa-Naphthidine in 3% hydrochloric acid at 0° is treated with sodium nitrite, and the tetrazotised solution is filtered into aqueous potassium cyanide and copper sulphate at 60°, whereby 4 : 4′ *dicyano-a : a′-dinaphthyl*, m. p. 280—281°, pale yellow needles, is obtained. The latter is hydrolysed by alcoholic sodium hydroxide at 160—190°, and the resulting *aa-dinaphthyl-4 : 4′-dicarboxylic acid*, m. p. 349—350°, colourless crystals, is converted by phosphoric and phosphoryl chlorides into the acid *dichloride*, pale brown crystals, from which 4 : 4′-dibenzoyl-*aa*-dinaphthyl is obtained by means of aluminium chloride and benzene in nitrobenzene at 70—75°. 4 : 4′-Dibenzoyl-*aa*-dinaphthyl has now been prepared in orange-yellow needles, m. p. 146—147°; it is converted into violanthrone by aluminium chloride at 95—100° (*loc. cit.*).

By treatment with hydriodic acid, b. p. 127°, and red phosphorus at 190° for ten hours, violanthrone is converted into a substance which is apparently its parent hydrocarbon, *violanthrene*, $C_{34}H_{20}$; it is a dark powder which is not attacked by alkaline sodium hyposulphite, and forms in concentrated sulphuric acid a blue solution with a brown fluorescence.

5-*Iodo*-1-*naphthoic acid*, m. p. 253—254°, colourless needles, prepared in the usual manner from 5-amino-1-naphthoic acid, forms a *methyl* ester, $C_{12}H_9O_2I$, m. p. 81—82°. By heating the latter with copper powder at 220—240° in a current of carbon dioxide, *methyl aa-dinaphthyl-5 : 5′-dicarboxylate*, $C_{24}H_{18}O_4$, m. p. 173—174°, faintly yellow needles, is obtained. The *acid*, $C_{22}H_{14}O_4$, m. p. 359—360°, microscopic needles, is converted into the crude *chloride*, m. p. about 150°, by phosphorus pentachloride, and the chloride is heated with aluminium chloride, benzene, and nitrobenzene at 70—80°, whereby 5 : 5′-*dibenzoyl-aa-dinaphthyl*, $C_{34}H_{22}O_2$, m. p. 248—250°, glistening leaflets, is obtained. By heating the latter with aluminium chloride at 145°, neither *Bz*-1 : 1′-dibenzanthronyl nor violanthrone is produced, but benzanthrone ; whether this is present as such in the crude 5 : 5′-dibenzoyl-*aa*′-dinaphthyl or is produced during the reaction was not determined.   C. S.

Conversion of 3-Dimethylaminophenyl Methyl Sulphide into 3-Methylthiol p-benzoquinone. THEODOR ZINCKE and JOHANNES MULLER (*Ber.*, 1913, **46**, 1777—1781. Compare this vol., i, 355).—3-*Methylthiol*-4 *nitrosodimethylaniline hydrochloride* separates in red needles when a solution of sodium nitrite is added to a well-cooled solution of 3-dimethylaminophenyl methyl sulphide in hydrochloric acid. The free *base* is best obtained by addition of sodium acetate, and forms green needles melting at 143° to a deep blue liquid. When boiled with *N*-sodium hydroxide, it yields dimethylamine and 4-*nitroso*-3-*methylthiolphenol*, yellow needles, m. p. 186°, which is converted by acetic anhydride and sodium acetate into the corresponding *acetyl* derivatives, yellow needles, m. p. 165°. 4-*Amino*-3-*methylthiolphenol* is obtained by reduction of a boiling ammoniacal solution of 4-nitroso-3-methylthiolphenol by hydrogen sulphide, and, after purification by sublimation in a vacuum, forms nearly colourless needles, m. p. 154°, which readily oxidise on exposure to air. The *alkali* salts and the *hydrochloride* are readily soluble; the *sulphate* is more sparingly soluble. The *diacetyl* derivative forms small, white crystals, m. p. 100°, which contain ½ mol. acetic acid. When warmed with salicylaldehyde in alcoholic solution, the free base yields a *substance*,

$$C_{14}H_{13}O_2NS,$$

yellowish-brown needles, m. p. 134°.
3 *Methylthiol* - p - *benzoquinone* (annexed formula) is obtained by addition of dichromate solution to a solution of 4-amino-3-methylthiolphenol in dilute sulphuric acid and subsequent oxidation of the bluish-black *product* so obtained with nitric acid in acetic acid solution. An excess of nitric acid causes the elimination of the methylthiol group. It is therefore preferable to reduce the above quinhydrone to the quinol and oxidise the latter with dilute sulphuric acid and dichromate solution. 3-Methylthiol-p-benzoquinone forms red needles, m. p. 148°. Concentrated nitric acid (D 1·4) dissolves it without change; sulphurous acid reduces it to the corresponding quinol. When dissolved in chloroform and treated with chlorine, it gives tetrachloro-p-benzoquinone, whilst with aniline in hot glacial acetic acid solution it yields 2 : 5-dianilino-p-benzoquinone and methyl mercaptan.

3-*Methylthiolquinol* forms white needles, m. p. 83°, which are readily oxidised on exposure to air. With acetic anhydride and sodium acetate it yields a *diacetyl* compound, m. p. 101°.　H. W.

2-Aminoanthraquinone. FRITZ ULLMANN and ROBERT MEDENWALD (*Ber.*, 1913, **46**, 1798—1809).—Two iminoanthraquinone nuclei have been linked together by an ethylene group, the sulphonic acid derived from aminoanthraquinone has been shown to be the 3-sulphonic acid, the preparation of the 1-nitro- and 3-nitro-2-aminoanthraquinones is described, and the condensation of 1 : 3-dibromo-2-aminoanthraquinone with bases has been studied.

Toluene-p-*sulpho* - 2 - *anthraquinonylamide*, $C_{14}H_7O_2 \cdot NH \cdot SO_2 \cdot C_7H_7$, from 2-aminoanthraquinone and p-toluenesulphonyl chloride in pyridine,

forms yellow needles, m. p. 304° (corr.), which give a red solution in hot alkalis or cold concentrated sulphuric acid. Excess of the sulphonyl chloride gives rise to the *disulphonamide*, $C_{28}H_{21}O_6NS_2$, in yellowish-brown crystals, m. p. 256° (corr.), whereas methyl sulphate yields *toluene-p-sulpho-2-anthraquinonylmethylamide* in yellow crystals, m. p. 195° (corr.), from which 2-*methylaminoanthraquinone*, $C_{14}H_7O_2 \cdot NHMe$, may be obtained in long, ruby-red needles, m. p. 226—227° (corr.), by warming with concentrated sulphuric acid. When condensed with ethylene dibromide in a sealed tube, the original sulphonamide yields *ethylenebistoluene*-p-*sulpho* - 2- *anthraquinonylamide*, $C_{44}H_{32}O_8N_2S_2$, in yellow crystals, m. p. 301° (corr.), which on hydrolysis with concentrated sulphuric acid give *ethylenebis-2-aminoanthraquinone*,

$$C_6H_4 <^{CO}_{CO}> C_6H_3 \cdot NH \cdot CH_2 \cdot CH_2 \cdot NH \cdot C_6H_3 <^{CO}_{CO}> C_6H_4.$$
This forms small, orange-yellow crystals, m. p. 400°, and gives a red vat with sodium hyposulphite, cotton being dyed orange.

Fuming sulphuric acid (18—20% SO_3) converts 2-aminoanthraquinone into 2-*aminoanthraquinone-3-sulphonic acid*, $C_{14}H_9O_5NS$, a faintly yellow powder, which forms a white sulphate by the addition of water to the red solution in concentrated sulphuric acid, and also a golden-yellow *sodium* salt. Its constitution is determined by the formation of Scholl's 1 : 3-dibromo-2-aminoanthraquinone [A., 1907, i, 541, m. p. 249·5° (corr.), and not 239°] under the influence of bromine water, and the transformation into 2-chloroanthraquinone by eliminating the amino-group and then replacing the sulphonic group through the medium of sodium chlorate and hydrochloric acid.

The chief product of the nitration of 2-acetylaminoanthraquinone is 1-*nitro-2-acetylaminoanthraquinone*, $C_{16}H_{10}O_5N_2$, which forms long, silvery needles, m. p. 277—278° (corr.), and is hydrolysed by warm concentrated sulphuric acid to 1-nitro-2-aminoanthraquinone, m. p. 310° (corr.) (Terres, this vol., i, 738, gives m p. 267°). Bayer & Co. (A., 1906, i, 677) also obtained the latter compound by nitrating the carbamate of 2-aminoanthraquinone, m. p. 279—280°, and hydrolysing the carbamate of 1-nitro-2-aminoanthraquinone, m. p. 205°. The addition of glacial acetic acid to the solution in fuming nitric acid, however, precipitates the isomeric *carbamate* of 3-*nitro-2-amino-anthraquinone*, $C_{17}H_{12}O_6N_2$, in faintly yellow needles, m. p. 225° (corr.), thus affording a means of obtaining 3-nitro-2-aminoanthraquinone (Scholl, A., 1905, i, 70). When the 1-nitroamine or the urethane is reduced with sodium sulphide, 1 : 2-diaminoanthraquinone is obtained, m. p. 303—304° (compare Terres, *loc. cit.*). Reduction of the acetylated base, however, gives rise to 2-*methyl-a-anthraquinoneiminazole* (annexed formula). This crystallises in yellow leaflets, m. p. 326° (corr.), which form a colourless hydrochloride and an orange-red sodium salt.
1 : 3-Dibromo-2-aminoanthraquinone condenses with *p*-toluidine in presence of anhydrous potassium acetate to form 3-*bromo-2-amino-1-toluidinoanthraquinone*, $C_{21}H_{15}O_2N_2Br$, in long, dark red, sparkling needles, m. p. 181° (corr.), which on oxidation with lead peroxide yields

3-bromoanthraquinone-1 : 2 : 1′ : 2′ : 4′-*methylphenazine*,

$$C_6H_4 <^{CO}_{CO}> C_6HBr <^N_N> C_6H_3Me,$$
in pale brown needles, m. p. 247° (corr.). The dye gives a blue hyposulphite vat which colours cotton light blue, but the shade changes to pale yellow in the air. **J. C. W.**

Preparation of Nitroaminoanthraquinones. CHEMISCHE FABRIK GRIESHEIM-ELEKTRON (D.R.-P. 259432).—When the anthraquinone-nitroamines (A, 1905, i, 447) are treated with mineral acids (such as hydrochloric or phosphoric) they are converted into nitroaminoanthraquinones; thus anthraquinone-1-nitroamine (*loc. cit.*) when left in contact with concentrated sulphuric acid for one hour furnishes a mixture of 1 : 2- and 1 : 4-nitroaminoanthraquinones.

Anthraquinone-2-nitroamine prepared by the action of sodium hypochlorite on anthraquinone-2-*iso*diazoxide yields 1-nitro-2-amino-anthraquinone (A., 1906, i, 677), and this on reduction (by ordinary methods) gives rise to 1 : 2-*diaminoanthraquinone*, m. p. 242—244°.

Anthraquinone-1 : 5-dinitroamine furnishes a mixture of 2 : 6-dinitro- and 4 : 8-dinitro-1 : 5-diaminoanthraquinones, whilst anthraquinone-2 : 6-dinitroamine gives rise to 1 : 5-*dinitro*-2 : 6-*diaminoanthraquinone*, brown crystals, m. p. over 300°, which on reduction yields 1 : 2 : 5 : 6-*tetra-aminoanthraquinone*. **F. M. G. M.**

1 : 2-Diaminoanthraquinone and a Synthesis from it of Indanthrene. ERNST TERRES (*Ber.*, 1913, **46**, 1634—1647).—Indanthrene can be obtained from 1 : 2-diaminoanthraquinone and 1 : 2-anthraquinone, and the author also describes other angular azines obtained by the interaction of 1 : 2-diaminoanthraquinone with diethyl oxalate, benzil, 1 : 2-naphthaquinone, and phenanthraquinone. The two last-named have already been obtained (Farbenfabriken vorm. Friedr. Bayer & Co., A., 1906, i, 905). The nomenclature employed is that proposed in a former paper (Bally and Scholl, *Ber.*, 1911, **44**, 1662). The paper also records a reducing action of potassium copper cyanide, which reacts with 2-methylanthraquinonyl-1-diazonium sulphate, yielding 2-methylanthraquinone. The nitrile simultaneously formed is removed by saponifying it to the corresponding acid, which is soluble in water.

In order to exclude the formation of isomeric products, 1 : 2-diamino-anthraquinone was made (but with poor yield) by a new method, starting from 1-nitro-2-methylanthraquinone. Oxidation of this substance (best effected by concentrated nitric acid and chromic anhydride. Badische Anilin- & Soda-Fabrik, D.R.-P. 228394) yields 1-nitroanthraquinone-2-carboxylic acid, m. p. 283°. On treatment of this acid with sodium sulphide solution on the water-bath, 1-*amino-anthraquinone*-2-*carboxylic acid*, $C_{15}H_9O_4N$, is obtained; it forms brownish-red, shimmering needles, m. p. 286°. When 1-nitroanthra-quinone-2-carboxylic acid is boiled for several hours with phosphorus pentachloride in benzene solution, the acid *chloride* (which crystallises in yellow needles) is produced, and if the reaction mixture is poured into cold alcoholic ammonia solution, the *amide*, $C_{15}H_8O_5N_2$, is

obtained ; it forms yellow leaflets or large, almost colourless prisms, m. p. 299—301°.   On reduction with ammonium sulphide, the amide yields 1-*aminoanthraquinone*-2-*carboxylamide*, $C_{15}H_{10}O_3N_2$, which crystallises in red needles, m. p. 279—281°.   2-Amino-1-nitroanthraquinone, m. p. 266—267° (Farbenfabriken vorm. Friedr. Bayer & Co., A., 1906, i, 677) can be obtained from 1-nitroanthraquinone-2-carboxylic acid by warming it with bromine, potassium hydroxide, and water, but it is necessary that the acid should be freshly precipitated (by pouring an acetic acid solution of it into water).   1 : 2-Diaminoanthraquinone is obtained by heating 2-amino 1-nitroanthraquinone with ammonium sulphide solution for five hours on the water-bath.

When a mixture of 1 : 2-diaminoanthraquinone and 1 : 2-anthraquinone in acetic acid is boiled, transbisangular *anthroanthraquinone-azine* (annexed formula) is rapidly deposited as a brownish-red, crystalline paste.   It gives a dark green solution in cold, concentrated sulphuric acid, and from this solution water precipitates at first the dark blue sulphate.   In concentrated nitric acid the substance dissolves, giving a bluish-green solution, which becomes blue and finally wine-red on warming.   Alkali hyposulphite solution yields an insoluble, bluish-green vat salt.   It is possible that the above product contains also the *cis*-isomeride.   That the *trans*-form is present is shown by the fact that, by oxidation with chromic acid to anthraquinoneazine and reduction of the latter by means of boiling quinoline, indanthrene is obtainable, although only in very minute quantities and by working in very definite conditions.
Condensation of ethyl oxalate with 1 : 2-diaminoanthraquinone (by boiling in acetic acid solution) yields 2 : 3-*diethoxypyrazinoanthraquinone* (annexed formula), which crystallises in red needles, m. p. 276—277°.   This azine gives a bright yellow solution in sulphuric acid. With hyposulphite solution it yields a red vat, which has, however, little affinity for unmordanted vegetable fibres.
Benzil yields by a similar condensation 2 : 3-*diphenylpyrazinoanthraquinone* (annexed formula), which forms yellow needles, m. p. 282—283°.   Concentrated sulphuric acid dissolves the substance with production of a dark reddish-brown coloration.   Alkali hyposulphite yields a bluish-black, insoluble vat salt.   R. V. S.

Preparation of Anthraquinone Derivatives Containing Halogens.   FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D R.-P. 258556).—When 1 : 4-diamino- or 1-amino-4-hydroxy-anthraquinone is treated with chloric acid it furnishes a chlorinated quinone.

1 : 4-Diaminoanthraquinone (50 parts) dissolved in concentrated sulphuric acid (1000 parts) at 5° is slowly treated during about four hours with finely powdered potassium chlorate (250 parts); the *product*, a grey powder, crystallises from xylene, contains 23·1% of chlorine, and no nitrogen.

By modifying the reaction, a *compound* (I) having a higher chlorine content is obtained, and when diaminoanthrarufin (46 parts) with potassium chlorate (450 parts) is employed it gives rise to *tetrachlorotriquinone* (II) :

(I.) and (II.)
These compounds condense with aromatic amines (eliminating one atom of chlorine), furnishing dyes.   F. M. G. M.

[Derivatives of] Some Aromatic Diketones. LUIGI ALESSANDRI (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 517—519).—When phenanthraquinone is boiled with an ethereal solution of diazomethane until no more diazomethane remains, nitrogen is evolved, and a *substance*, $C_{15}H_{10}O_2$, is formed ; it crystallises in thin, orange-yellow needles, m. p. 167°. The compound is stable towards permanganate.   R. V. S.

The Aliphatic Sequiterpene-Alcohol, Farnesol. MAX KERSCHBAUM (*Ber.*, 1913, **46**, 1732—1737).—The author has investigated a number of derivatives of farnesol, an alcohol which is widely distributed in flower-blossom oils (compare A., 1904, i, 513 ; Soden and Treff, A., 1904, i, 439).

Farnesol, obtained from *Hibiscus Abelmoschus*, L., and purified by the phthalic ester method, has b. p. 160°/10 mm., D^{18} 0·885, n_D 1·48809, $a_D \pm 0°$. It may be preserved in closed vessels for years without alteration. Solid derivatives have not been obtained. The *acetate* has b. p 169—170°/10 mm., and is practically odourless. When heated with potassium hydrogen sulphate at 160—170°, farnesol loses water, form'ng *farnesene*, a colourless, mobile oil, b. p. 129—132°/12 mm., D^{18} 0·877, n_D 1·49951, $a_D \pm 0°$. Oxidation of farnesol by means of chromic acid and dilute sulphuric acid leads to the formation of farnesaldehyde, which, after purification by means of the solid bisulphite *compound*, has b. p. 172—174°/14 mm., D^{18} 0·893, n_D 1·49951, $a_D \pm 0°$. The corresponding *semicarbazone*, leaflets, m. p. 133—135° after slight previous softening, is well adapted for the identification of farnesol.

Attempts to determine the constitution of farnesol by a study of the products of the action of potassium permanganate on it were not completely successful. Acetone was, however, isolated. When, however, *farnesaldoxime* was converted into the corresponding *nitrile* and the latter saponified by alcoholic sodium hydroxide, *farnesenic acid*, b. p. 202—206°/16 mm., acetic acid, and a ketone were obtained. The latter substance was identified as dihydro-ψ-ionone by

means of its semicarbazone. Since the constitution of the latter follows from its synthesis from geranyl chloride and ethyl sodio-acetoacetate followed by saponification of the ethyl geranylaceto-acetate by sodium hydroxide, the following formula is ascribed to farnesol : $CMe_2:CH\cdot[CH_2]_2\cdot CMe:CH\cdot[CH_2]_2\cdot CMe:CH\cdot CH_2\cdot OH$ (compare following abstract).

Dihydro-ψ-ionone is converted by methyl magnesium bromoacetate into a *methyl hydroxydihydrofarnesenate*, which, on prolonged heating with acetic anhydride and sodium acetate at 160—165°, loses water, and yields *methyl farnesenate*, b. p. 177—185°/10 mm. The corresponding free acid has a b. p. identical with that of the acid obtained from farnesol. Solid derivatives could not, however, be prepared.

Reduction of methyl farnesenate by sodium and absolute alcohol gives rise to a mixture of dihydro-ψ-ionol. dihydrofarnesol, and, probably, farnesol. The presence of the latter could not, however, be definitely established.   H. W.

Farnesol. CARL HARRIES and REINHOLD HAARMANN (*Ber.*, 1913, **46**, 1737—1741).—A study of the action of ozone on farnesol has confirmed the formula ascribed to the latter by Kerschbaum (preceding abstract).

When farnesol is ozonised in hexane solution, a gelatinous *diozonide* is obtained, which, on further treatment with azone in chloroform solution, is transformed into the *triozonide*. The latter, when boiled with water, gave the tests for hydrogen peroxide, for the group $C\cdot CO\cdot C\cdot C\cdot CHO$ and for aldehydes, whilst acetone, formic and acetic acids, lævulinaldehyde, and lævulic acid were identified among the products formed.

The action of ozone on farnesene was also investigated, the latter substance having been obtained by the fractionation of a specimen of crude farnesol which had been preserved during several years and which had undergone decomposition to a considerable extent with elimination of water. In carbon tetrachloride solution, the hydrocarbon yields a stable, glassy *tetra-ozonide*, which is decomposed by boiling water with formation of lævulinaldehyde. The latter was identified by conversion into phenylmethyldihydropyridazine, m. p. 197° (Harries, A., 1898, i, 233).   H. W.

Methylcamphoroxime,   Methylcampholenonitrile,   and Methylcampholenic Acid. ALBIN HALLER and ÉDOUARD BAUER (*Compt. rend.*, 1913, **156**, 1503—1506).—The mixture of methyl- and dimethyl-camphor obtained by the action of methyl iodide on sodium camphor (compare A., 1909, i, 594) can be separated by the action of hydroxylamine zinc chloride, the methylcamphor being converted into its oxime, m. p. 60°, b. p. 134—135°/11 mm., $[\alpha]_D^{22} +25\cdot15°$ (compare Glover, T., 1908, **93**, 1285). It gives a *phenylurethane*, prismatic crystals, m. p. 112—113°, $[\alpha]_D^{22} +24\cdot8°$, and at the same time a small quantity of slender needles, m. p. 110—111°, which are inactive. The oxime is hydrolysed by hydrochloric acid into the nitrile, b. p. 105—106°/15 mm., $[\alpha]_D^{22} +45°$ (compare Glover, *loc. cit.*). In solution in alcohol it has $[\alpha]_D^{23} +53\cdot9°$. The nitrile is hydrolysed by

alcoholic potassium hydroxide to *methylcampholenamide*, m. p. 91—92°, which is completely inactive, and this in its turn is hydrolysed by more concentrated alkali to *methylcampholenic acid*, m. p. 30°, b. p. 153°/ 20 mm., which is also inactive. It is probable that the methylcampholenonitrile by reason of its optical activity is analogous to a-campholenonitrile, but in the course of hydrolysis undergoes transformation, its derivatives being of the β-type. W. G.

*iso*Nitroamines of the Terpenes. GUIDO CUSMANO (*Atti R. Accad. Lincei*, 1913, [v], 22, i, 616—622. Compare Cusmano and Linari, A., 1912, i, 272) —*Carvomenthone-aβ-hydroxylamineoxime* (annexed formula) is obtained by the action of hydroxylamine on carvomenthone bisnitroso-chloride ; it forms tufts of long, colourless needles, m. p. 118°. From the mother liquor the following substances can be isolated in small quantity : active carvotanacetoneoxime, oxytetrahydrocarvoneoxime, and two other *oximes* of m. p. 120° and 160° respectively. The hydroxylamineoxime reduces ammoniacal silver nitrate and Fehling solution. When treated with ferric salts, it yields an amorphous, yellow powder, which is soluble in ether and contains iron. This *substance* gives Liebermann's reaction, and when shaken in ethereal solution with concentrated hydrochloric acid, it loses its iron, and is converted into a blue *compound*. The hydroxylamineoxime yields a *benzylidene* derivative, $C_{17}H_{23}O_2N_2$, which crystallises in hard, colourless prisms, m. p. 141°. The p-*nitrobenzylidene* derivative is a yellow powder.
CMe·NH·OH
H_2C C:NH·OH
H_2C CH₂
CH·CHMe₂

Carvomenthone-aβ-isonitroamineoxime, $C_{10}H_{19}O_3N_3·H_2O$, obtained by the action of sodium nitrite on the hydrochloride of the hydroxylamineoxime above described, forms rectangular tablets, m. p. 64°. It gives blue colorations with sulphuric acid solutions of phenol and diphenylamine. The *ammonium* and *silver* salts were prepared. When the aqueous solution of the *potassium* salt is boiled, the active oxime of carvotanacetone is produced. The *iso*nitroamineoxime is fairly stable towards acids ; after prolonged boiling with acetic acid or hydrochloric acid only small quantities of tanacetone are formed. When the *iso*nitroamineoxime is dissolved in the equimolecular quantity of potassium carbonate and the solution is placed over sulphuric acid, nitrous oxide is evolved, and the *salt* of oxycarvomenthoneoxime is produced. If this is decomposed with carbonic acid, the *oxime*, $C_{10}H_{18}O(NOH)$, is obtained in rhomboidal leaflets, m. p. 102°. On evaporating a solution of the oxime in ethyl nitrite the *pernitrosyl* compound is deposited as an oil, and this reacts with semicarbazide to form *oxycarvomenthonesemicarbazone*, m. p. 172°.

If concentrated methyl-alcoholic solutions of hydroxylamine and 8-*iso*nitroaminomenthone are mixed (being cooled meanwhile with ice and salt) the *hydroxylammonium* salt, $C_{10}H_{18}O_3N_2·NH_2·OH$, is precipitated in long, colourless needles, m. p. 68°. Acids decompose the salt in the cold, yielding the original *iso*nitroamine, whilst cold alkalis convert it into pulegone. The salt remains unaltered for a long time in the solid state, but in alcoholic or ethereal solution it is rapidly

transformed into *menthoneisonitroamineoxime*, $C_{10}H_{19}O_3N_3$, which forms large, prismatic crystals, m. p. 77°. This substance gives blue colorations with sulphuric acid solutions of diphenylamine and phenol. It is very stable towards heat, remaining unaltered for a long period at 150°. The *potassium* salt, $C_{10}H_{18}O_3N_3K,2H_2O$, explodes above 350°. The *sodium* salt, $C_{10}H_{18}O_3N_3Na,4H_2O$, has m. p. 66°, or when anhydrous, 220° (decomp.). The *ammonium* salt dissociates at about 100° into its components.   R. V. S.

The Constituents of Ethereal Oils. Synthesis of the Diterpene, α-Camphorene, $C_{20}H_{32}$, and of the Sesquiterpene *cyclo*Isoprenemyrcene, $C_{15}H_{24}$. FRIEDRICH W. SEMMLER and K. G. JONAS (*Ber.*, 1913, 46, 1566—1571. Compare Semmler and Rosenberg, this vol., i, 377).—Unsuccessful attempts have been made to synthesise α-camphorene from isoprene, and also by the addition of two isoprene radicles to limonene.

Myrcene was heated in a sealed tube at 250—260° for four hours, and the product subjected to fractional distillation, whereby a portion, b. p. 175—195°/8 mm., was obtained, analyses of which gave results agreeing with the formula $C_{20}H_{32}$. When a cooled, absolute ethereal solution of the product was saturated with dry hydrogen chloride, a crystalline product was obtained identical in all respects with α-camphorene tetrahydrochloride. Successive treatment with glacial acetic acid and sodium acetate, and with alcoholic potassium hydroxide, converted it into *o*-camphorene identical with the substance obtained from camphor oil of high boiling point, from which the tetrahydrochloride could be regenerated. The mother liquor obtained from the α-camphorene tetrahydrochloride, on treatment with glacial acetic acid and sodium acetate and, subsequently, with alcoholic potassium hydroxide, yielded other diterpenes which appeared to be bicyclic.

Since myrcene is a butadiene and undergoes condensation when heated, attempts were made to obtain a condensation product from myrcene and isoprene. When these substances were heated in a sealed tube for three and a-half hours at 225° and the product fractionated, the following fractions were obtained: (i) unchanged isoprene; (ii) b. p. 52—65°/8 mm., consisting of dipentene obtained partly from the condensation of two isoprene molecules, and partly by the isomerisation of myrcene; (iii) b. p. 120—150°/8 mm., which, on subsequent distillation, yielded cyclo*isoprenemyrcene*, b. p. 125—135°/8 mm., n_D 1·49166, $a_D \pm 0°$, D^{18} 0·8685. The latter yielded a *trihydrochloride*, m. p. 83°, from which the hydrocarbon could be regenerated in the usual manner, and again converted into the hydrochloride; (iv) b. p. 175—195°/8 mm., n_D 1·5034, $a_D \pm 0°$, D^{20} 0·8890, and (v) a considerable residue.   H. W.

The Constituents of Essential Oils. The Constitution of Zingiberene. Transformation of the Monocyclic Zingiberene into the Bicyclic *iso*Zingiberene. FRIEDRICH W. SEMMLER and A. BECKER (*Ber.*, 1913, 46, 1814—1822).—Of the naturally-occurring monocyclic sesquiterpenes, only limene and zingiberene have been studied. The former can be regenerated from its trihydrochloride, but

the latter gives a dihydrochloride which no longer yields the original oil with alkalis. The conclusion is therefore drawn that the hydrochloride contains a different ring system. In addition, the abnormal molecular refraction, 68·37 instead of 67·86, suggests that two of the three unsaturated linkings are adjacent in a side-chain.

Consequently, like myrcene, which has a similar structure and may be reduced to dihydromyrcene and readily transformed into cyclic terpenes, zingiberene (I) may be reduced to dihydrozingiberene and also converted into a dicyclic hydrocarbon. The latter is found to yield the above hydrochloride, from which it may be regenerated. It receives the name, *iso*zingiberene (II).
Finally, like other butadienes, zingiberene may be polymerised or condensed with isoprene.

The reduction of zingiberene (b. p. 128—129°/9 mm., D^{20} 0·8684, n_D 1·4956) by means of sodium and alcohol results in the formation of monocyclic *dihydrozingiberene*, $C_{15}H_{26}$, with b. p. 122—125°/7 mm., D^{20} 0·8557, n_D 1·4837, $[\alpha]_D$ - 37°. The complete reduction with platinum and hydrogen yields monocyclic *hexahydrozingiberene*, $C_{15}H_{30}$, with b. p. 128—130°/11 mm., D^{20} 0·8264, n_D 1·4560, $[\alpha]_D$ - 10°12'. The linking-up of the side-chain into a ring is effected by dissolving the zingiberene in glacial acetic acid containing a small amount of sulphuric acid, and agitating for some hours at 60—65°. iso*Zingiberene*, $C_{15}H_{24}$, yields the same chloride as zingiberene itself (Schreiner and Kremers, A., 1902, i, 108) and also a *dihydrobromide*, m. p. 175°, from which alcoholic potassium hydroxide regenerates the pure hydrocarbon, with b. p. 120—123°/8 mm., D^{20} 0·9150, n_D 1·5034, $[\alpha]_D$ - 41°. Reduction with platinum and hydrogen converts the substance into *tetrahydro*iso*zingiberene*, $C_{15}H_{28}$, which is similar to other bicyclic tetrahydrosesquiterpenes, and has b. p. 123—123·5°/10 mm., D^{20} 0·8822, n_D 1·4791, and $[\alpha]_D$ + 4°36'.

When heated with isoprene in a sealed tube, zingiberene gave a mixture which was fractionated, and found to contain *i*-limonene, a bicyclic, dextrorotatory, modified zingiberene, "meta-zingiberene," a diterpene from the condensation of isoprene with zingiberene, and dizingiberene.   J. C. W.

[Essential Oils.] SCHIMMEL & Co. (*Semi-Annual Report*, April, 1913, pp. 20—153. Compare A., 1912, i, 880).—First runnings from the distillation waters of angelica contained methyl alcohol, ethyl alcohol, furfuraldehyde, diacetyl, and a base having an odour of pyridine.

Angostura bark (*Cusparia trifoliata*, Engl.) yielded 1·03% of oil, D^{15}_5 0·9285, α_D^{20} - 7°32', n_D^{20} 1·50744, of pale brown colour and having

acid number 1·8, ester number 5·5, acetyl ester number 35·7 ; the oil is not completely soluble even in 9 vols. of 90% alcohol.

Arnica root oil, D_{15}^{15} 0·984—1·00, $a_D^{20} + 0°25'$—2°, n_D^{20} 1·507—1·508, had acid number 4 to 10, ester number 60 to 100, and gives a turbid solution with 7 to 12 vols. of 80% or 0·5 to 6·0 vols. of 90% alcohol. Arnica flower oil, D_{30}^{30} 0·8905 to 0·9029, acid number 62·6 to 127·3, ester number 22·7 to 32·2, is a buttery mass, m. p. 20—30° (approx.), and very sparingly soluble in alcohol.

Artemisia vulgaris, L., oil from India, had D_{15}^{15} 0·9219, $a_D^{20} - 8°52'$, n_D^{20} 1·46201, acid number 1·2, ester number 22·1, acetyl ester number 55·5, and was soluble in 1 vol. of 80% alcohol, becoming turbid and depositing crystals of a solid paraffin on further dilution. The oil was of greenish-yellow colour and sage-like odour. It contains a-thujone, and possibly borneol.

Banana fruit oil according to Kleber (*Amer. Perf.*, 1912, **7**, 235) contains amyl acetate and traces of a phenol.

Borneo camphor oil, D_{15}^{15} 0·9180, $a_D^{20} + 11°5'$, n_D^{20} 1·48847, was of dark brown colour, soluble in 5 vols. or more of 90% alcohol, and had acid number 5·6, ester number 0, acetyl ester number 50·5. It contained d-a-pinene, β-pinene, dipentene, and camphene (35% of terpenes in all), borneol, and a-terpineol (10% together), sesquiterpenes 20%, and resin 35%.

The "Camphor leaf oil" (*Cinnamomum camphora*) described previously (A., 1905, i, 537) is now stated to be from the leaves of *Cinnamomum glanduliferum*, Meissn. It contains no camphor (compare Pickles, T., 1912, **101**, 1433). An oil from a hybrid between these two species deposited 58% camphor on freezing, and then had D_{15}^{15} 1·0465, $a_D^{20} + 34°24'$, acid number 1·0, ester number 23·3, acetyl ester number 46·2, and was soluble in 0·8 vol. of 80% alcohol. It still contained camphor, but no safrole could be detected.

Further investigation of Seychelles cinnamon bark oil (A., 1909, i, 112) shows that it contains the same constituents as Ceylon cinnamon bark oil.

The comparison of various methods for the estimation of geraniol and citronellal in citronella oils has been continued (A., 1912, i, 880). Kleber's phenylhydrazine process gives the following percentage values: *Java oil*, citronellal 35—41·3, geraniol 26·6—40·1 ; *Ceylon oil*, citronellal 7·5—11·6, and geraniol 29·6—34·4. Dupont and Labaune's method gives citronellal 35·4—46·3% and 6·5—8·0% for Java and Ceylon oils respectively. Kleber's phenylhydrazine process may also be used for cuminaldehyde, benzaldehyde, and methyl nonyl ketone ; in the case of oil of bitter almonds only the free benzaldehyde reacts with phenylhydrazine. The process is being tried for the estimation of ketones in rue oil.

The two alcohols already noticed in cypress oil (A., 1904, i, 604) have been further examined : the chief constituent of the mixture is now shown to be 4-terpineol ; the second alcohol, $C_{10}H_{18}O$, has D_{15}^{15} 0·9422, $a_D^{20} + 43°38'$, n_D^{20} 1·46678, b. p. 76—77°/4—5 mm., and has a rose odour with a suggestion of borneol. The highest fractions of the oil contain in addition to cypress camphor and cadinene, a liquid

sesquiterpene *alcohol*, $C_{15}H_{26}O$, b. p. 136—138°/4—5 mm., which on treatment with formic acid yields a hydrocarbon.

Dipterocarpus turbinatus, Gaertn., oleo-resin yielded 46% of a pale yellow balsamic oil, D_{15}^{15} 0·9271, a_D^{20} − 37°, n_D^{20} 1·50070, acid number 0, ester number 1·9, soluble in 7 vols. of 95% alcohol. *D. tuberculatus*, Roxb., oleo-resin gave 33% of a yellowish-brown oil, D_{15}^{15} 0·9001, a_D − 99°40′, n_D^{20} 1·50070, soluble in 6 vols. of 95% alcohol. Both these oleo-resins and oils gave Turner's colour reaction.

Caryophyllene was detected in a French lavender oil.

Lemon-grass oils from Assam, Burma, Formosa, Celebes, and Mayotte are described : these are mostly of the "insoluble" type.

Mentha aquatica, L., herb yielded 0·8% of oil, D_{15}^{15} 0·9553, a_D^{20} + 64°56′, n_D^{20} 1·48276, of pale yellow colour and having a faint odour of mint. *Mentha sylvestris*, L., herb gave 0·9% of similar oil, D_{15}^{15} 0·9852, a_D^{20} − 132°52′, n_D^{20} 1·46856. *M. viridis* herb gave 0·17% of oil, D_{15}^{15} 0·9512, a_D^{20} − 52°5′.

Mosla Japonica, Max., oil according to Nurayama and Nara (*J. pharm. Soc. Japan*, 1912) contains a-pinene (compare A., 1910, i, 328).

Ocotea pretiosa, Benth., bark gave 0·83% of a brown oil, D_{15}^{15} 1·1200, n_D^{20} 1·52712, soluble in 6·5 vols. of 88% alcohol, and having a cinnamon-like odour. The oil is nitrogenous, contains no cinnamaldehyde, but probably contains caryophyllene, phenols, and lactones.

d-Ethyl-*n*-amylcarbinol from Japanese peppermint oil (A., 1912, i, 370) yields a *benzoate*, D_{15}^{15} 0·9641, a_D^{20} + 5°58′, n_D^{20} 1·48905, b. p. 126·5°/ 3 mm., which is viscous, colourless, and possesses a faint odour. The *acetate*, D_{15}^{15} 0·8693, a_D^{20} − 4°46′, n_D^{20} 1·41535, b. p. 194—194·5°/760 mm., has a peculiar odour of fruit and roses. The inactive modification of the alcohol, D_{15}^{15} 0·8286, n_D^{20} 1·42785, b. p. 176—177·5°, has been synthesised by the action of magnesium ethyl iodide on *n*-hex-aldehyde.

Rhus Cotinus, L., leaves and flowers yielded a very pale yellow oil, D_{15}^{15} 0·8710, a_D^{20} + 32°54′, n_D^{20} 1·4887, acid number 0·9, ester number 20·4, soluble in 6 vols. 90% alcohol, and having an odour of terpenes, but slightly suggestive of neroli ; it contained camphene, β-pinene (?), and limonene ; no phellandrene or terpinene could be detected.

Amomum globosum fruits ("wild cardamoms") from Indo-China yielded 4% of a colourless oil, D_{15}^{15} 0·9455, a_D^{20} + 43°54′, n_D^{20} 1·47141, acid number 0·8, ester number 128·4, insoluble in 10 vols. of 70% alcohol, but soluble in 1 vol. of 80% alcohol and having a strong odour of camphor.

Cherry stones when ground and left for several hours furnished, on steam distillation, 0·016% of an oil, D_{15}^{15} 1·0532, a_D^{20} 0°, n_D^{20} 1·53888, soluble in 2·5 vols. of 60% alcohol, having an odour similar to, but clearly different from, that of bitter almond oil, and containing 0·27% of hydrocyanic acid.

Fennel herb from Jersey yielded an oil, D_{15}^{15} 0·9561, a_D + 16°40′, soluble in 5 vols. 80% alcohol. Its odour indicated that methyl-chavicole was the chief constituent, and that very little anethole was present.

Meum athamanticum, Jacq., herb from the Harz mountains yielded

0·88% of a deep reddish-brown oil, D_{15}^{17} 0·9053, n_D^{20} 1·50327, acid number 8·8, ester number 63·1, soluble in 3 vols. of 90% alcohol, which had a celery-like odour, and on keeping deposited crystals, m. p. 91° (guaiacol?)

The Report also contains a résumé of recent work on the chemistry, pharmacology, etc., of essential oils and their constituents.

<div style="text-align:right">T. A. H.</div>

[Essential Oils.] ROURE-BERTRAND FILS (*Sci. Ind. Bull.*, 1912, [iii], **6**, 3—191 ; 1913, [iii], **7**, 3—147).—*Calamintha Nepeta*, Lk. and Hoff., grown in Sicily, yielded 0·1426% of a brown oil, D_{17}^{17} 0·9249, a_D +17°48′, acid number 1·4, saponification number 12·6, which has an odour of pennyroyal, is soluble in 0·5 or more vols. of 80% alcohol, contains 20% of pulegone and 14% of alcohols, with a considerable quantity of a second ketone (menthone?).

Lemon grass oils from Mayotte, distilled from *Cymbopogon citratus*, had D_{15}^{17} 0·8877—0·9072, a −0°4′—0°6, aldehydes 75·5 to 78% and were insoluble in 90% alcohol.

Basil oils from Mayotte had D_{15}^{17} 0·9630—0·9677, a_D +0°56′—0°58′, acid number 0·7 to 1·4, saponification number 5·6 to 6·3, esters 1·9 to 2·2%, and were soluble in 3·0 to 3·2 or more vols. of 80% alcohol. These oils had an odour of anethole as well as of estragol.

[JUSTIN DUPONT and LOUIS LABAUNE.]—With a view to ascertaining the cause of the anomalous results obtained in estimating aldehydes in essential oils by means of sodium hydrogen sulphite solution, the authors have investigated the action of such solutions on a large number of common unsaturated constituents of essential oils and find that many of these are wholly or partly converted into hydro-sulphonates when shaken for some time with aqueous solutions of sodium hydrogen sulphite. Among the unsaturated substances which do not react in this way are hydrocarbons (for example, *l*-pinene, limonene, and styrene), esters, ethers, *iso*eugenol, and ionones. The results with all the substances examined are tabulated in the original. The following were isolated, the *sodium hydrogen sulphite* compounds of *geraniol* $C_{10}H_{18}O,2NaHSO_3$; *linalool*, $C_{10}H_{18}O,2NaHSO_3$; *terpineol*, $C_{10}H_{18}O,NaHSO_3$; *methylheptenone*, $C_8H_{14}O,NaHSO_3$; they are all hygroscopic masses (compare Labbe, A., 1900, i, 149), and are stable, since they do not regenerate the original organic constituent on addition of alkali. In a second paper on the analysis of citronella oil the authors point out that in Boulez's method for the assay of this oil (A., 1912, ii, 1105 ; Schimmel & Co., A., 1912, i, 880), the results for citronellal are liable to be rendered inaccurate by the absorption of a larger or smaller portion of the geraniol in the hydrogen sulphite solution.

Both "Bulletins" contain summaries of work recently published on essential oils.

<div style="text-align:right">T. A. H.</div>

Theory of the Vulcanisation of Caoutchouc. II. GUSTAV BERNSTEIN (*Zeitsch. Chem. Ind. Kolloide*, 1913, **12**, 273—277. Compare A., 1912, ii, 1007).—A continuation of the discussion of the theory of vulcanisation. It is shown that before vulcanisation occurs

a depolymerisation of the caoutchouc must take place, and that at the same time a polymerisation of the sulphur occurs. These two changes are shown to take place under the same conditions, whether the vulcanisation is effected by heat or by ultra-violet light. It is stated that the absorption of sulphur begins only when it has been converted into the insoluble form. It is also stated that the physical properties of the vulcanised product depend on the condition of aggregation of the caoutchouc at the moment of the formation and absorption of the insoluble sulphur. J. F. S.

Biochemical Synthesis of Alkylglucosides (a-Glucosides) by means of a Ferment (a-Glucosidase) contained in Air-dried, Bottom Yeast: a-Propylglucoside and a-Allylglucoside. ÉMILE BOURQUELOT, HENRI HÉRISSEY, and MARC BRIDEL (*Compt. rend.*, 1913, **156**, 1493—1495; *J. Pharm. Chim.*, 1913, [vii], **7**, 525—529. Compare this vol., i, 323, 428).—a-*Propylglucoside*, crystallising in long needles, having a bitter taste, $[a]_D$ +140·8°, and a-*allylglucoside*, colourless needles, m. p. 85—90°, $[a]_D$ +131·72°, are obtained by the action of a-glucosidase on solutions of dextrose in water containing 15% of the respective alcohols. They are both very soluble in water, and are readily hydrolysed in aqueous solution by the above ferment.
W. G.

Biochemical Synthesis, by means of Emulsin, of a Glucoside Isomeric with Salicin, β-Salicylglucoside. ÉMILE BOURQUELOT and HENRI HÉRISSEY (*Compt. rend.*, 1913, **156**, 1790—1792).— Emulsin acts on a solution of salicyl alcohol and dextrose in acetone, containing 20% water, giving β-*salicylglucoside*, which is finally obtained crystallising in long, colourless needles, $[a]_D$ −37 5°, the melting point varying considerably with the rate of heating. It is odourless, but possesses a bitter taste and is soluble in water, crystallising with $4H_2O$. It reduces Fehling's solution and gives a violet colour with ferric chloride, which does not disappear on shaking with ether. The yield of glucoside varies with the dilution of the acetone and the amounts of alcohol and dextrose used, the presence of an excess of alcohol favouring the synthesis. The glucoside is readily hydrolysed in aqueous solution by emulsin. W. G.

Cerebrosides of the Brain. III. HANS THIERFELDER (*Zeitsch. physiol. Chem.*, 1913, **85**, 35—58. Compare Loening and Thierfelder A., 1911, i, 898; 1912, i, 372).—Prolonged treatment of cerebrone with barium hydroxide is shown not to produce any marked change. The cerebrone fraction is found to consist of a crystalline and an amorphous component which have the same composition and optical rotatory power, but differ in solubility. The name cerebrone is retained for the crystalline substance and that of phrenosin restricted to the amorphous form. In addition to the cerebrone fraction the use of a mixture of chloroform and methyl alcohol as solvent resolves the mixed cerebrosides into a very soluble fraction and a fraction of intermediate solubility to which the term kerasin is applied. Acid hydrolysis of

this fraction shows it to be broadly similar to cerebrone. It yields about 20% of galactose, some quantity of dimethylsphingosine as sulphate, and *kerasinic acid*, $C_{24}H_{48}O_2$, which crystallises in slender, long needles, m. p. 77—78°.   E. F. A.

New Derivatives of Artemisin and Santonin. ENRICO RIMINI and TEMISTOCLE JONA (*Chem. Zentr.*, 1913, i, 1773; *from Rend. Soc. Chim. Ital.*, 1913, 5, ii, 52—53. Compare Weinhaus and Oettingen, this vol., i, 474, and Wedekind and Beniers, this vol., i, 476).—These substances have been reduced by Paal's method. *Tetrahydroartemisin*, $C_{15}H_{22}O_4$, forms lustrous leaflets, m. p. 192—193°, and tetrahydrosantonin has m. p. 153—155°. Both compounds are stable towards permanganate.   J. C. W.

"Tecomin." OTTO A. OESTERLE (*Arch. Pharm.*, 1913, 251, 301—303).—The colouring matter described under this name by Lee (T., 1901, 79, 284) as occurring in the wood of *Bignonia tecoma* (Ipé wood or Ipé-tabaco wood) is now shown to be lapachol. The latter also occurs in the timbers of *Tecoma Ipé*, Mart. (Ipé preto), and *Tecoma ochracea* (Ipé amarillo), but not in greenheart wood, derived from *Nectandra Rodiaei.* The usual source of lapachol is "Surinam greenheart" derived from *Bignonia leucoxylon* (compare Stein, *Jahresb.*, 1866, 651).   T. A. H.

[**Bibirubic Acid and Derived Substances.**] HANS FISCHER (*Ber.*, 1913, 46, 1574—1577. Compare Piloty, this vol., i, 500).—Polemical. In regard to disputed questions of nomenclature, the author's proposals are as follow : (1) the acid $C_{17}H_{24}O_3N_2$ (Fischer and Röse, A., 1912, i, 575) is bilirubic acid ; (2) the acid $C_9H_{13}O_2N$ (Piloty and Thannhauser, A., 1912, i, 736) is *iso*phonopyrrolecarboxylic acid ; (3) if, as is probable, xanthobilirubic acid is identical with Piloty's dehydrobilirubic acid (dehydrobilic acid, Piloty and Thannhauser, A., 1912, i, 925), then the latter name should be adopted.   R. V. S.

Constitution of Lutein. CESARE SERONO (*Chem. Zentr.*, 1913, i, 1198; *from Arch. Farmacol. Sperim.*, 1912, 14, 509—511. Compare A., 1911, ii, 1005).—The opinion expressed by Willstätter and Escher that lutein from the yolks of eggs is a xanthophyll (A., 1912, i, 125) cannot be reconciled with that of the author who believes it to be an ethereal combination of cholesterol with unsaturated fatty acids.
       J. C. W.

Angostura Alkaloids. Decomposition Experiments with Cusparine. JULIUS TROGER and W. BECK (*Arch. Pharm.*, 1913, 251, 246—290. Compare A., 1912, i, 895).—Further analyses of cusparine and of its derivatives show that this alkaloid has the formula $C_{19}H_{17}O_3N$ (compare Körner and Böhringer, A., 1884, 341, and Troger and Muller, A., 1910, i, 414). Further descriptions of the purification of this alkaloid and of the isolation of galipoidine and of a new alkaloid are given.

Cusparine, $C_{19}H_{17}O_3N$, appears to be trimorphic, since in addition

to the two forms already described (*loc. cit.*, and A., 1911, i, 482) a third crystallising in long, pale yellow needles, m. p. 91—92°, was obtained by slow crystallisation from light petroleum. The oxalate, $B,C_2H_2O_4,1\frac{1}{2}H_2O$, m. p. 140—150°, crystallises in sulphur-yellow needles from water and is efflorescent. The *succinate*, $B_2,C_4H_6O_4,4\frac{1}{2}H_2O$, m. p. 80°, crystallises in greenish-yellow needles, loses water on standing in a desiccator and becomes anhydrous and colourless when crystallised from alcohol and then melts at 113°. The *malate*, $B,C_4H_6O_5$, m. p. 152°, forms heavy, prismatic crystals from water. The *tartrate*, $B,C_4H_6O_6,1H_2O$, m. p. 161—162°, forms yellow, microscopic crystals from water. The *citrate*, $B,C_6H_8O_7$, m. p. 174° (decomp.), crystallises in long, sulphur-yellow, prismatic needles. All these organic salts on melting yield pyrocusparine, $C_{18}H_{15}O_3N$, m. p. 255°, which crystallises from alcohol in masses of slender, colourless needles (compare Beckurts and Frerichs, A., 1904, i, 84), and yields well-crystallised salts: *hydrochloride*, B,HCl, m. p. 207°, stellate groups of colourless needles; *platinichloride*, B_2,H_2PtCl_6, m. p. above 150° (decomp.), reddish-yellow, glancing needles. Cusparine methiodide, m. p. 190°, yellow prisms; *ethiodide*, m. p. 206—212°, yellowish-brown, prismatic crystals, and the n-*propyl iodide*, m. p. 187° (decomp.), yellow prisms, were prepared. These on treatment with silver hydroxide or potassium hydroxide do not yield as Beckurts supposed (A., 1896, i, 66) the corresponding alkylcusparines, but the same *isomeride* of cusparine, m. p. 194°, crystallising from alcohol in colourless, prismatic needles, containing water of crystallisation, which is lost at 105°. This substance yields a *platinichloride*, m. p. 185° (approx.), crystallising in microscopic needles and with nitric acid yields a *nitro*-compound, $C_{19}H_{16}O_5N_2$, m. p. 234—235°, which forms greenish-yellow crystals from alcohol. Cusparine is optically inactive, does not react with hydroxylamine, yields no definite products when treated with acids or alkalis in closed vessels at 100° and in common with pyrocusparine and "nitrocusparine" (Tröger and Runne, A., 1911, i, 482) contains no ·OH group. When heated for several days at 100° with nitric acid (D = 1·075), cusparine yields an *acid*, $C_{10}H_7O_3N,H_2O$, m. p. 271—272°, which is probably a hydroxyquinolinecarboxylic acid, since on heating at 300° it loses carbon dioxide and furnishes a *base* from which a *platinichloride*, $(C_9H_7ON)_2,H_2PtCl_6,2H_2O$, m. p. 220° (decomp.), forming yellowish-red crystals, was obtained. On distillation over zinc dust the acid yielded quinoline (identified by means of the platinichloride). On the basis of these results a skeleton-formula for cusparine is suggested.

When galipoidine is examined by Zeisel's method it yields less methyl iodide than is required for ·OCH₃ in the formula $C_{19}H_{15}O_4N$ (A., 1911, i, 482).

In the purification of cusparine a fourth *alkaloid*, $C_{10}H_{13}O_2N$ (?), m. p. 186°, crystallising from boiling alcohol in sulphur-yellow, rhombic crystals was obtained.　　　　　　　　　　　　　　　　　　　　　　　T. A. H.

Carpiline or Pilosine. ÉMILE LÉGER and FERDINAND ROQUES (*Compt. rend.*, 1913, 156, 1687—1689).—The two bases, one soluble and the other insoluble in water, obtained by heating carpiline with

water in a sealed tube at 140° for ten hours (compare this vol., i, 83), are shown to be identical with the pilosinine and anhydropilosine of Pyman (compare T., 1912, **101**, 2260).   W. G.

Ephedrine. ERNST SCHMIDT (*Arch. Pharm.*, 1913, **251**, 320).—It is shown that the asymmetry of ephedrine and ψ-ephedrine cannot be solely dependent on the ·CH(OH)· group, since the conversion of this into a ·CH$_2$· group does not destroy the optical activity.

A *base*, C$_{10}$H$_{15}$N (hydrochloride has $[a]_D$ +19·14°), has been prepared by treating ephedrine hydrochloride with phosphorus pentabromide and reducing the *bromide*, C$_{10}$H$_{14}$NBr,HBr (glistening leaflets), with zinc and hydrochloric acid. This bromide on treatment with silver nitrate does not regenerate ephedrine, but gives ψ-ephedrine, m. p. 117°, $[a]_D$ +49·45° (compare A., 1912, i, 644). The optical activity of the base C$_{10}$H$_{15}$N must be due to the ·CHNMe group (compare Emde, A., 1909, i, 77; Gadamer, *ibid.*, i, 49), which, moreover, cannot be situated at the end of the ·C$_3$H$_7$ chain.   T. A. H.

The Homologues of Morphine, Codeine and Dionine, and Some of their Derivatives. FRIEDRICH FERREIN (*Chem. Zentr.*, 1913, i, 1696—1698).—Attempts have been made to prepare a hydroxycodeine by the elimination of the amino-group from amino-codeine and to obtain nitroethyl- and aminoethyl-morphine. Vonger-ichten and Weilinger (A., 1905, i, 542) obtained diacetylaminocodeine by the reduction of nitrocodeine with tin and acetic acid, whereas the *mono*-derivative, C$_{20}$H$_{24}$O$_4$N$_2$, has now been obtained by the same method. It yields a hydrochloride and a sulphate, and also *acetylamino-codeine methiodide*, C$_{21}$H$_{27}$O$_4$N$_2$I, as a white substance, m. p. 215—216°, which is converted into triacetylaminomethylmorphol (*ibid.*) on heating with acetic anhydride and silver acetate. When nitrocodeine is reduced by stannous chloride, however, the product is *aminocodeine*, C$_{18}$H$_{22}$O$_3$N$_2$, which forms pale yellow crystals, m. p. 224°, and gives what is probably a hydroxy-compound on diazotising and warming.

Ethylmorphine (dionine) has also been nitrated. *Nitroethylmorphine*, C$_{19}$H$_{22}$O$_5$N$_2$, forms yellow crystals, m. p. 166—167°; *aminoethyl-morphine*, obtained by reduction with stannous chloride, has m. p. 115—116°; *acetylaminoethylmorphine*, by reduction with tin and acetic acid, forms a pale yellow *hydrochloride*; and *diacetylaminoethyl-morphine*, C$_{23}$H$_{28}$O$_5$N$_2$, prepared by acetylating the amino-compound, has m. p. 156°.

All these substances give very similar reactions with formaldehyde-sulphuric acid, Froehde's and Erdmann's reagents.   J. C. W.

Action of Acylamino-acid Chlorides on Ethyl and Methyl Sodiomalonate and Ethyl Sodiocyanoacetate. II. ERNST PFAEHLER (*Ber.*, 1913, **46**, 1702—1716. Compare this vol., i, 622).— A mixture of a benzene solution of phthalylglycyl chloride with ethyl sodiomalonate (compare Gabriel and Colman, A., 1909, i, 491) gives a clear liquid from which during several days there separates the sodium derivative of *ethyl γ-phthalimino-β-ketopropanedicarboxylate*,

$$C_6H_4\!\!<^{CO}_{CO}\!\!>N\cdot CH_2\cdot CO\cdot CH(CO_2Et)_2,$$
prisms, m. p. 68—68·5°; this ester with an alcoholic solution of sodium ethoxide yields needles of the *sodium* derivative, whilst it dissolves in aqueous ammonia solution shortly depositing the *ammonium* derivative, decomp. at 210°, m. p. 255—260°; it has an acid reaction, and gives a deep red coloration with ferric chloride in alcoholic solution; in chloroform solution it reacts with bromine, forming a *bromo*-derivative, $C_{17}H_{16}O_7NBr$, needles, m. p. 122—122·5°, whilst the corresponding *chloro*-compound forms needles, m. p. 95—96°. The sodium derivative when boiled with water and the solution acidified yields phthalylglycine, whilst the ketonic acid is decomposed by boiling with concentrated hydrochloric acid with the production of aminoacetone hydrochloride. When heated for six hours at 185° with benzyl chloride, the sodium derivative is converted into *ethyl γ-phthalimino-β-keto-a-benzylpropanedicarboxylate*,

$$C_6H_4{<}^{CO}_{CO}{>}N·CH_2·CO·C(CH_2Ph)(CO_2Et)_2,$$
cubes, m. p. 98°. The free ester, ethyl phthalylglycylmalonate, when warmed with water at 100°, undergoes hydrolysis with subsequent loss of a molecule of carbon dioxide, giving rise to *ethyl γ-phthaliminoacetoacetate*, m. p. 110°; this gave a coloration with ferric chloride, but no metallic derivatives could be isolated ; the *aa-dibromo*-derivative,

$$C_6H_4{<}^{CO}_{CO}{>}N·CH_2·CO·CBr_2·CO_2Et,$$
m. p. 87—88°, was obtained by direct substitution in chloroform solution.

Phthalylglycyl chloride in benzene solution readily reacts with a bimolecular proportion of ethyl sodiocyanoacetate ; the *sodium* derivative which separates, on treatment with hydrochloric acid, yields the free *ethyl γ-phthalimino-a-cyano-β-keto-n-butyrate*,

$$C_6H_4{<}^{CO}_{CO}{>}NH·CH_2·CO·CH(CN)·CO_2Et,$$
needles, m. p. 148—149°; on boiling with water, this substance undergoes considerable change, and after a few hours pure phthalic acid is obtained.

The clear liquid, obtained by mixing ethyl sodiomalonate and phthalyl-β-alanyl chloride in benzene slowly deposits the *sodium* derivative of *ethyl δ-phthalimino-β-ketobutanedicarboxylate*,

$$C_6H_4{<}^{CO}_{CO}{>}NH·CH_2·CH_2·CO·CH(CO_2Et)_2 ;$$
the free ester, needles, m. p. 68—69°, can be liberated by hydrochloric acid ; it is a strongly acidic substance, which with ferric chloride gives a red coloration, and when boiled with water yields ethyl δ-phthalimino-β-keto-*n*-valerate, m. p. 121—122°.

Phthalylphenylglycyl chloride, m. p. 141—143°, was prepared by treating the acid with phosphorus pentachloride ; its interaction with ethyl sodiomalonate yielded the *sodium* derivative of *ethyl γ-phthalimino-β-keto-γ-phenylpropanedicarboxylate*,

$$C_6H_4{<}^{CO}_{CO}{>}N·CHPh·CO·CH(CO_2Et)_2 ;$$
the free ester, leaflets and prisms, m. p. 104—105°, is acid in reaction,

and gives a red colour with ferric chloride ; when boiled with a mixture of concentrated hydrochloric acid and acetic acid it undergoes scission, producing α-aminobenzyl methyl ketone.

α-Phthalimino-α-ethyl-n-butyryl chloride and ethyl sodiomalonate give as reaction product the yellow *sodium* salt of *ethyl γ-phthalimino-β-keto-γ-ethyl-n-pentanedicarboxylate,*

$$C_6H_4\!<^{CO}_{CO}\!\!>\!N\cdot CEt_2\cdot CO\cdot CH\cdot(CO_2Et)_2 \; ;$$
the free ester, prisms, m. p. 72—73°, gives the ferric chloride reaction, but is not appreciably acidic ; unlike the esters described above, when warmed with sodium ethoxide, it undergoes rearrangement, yielding an acid *substance*, which from analogy with the corresponding *gem*-dimethyl compound (Pfaehler, *loc. cit.*) is probably a pyrrolidone derivative of the structure $CO_2Et\cdot C_6H_4\cdot CO\cdot N\!<^{CO-CH\cdot CO_2Et}_{CEt_2\cdot CO}$. In the original preparation, involving the acid chloride and ethyl sodiomalonate, the sodium derivative produced is accompanied by a substance, cubical crystals, m. p. 229—230°, insoluble in water, which proves to be *α-phthalimino-α-ethyl-n-butyric anhydride,* a remarkably stable substance, which is not affected by phosphorus pentachloride or boiling water or alcohol. Another by-product occurring in smaller quantity is *ethyl benzoylenediethylpyrrolonecarboxylate,* $^{C_6H_4\cdot C:C(CO_2Et)}_{CO-N-CEt_2}\!\!>\!CO$, a lemon-yellow substance, m. p. 85—85·5°, which is obtained in larger quantity if the reaction mixture is kept for a longer time under benzene containing an additional quantity of ethyl sodiomalonate. The normal ester, m. p. 72—73°, when boiled for thirty minutes with hydriodic acid (b. p. 127°) undergoes scission, yielding *methyl α-amino-α-ethyl-n-propyl ketone hydriodide,* short, columnar crystals, m. p. 184—186° ; *hydrochloride,* silky needles, m. p. 236—236·5° ; *platinichloride,* lemon-yellow needles, m. p. 188° (decomp.) ; *picrate,* yellow needles, m. p. 166° ; *benzoyl* derivative, needles, m. p. 80—81° ; the free base has an odour resembling that of turpentine.

Methyl sodiomalonate behaves like the corresponding ethyl compound towards phthaliminoethylbutyryl chloride, producing as by-product the same acid anhydride as mentioned above, together with the *sodium* derivative of *methyl γ-phthalimino-β-keto-γ-ethyl-n-pentanedicarboxylate* as main product ; the free ester, prisms, m. p. 97—98°, is neutral, but gives the ferric chloride reaction ; with sodium ethoxide it shows the same behaviour as the ethyl ester, whilst its sodium derivative when heated with methyl iodide in acetone solution is converted into *methyl δ-phthalimino-γ-keto-γ-ethyl-n-hexane-$\beta\beta$-dicarboxylate,*

$$C_6H_4\!<^{CO}_{CO}\!\!>\!N\cdot CEt_2\cdot CO\cdot CMe(CO_2Me)_2,$$
needles, m. p. 113—114°, which gives no ferric chloride reaction. Again, like the ethyl ester, the methyl ester in benzene solution is converted by the action of methyl sodiomalonate into *methyl benzoylenediethylpyrrolonecarboxylate,* lemon-yellow needles, m. p. 109—110° ; this and also the corresponding ethyl ester are converted by hydrobromic acid into

diethylpy rrolonebenzo acid hydrobromide, yellow cubes, m. p. 214° (decomp.), which by the action of water or alkali yields *diethyl-pyrrolonebenzoic acid,* $\mathrm{CO-CH}^{\mathrm{CEt_2 \cdot NH}} > \mathrm{C \cdot C_6H_4 \cdot CO_2H}$, prisms and leaflets, m. p. 184·5—185° (decomp.); this on heating to 200° passes into the corresponding *lactam (benzoylenediethylpy rrolone),* $\mathrm{CO-N-CEt_2}^{\mathrm{C_6H_4 \cdot C=CH}} > \mathrm{CO}$, colourless needles, m. p. 71°.

a-Phthalimino-a-methyl-*n*-butyryl chloride in a similar manner with ethyl sodiomalonate gives the corresponding *phthaliminomethylbutyric anhydride,* cubes, m. p. 183°, insoluble in water, together with the expected sodium derivative, from which carbon dioxide liberates *ethyl γ-phthalimino-β-keto-γ-methyl-n-pentanedicarboxylate,*

$$\mathrm{C_6H_4}{<}^{\mathrm{CO}}_{\mathrm{CO}}{>}\mathrm{N \cdot CMeEt \cdot CO \cdot CH \cdot (CO_2Et)_2} \ ;$$
this is a neutral oil which gives an intense coloration with ferric chloride. When this substance is heated in alcoholic solution with sodium ethoxide, or its sodium derivative heated in alcohol, a soluble sodium salt is produced, from which hydrochloric acid frees an isomeric *pyrrolidine derivative,* $\mathrm{CO-CMeEt}^{\mathrm{CH(CO_2Et) \cdot CO}} > \mathrm{N \cdot CO \cdot C_6H_4 \cdot CO_2Et}$, m. p. 110°, which on heating with dilute acid is converted into *carbethoxybenzoyl-methylethyltetramic acid* [*ethyl 3 : 5-diketo-1-benzoyl-2-methyl-2-ethylpyr rolidine-o-carboxylate*], $\mathrm{CO \cdot CMeEt}^{\mathrm{CH_2-CO}} > \mathrm{N \cdot CO \cdot C_6H_4 \cdot CO_2Et}$, an acidic substance, m. p. 186—187°. The application of sodium methoxide to the same oily ethyl ester, or of methyl alcohol to its sodium derivative in a similar manner, causes a replacement of ethyl by methyl, the pyrrolidine *derivative,* prisms, m. p. 139—140°, produced being of the structure $\mathrm{CO-CMeEt}^{\mathrm{CH(CO_2Et) \cdot CO}} > \mathrm{N \cdot CO \cdot C_6H_4 \cdot CO_2Me}$; the acidity of this substance is sufficient to cause its aqueous solution when heated to eliminate the carbethoxy-group with formation of *methyl 3 : 5-diketo-1-benzoyl-2-methyl-2-ethylpyrrolidine-o-carboxylate,*

$$\mathrm{CO-CMeEt}^{\mathrm{CH_2-CO}} > \mathrm{N \cdot CO \cdot C_6H_4 \cdot CO_2Me},$$
m. p. 209°, which reacts with bromine in chloroform solution, giving a neutral *dibromo*-derivative, m. p. 166—167°, by displacement of the methylene hydrogen atoms in the ring.

a-Phthalimino-a-methyl-*n*-butyryl chloride reacts with methyl sodiomalonate, yielding needles or prisms of *methyl γ-phthalimino-β-keto-γ-methyl-n-pentanedicarboxylate,* m. p. 98—99°, which colours ferric chloride blood-red. This substance with sodium ethoxide undergoes rearrangement into a pyrrolidine *compound,*

$$\mathrm{CO-CMeEt}^{\mathrm{CH(CO_2Me) \cdot CO}} > \mathrm{N \cdot CO \cdot C_6H_4 \cdot CO_2Et},$$
needles, m. p. 108—109ᵛ (of which an isomeride, m. p. 139—140°, has been described above), which when boiled with water yields the

pyrrolidine derivative, m. p. 186—187°, described earlier. Sodium methoxide on the other hand yields a *compound*,

$$\begin{array}{c} CH(CO_2Me)\cdot CO \\ CO\text{-----}CMeEt \end{array}\!\!>\!N\cdot CO\cdot C_6H_4\cdot CO_2Me,$$
prisms, m. p. 146—147°, which is more acid in character than acetic acid, and which easily loses the carbomethoxy-group, producing the pyrrolidine derivative, m. p. 209°.

The action of ethyl sodiocyanoacetate on α-phthalimino-α-methyl-*n*-butyryl chloride gives a yellow *sodium* derivative, from which acetic acid liberates *ethyl γ-phthalimino-α-cyano-β-keto-γ-methyl-n-hexoate*,

$$C_6H_4\!\!<\!\!\begin{array}{c} CO \\ CO \end{array}\!\!>\!N\cdot CMeEt\cdot CO\cdot CH(CN)\cdot CO_2Et,$$
m. p. 140°; this loses carbon dioxide when boiled with water, but the decomposition is not a simple one.

The pyrrolone condensation observed with phthaliminoethyl-*n*-butyryl chloride and excess of ethyl or methyl sodiomalonate occurs under the same conditions with the phthaliminomethylbutyryl compounds. *Methyl benzoylenemethylethylpyrrolonecarboxylate*,

$$\begin{array}{c} C_6H_4\cdot C\!=\!C(CO_2Me) \\ CO\text{---}N\text{-----}CMeEt \end{array}\!\!>\!CO,$$

forms yellow prisms, m. p. 130—131°; the corresponding yellow *ethyl* ester forms prisms, m. p. 112°. Both these esters react with hydrobromic acid, D 1·48, producing *methylethylpyrrolonebenzoic acid hydrobromide*, yellow needles, from which alkali in theoretical quantity separates the free *acid*,

$$\begin{array}{c} CO\text{-----}OH \\ CMeEt\cdot NH \end{array}\!\!>\!C\cdot C_6H_4\cdot CO_2H,\ \text{prisms,}$$

m. p. 177° (decomp.), which above its m. p. passes into *benzoylenemethylethylpyrrolone*,

$$\begin{array}{c} C_6H_4\cdot C\!=\!CH \\ CO\text{---}N\cdot CMeEt \end{array}\!\!>\!CO,\ \text{needles, m. p. 94—95°.}$$

If methyl γ-phthalimino-β-keto-γ-methyl-*n*-pentanedicarboxylate is submitted to the action of methyl iodide in boiling acetone solution it is methylated to *methyl δ-phthalimino-γ-ketomethyl-n-hexane-ββ-dicarboxylate*, $C_6H_4\!\!<\!\!\begin{array}{c} CO \\ CO \end{array}\!\!>\!N\cdot CMeEt\cdot CO\cdot CMe(CO_2Me)_2,$ prisms, m. p.

104°; this substance, which gives no ferric chloride reaction, is converted by boiling hydrochloric acid into oily *γ-amino-γ-methylhexan-δ-one*,

$$NH_2\cdot CMeEt\cdot COEt,$$

hydrochloride, crystalline; *picrate*, leaflets, m. p. 147—148°.　D. F. T.

3-Nitropyridine and some of its Reduction Products. FRANZ FRIEDL (*Monatsh.*, 1913, **34**, 759—767).—The nitration of pyridine (A., 1912, i, 299) is most conveniently effected by the gradual addition of a solution of potassium nitrate in nitric acid (D 1·5) to a mixture of pyridine with an excess of sulphuric acid at 290—300°. It has already been shown that the product, 3-nitropyridine, is convertible by energetic reduction in acid solution into 3-aminopyridine, but it is now found that the analogy to nitrobenzene is still greater, extending to the successive formation of an azoxy-, azo-, and hydrazo-derivative when reduced in alkaline media.

3-Nitropyridine forms colourless needles, m. p. 41°, b. p. 216°;

hydrochloride, colourless leaflets, m. p. 154°; *sulphate*, hygroscopic crystals; *aurichloride*, yellow needles, m. p. 140°, *platinichloride*, broad, yellow needles, decomp. at 254°; *argentonitrate*,

$$(C_5H_4O_2N_2)_2,AgNO_3,$$
colourless needles, m. p. 175—176°.

When 3-nitropyridine is treated with a boiling solution of arsenious oxide in aqueous sodium hydroxide under reflux, it is reduced almost quantitatively to the corresponding *azoxypyridine*, silky needles, m. p. 130—131°, to a yellow liquid, which can be further reduced by zinc dust and alcoholic sodium hydroxide to *azopyridine*, orange-red needles, m. p. 142°, the yield again being almost the theoretical. The application of sodium methoxide as reducing agent for the production of the azoxy-compound and of iron filings for the azo-compound is unsatisfactory, yielding a complex mixture in each case and consequently an impure product.

If azopyridine is treated with zinc dust and boiling aqueous alcoholic sodium hydroxide in an atmosphere of hydrogen, reduction occurs with the formation of an 80% yield of *hydrazopyridine*, colourless needles, m. p. 202°; the pure substance is stable, but in alkaline alcoholic solution it undergoes atmospheric oxidation, especially readily on warming, with the production of azopyridine. It was not found possible to reduce hydrazobenzene further.

Partial nitration of pyridine occurs when nitric acid vapour is led into boiling pyridine nitrate, but there are formed simultaneously with 3-nitropyridine, also three other basic substances, m. p. 80°, 120, and 258° respectively; oxides of nitrogen in place of nitric acid lead to a similar result. Pyridine sulphate likewise gives a little 3-nitropyridine, but the main portion of the product consists of an oily mixture, b. p. 240—300°, of basic nature, from which could be isolated a *base*, woolly needles, m. p. 110°; *nitrate*, m. p. 245°; the base is very resistant to oxidising and reducing agents, and it is possibly related to the polymerised nitropyridine obtained by Spencer (P., 1903, **19**, 79).

D. F. T.

Syntheses of the Indole Group. IV. Basic Properties of Indoles, and Polymerides of Indoles. BERNARDO ODDO (*Gazzetta*, 1913, **43**, i, 385—394. Compare A., 1912, i, 649).—The publication of the author's results on polymeric indoles has been anticipated to some extent by that of Keller (this vol., i, 403). Di-indole hydrochloride (compare Keller, *loc. cit.*) is a microcrystalline powder, m. p. 180°, forming a yellow liquid. It can be prepared by the prolonged action of dilute aqueous hydrochloric acid on indole at the ordinary temperature, or by treating indole with concentrated hydrochloric acid for a few minutes, as well as by the action of hydrogen chloride on an anhydrous ethereal solution of indole.

a-Methylindole hydrochloride, C_9H_9N,HCl, may be obtained by the action of hydrogen chloride on an anhydrous ethereal solution of a-methylindole.

The author gives also the results of some preliminary experiments regarding the power of indoles to form simple or double salts.

R. V. S.

Condensation of Primary and Secondary Aromatic Amines with Mesoxalic Esters. Synthesis in the Indole Series. ALFRED GUYOT and J MARTINET (*Compt. rend.*, 1913, **156**, 1625—1628).—Schmitt (A., 1905, i, 585) and Curtiss, Hill and Lewis (A., 1911, i, 366) obtained anilino-derivatives of the type $NHPh \cdot C(CO_2R)_2 \cdot OH$; $NPh:C(CO_2R)_2$; $NHPh \cdot C(CO_2R)_2 \cdot NHPh$ by the interaction of aromatic amines with mesoxalic esters. The authors have, however, obtained, as principal product of such reactions an ester of dioxindole-3-carboxylic acid (annexed formula), which is saponified by aqueous potassium hydroxide in the absence of air, giving the corresponding dioxindole, carbon dioxide being eliminated. In an open vessel oxygen is rapidly absorbed, and the product formed is the corresponding isatin. The amine is warmed with the mesoxalic ester in acetic acid solution at 60° for one hour, and then the acid and residual amine are removed by steam. From the product any phenyltartronic acid produced is extracted with hydrochloric acid, and the residual indole derivative is crystallised from ether.
From *p*-toluidine the authors have prepared *methyl 5-methyldioxindole-3-carboxylate*, m. p. 251°, the *ethyl* ester, m. p. 212°, 5-*methyldioxindole*, m. p. 210°, and the corresponding isatin.

From β-naphthylamine, *methyl 3-hydroxy-2-ketodihydro-ββ-naphthindole-3-carboxylate*, m. p. above 300°, the *ethyl* ester, m. p. 210°, and the corresponding dioxindole and isatin.

From methylaniline, *methyl 1-methyldioxindole-3-carboxylate*, m. p. 217°, the *ethyl* ester, m. p. 130°, *methyl p methylaminophenyltartronate*, m. p. 85°, and the dioxindole and isatin.

From ethylaniline, *ethyl 1-ethyldioxindole-3-carboxylate*, m. p. 141°, *ethyl p-ethylaminophenyltartronate*, m. p. 65°, the dioxindole, and isatin.

From ethyl-β-naphthylamine, *ethyl 2-hydroxy-3-keto-1-ethyldihydro-ββ-naphthindole-3-carboxylate*, m. p. 181°, the *dioxindole*, m. p. 172°, and the *isatin*, fine red needles, m. p. 173°.

From tetrahydroquinoline, *methyl 1:7-trimethylenedioxindole-3-carboxylate* (formula I), m. p. 188°, the *ethyl* ester, m. p. 174°, 1:7-*trimethylenedioxindole* (formula II), m. p. 160°, and 1:7-*trimethyleneisatin* (formula III), deep red prisms, m. p. 195°.
W. G.

1-Methylisatins. MORITZ KOHN and ALFONS OSTERSETZER (*Monatsh.*, 1913, **34**, 787—794).—In the preparation of 1-methylisatin from isatin there is no necessity to isolate the intermediate

sodium derivative of isatin (compare Heller, A., 1907, i, 442), and the subsequent reaction with methyl iodide in a sealed tube can also be avoided. If isatin is treated with the calculated quantity of 25% methyl-alcoholic potassium hydroxide, the separation of the blue potassium derivative gives rise to a paste which on the addition of methyl sulphate (under reflux) enters into reaction so vigorously that the mixture boils; 1-methylisatin can be easily separated from the reaction mixture (compare Friedländer and Kielbasinski, A., 1911, i, 1021).

Following a similar course 5-bromoisatin can be converted into 5-*bromo*-1-*methylisatin*, red, microscopic needles, m. p. indistinct at 164°, and 5 : 7-dibromoisatin into 5 : 7-*dibromo*-1-*methylisatin*, red, microscopic needles, m. p. indistinct at 171°. In these cases the sodium compounds react less vigorously with methyl sulphate than does the sodium compound of the unsubstituted isatin.

If carefully dried methylisatin is treated in boiling acetic anhydride containing a little acetic acid, with small quantities of zinc dust until decolorisation is complete, diacetyl-1 : 1'-dimethylisatyd,

$$NMe\left\langle{}^{C_6H_4}_{CO}\right\rangle{}O(OAc)\cdot C(OAc)\left\langle{}^{C_6H_4}_{CO}\right\rangle{}NMe,$$
colourless, rhombohedral crystals, m. p. 218—220°, is obtained.

1-Methylisatin reacts with magnesium phenyl bromide in ethereal solution, giving a yellow, microcrystalline *substance*, $C_{21}H_{17}ON$, m. p. 145°; this is probably of the structure $^{C_6H_4\cdot CPh}_{NMe-CPh}\!\!>\!\!O$, produced by elimination of the elements of water from the ditertiary alcohol first formed by the action of the Grignard reagent on the two ketonic groups. **D. F. T.**

Some Derivatives of *cyclo*Hexanone and the Three Methyl-*cyclo*hexanones. VINCENZO SQUINTANI (*Atti R. Accad. Sci. Torino*, 1912–13, **48**, 675—686. Compare Guareschi, A., 1911, i, 792).—On warming a mixture of *cyclo*hexanone, ethyl cyanoacetate, and an alcoholic solution of methylamine, *aa'*-*dicyanocyclohexane*-1 : 1-*diaceto-methylimide*, $CH_2\left\langle{}^{CH_2\cdot CH_2}_{CH_2\cdot CH_2}\right\rangle{}C\left\langle{}^{CH(CN)\cdot CO}_{CH(CN)\cdot CO}\right\rangle{}NMe$, is produced; it has m. p. 175°. Its aqueous solution, when neutralised by ammonia, gives a blue precipitate with copper sulphate and a white, flocculent precipitate with silver nitrate. When treated with bromine it yields a white, flocculent compound, probably the *dibromide*, and when this is boiled with 10% alcoholic formic acid, *aβ-dicyano-aβ-cyclohexane-succinomethylimide*, $CH_2\left\langle{}^{CH_2\cdot CH_2}_{CH_2\cdot CH_2}\right\rangle{}C\left\langle{}^{C(CN)\cdot CO}_{C(CN)\cdot CO}\right\rangle{}NMe$, is formed; it is a white, crystalline substance, m. p. 222°.

When a mixture of 1-methyl*cyclo*hexan-4-one, ethyl cyanoacetate and alcoholic ammonia is kept for some hours, an ammoniacal salt is deposited; from this, by the action of dilute acid, the *imide* of *aa'-dicyano-1-methylcyclohexane-4 : 4-diacetic acid*,

$$CHMe\left\langle{}^{CH_2\cdot CH_2}_{CH_2\cdot CH_2}\right\rangle{}C\left\langle{}^{CH(CN)\cdot CO}_{CH(CN)\cdot CO}\right\rangle{}NH,$$
m. p. 210—211°, is obtained. Its *copper* salt is a chestnut-coloured precipitate which becomes yellowish-green ; when it is made anhydrous and heated, it assumes at about 120° a red tint, which disappears on cooling. The imide of m. p. 210—211° yields a *dibromo*-derivative, from which *αβ-dicyano-αβ-1-methylcyclohexane-4 : 4-succinimide*,

$$\text{CHMe} \begin{array}{c} \text{CH}_2\cdot\text{CH}_2 \\ \text{CH}_2\cdot\text{CH}_2 \end{array} \text{C} \begin{array}{c} \text{C(CN)}\cdot\text{CO} \\ \text{C(CN)}\cdot\text{CO} \end{array} \text{NH},$$
m. p. 207—208°, can be prepared.

αα'-Dicyano-1-methylcyclohexane-4 : 4-diacetomethylimide,

$$\text{CHMe} \begin{array}{c} \text{CH}_2\cdot\text{CH}_2 \\ \text{CH}_2\cdot\text{CH}_2 \end{array} \text{C} \begin{array}{c} \text{CH(CN)}\cdot\text{CO} \\ \text{CH(CN)}\cdot\text{CO} \end{array} \text{NMe},$$
has m. p. 181—182°. It yields a crystalline *bromo*-derivative, m. p. 137°, which on treatment with an aqueous solution of sulphurous acid gives *αβ-dicyano-αβ-1-methylcyclohexane-4 : 4-succinomethylimide*,

$$\text{CHMe} \begin{array}{c} \text{CH}_2\cdot\text{CH}_2 \\ \text{CH}_2\cdot\text{CH}_2 \end{array} \text{C} \begin{array}{c} \text{C(CN)}\cdot\text{CO} \\ \text{C(CN)}\cdot\text{CO} \end{array} \text{NMe},$$
m. p. 182—183°.

1-Methyl*cyclo*hexan-2-one yields similar products.

The *ammonium* salt, $C_{13}H_{18}O_2N_4$, obtained from 1-methyl*cyclo*hexan-2-one, ethyl cyanoacetate, and alcoholic ammonia has m. p. 165°. The corresponding *αα'-dicyano-1-methylcyclohexane-2 : 2-diacetimide*,

$$\text{CH}_2 \begin{array}{c} \text{CH}_2\cdot\text{CHMe} \\ \text{CH}_2\text{---}\text{CH}_2 \end{array} \text{C} \begin{array}{c} \text{CH(CN)}\cdot\text{CO} \\ \text{CH(CN)}\cdot\text{CO} \end{array} \text{NH},$$
has m. p. 210°. Its *copper* salt is a rusty-red precipitate which turns bluish-green.

αβ-Dicyano-αβ-1-methylcyclohexane-2 : 2-succinimide,

$$\text{CH}_2 \begin{array}{c} \text{CH}_2\cdot\text{CHMe} \\ \text{CH}_2\text{---}\text{CH}_2 \end{array} \text{C} \begin{array}{c} \text{C(CN)}\cdot\text{CO} \\ \text{C(CN)}\cdot\text{CO} \end{array} \text{NH},$$
is a microcrystalline substance, m. p. 235—236°.

αα'-Dicyano-1-methylcyclohexane-2 : 2-diacetomethylimide,

$$\text{CH}_2 \begin{array}{c} \text{CH}_2\cdot\text{CHMe} \\ \text{CH}_2\text{---}\text{CH}_2 \end{array} \text{C} \begin{array}{c} \text{CH(CN)}\cdot\text{CO} \\ \text{CH(CN)}\cdot\text{CO} \end{array} \text{NMe},$$
has m. p. 181—182°.

αα'-Dicyano-1-methylcyclohexane-3 : 3-diacetomethylimide,

$$\text{CH}_2 \begin{array}{c} \text{CHMe}\cdot\text{CH}_2 \\ \text{CH}_2\text{---}\text{CH}_2 \end{array} \text{C} \begin{array}{c} \text{CH(CN)}\cdot\text{CO} \\ \text{CH(CN)}\cdot\text{CO} \end{array} \text{NMe},$$
has m. p. 154°; in its preparation, a *substance* of m. p. 195—198° is also met with.   R. V. S.

Preparation of Nitro-*N*-alkylcarbazoles. FARBWERKE VORM. MEISTER, LUCIUS & BRUNING (D.R.-P. 259504).—The nitration of *N*-alkylcarbazoles has previously given rise to a mixture of difficultly separable nitro-derivatives, but it is now found that if nitrous acid is employed definite compounds are obtained.

Nitro-9-ethylcarbazole, yellow crystals, m. p. 128°, is obtained when 9-ethylcarbazole (200 parts) in benzene (1000 parts) is mixed with a concentrated aqueous solution of sodium nitrite, and 600 parts of hydrochloric acid slowly added with efficient stirring at the ordinary temperature and the mixture subsequently boiled. *Nitro-9-methylcarbazole* forms small needles, m. p. 147—148°.   F. M. G. M.

Preparation of Arylanthraquinone Derivatives. FARBEN-
FABRIKEN VORM. FRIEDR. BAYER & CO. (D.R.-P. 259037. Compare this
vol., i, 95—105).—4-p-*Toluidino*-1 : 2 *anthrathiazole*, dark blue needles,
is obtained by boiling 1-amino-4-p-toluidinoanthraquinone-2-
mercaptan with benzaldehyde (3 parts) and nitrobenzene (3 parts) ; on
sulphonation it furnishes a *compound* which dyes wool a fast violet
colour.

The analogous *compound* from 2-amino-1-p-toluidino-3-thioanthra-
quinone and benzaldehyde is obtained in brownish-violet prisms.

F. M. G. M.

Syntheses of Alkyloxymalachite-greens by means of
Magnesium Aryl Haloids. EMIL VOTOČEK and J. MATĚJKA (*Ber.*,
1913, 46, 1755—1759).—The present work has been undertaken with
the object of gaining insight into certain discrepancies observed in
condensations with tetramethyldiaminobenzhydrol (Votoček and
Jelínek, A., 1907, i, 245 ; Votoček and Krauz, A., 1909, i, 518).
The use of Grignard's reagents presents the advantage that operations
can be performed at a comparatively low temperature. A series of
alkyloxymalachite-greens has been prepared from the magnesium
derivatives of halogenated phenol ethers and Michler's ketone on the
one hand, and from methyl anisate and the magnesium derivative of
p-bromodimethylaniline on the other.

p-Methoxymalachite-green, obtained by the action of magnesium
p-anisyl bromide on an ethereal suspension of Michler's ketone and
subsequent decomposition of the product formed with hydrochloric acid
and reduction with sodium hyposulphite, has m. p. 106°, and is
identical with the compound prepared from anisaldehyde and dimethyl-
aniline. The same substance is formed when ethereal solutions of
magnesium p-dimethylaminophenyl bromide and methyl anisate (m. p.
46°, b. p. 255°) are mixed.

p-Ethoxymalachite-green is obtained in a similar manner from
magnesium p-phenetole bromide and Michler's ketone, and is identical
with the substance produced from p-ethoxybenzaldehyde and dimethyl-
aniline.

m-Methoxymalachite-green is prepared by the gradual addition of an
ethereal solution of magnesium m-methoxyphenyl iodide to a boiling
solution of Michler's ketone in benzene and subsequent reduction to
the leuco-base. It has m. p. 123°, and is identical with m-methoxy-
tetramethyldiaminotriphenylmethane prepared from m-methoxybenz-
aldehyde and dimethylaniline.

o-Methoxymalachite-green, prepared from magnesium o-methoxy-
phenyl iodide and Michler's ketone, is identical with the product
obtained from o-methoxybenzaldehyde and dimethylaniline. H. W.

Further Investigations of Alkyloxy-derivatives of Malachite-
Green. EMIL VOTOČEK and J. KOHLER (*Ber.*, 1913, 46, 1760—1769.
Compare A., 1907, i, 245 ; 1909, i, 518 ; also previous abstract).—A
difference has been previously noted between the leuco-bases obtained
from alkyloxybenzaldehydes and dimethylaniline, and those prepared

from tetramethyl-*p*-diaminobenzhydrol and phenolic ethers. This is now attributed to the transformation of the methoxy- into the hydroxy-group under the conditions of the experiments. The work has been further extended to ethoxy-derivatives and to polyhydroxy-phenols.

Tetraethyldiaminobenzhydrol is prepared by reduction of tetra-ethyldiaminobenzophenone by sodium and alcohol or by oxidation of *tetraethyldiaminodiphenylmethane*, m. p. 41°, with lead peroxide. It condenses with phenol in the presence of hydrochloric acid, forming p′-*hydroxy*-p″ : p‴-*tetraethyldiaminotriphenylmethane*, m. p. 110—111°, which is also obtained by heating *p*-hydroxybenzaldehyde and diethyl-aniline with hydrochloric acid and a little alcohol at 125° for twelve hours. When oxidised with chloranil, it gives a green dye which becomes violet on addition of alkali.

Tetraethyldiaminobenzhydrol does not react readily with anisole in the presence of hydrochloric acid, and does not yield a uniform product. On the other hand, anisaldehyde readily condenses with diethylaniline, yielding p′-*methoxy*-p″ : p‴-*tetraethyldiaminotriphenylmethane*, m. p. 65°. In the hope of obtaining an abnormal base of betaine-like structure (A., 1909, i, 519), the substance was heated with hydrochloric acid at 120° during two hours. The products of the action consisted of methyl chloride and *p*′-hydroxy-*p*″ : *p*‴ - tetraethyldiaminotriphenyl-methane. Since hydrochloric acid was found to have a similar action in the methoxy-series, the supposed existence of a larger number of isomerides is disproved, and the supposition of a betaine-like structure is rendered unnecessary.

p′-Hydroxy-*p*″ : *p*‴-tetramethyldiaminotriphenylmethane, m. p. 165°, is obtained from *p*-hydroxybenzaldehyde and dimethylaniline, and also from phenol and Michler's hydrol. The same substance is isolated with difficulty from the product of the action of hot concentrated hydro-chloric acid on a mixture of anisole and Michler's hydrol, the methyl group being partly eliminated during the reaction. That this is actually the case is proved by the isolation of the acetyl derivative of *p*′-hydroxy-*p*″:*p*‴-tetramethyldiaminotriphenylmethane, m. p. 145—146°, by the action of acetic anhydride on the above product, whereas, under the conditions employed, this reagent does not attack *p*′-methoxy-*p*″ : *p*‴-tetramethyldiaminotriphenylmethane. The latter substance evolves methyl chloride when heated with hydrochloric acid at 120°, and is converted into *p*′-hydroxy-*p*″ : *p*‴-tetramethyldiaminotriphenyl-methane. When the last-named substance is acted on by methyl sulphate, an impure product is obtained from which the hydroxy-compound can be regained after repeated crystallisation (compare A., 1909, i, 519).

Similarly, the compound obtained from Michler's hydrol and phenetole, and that from *p*-ethoxyleucomalachite-green and hydrochloric acid are shown to be *p*-hydroxyleucomalachite-green.

The methyl group is also completely eliminated from *m*-methoxy-leucomalachite-green by treatment with hydrochloric acid at 120° during two hours. *o*-Methoxyleucomalachite-green is not completely decomposed under these conditions.

p-*Dimethoxyleucomalachite-green*, m. p. 129—130°, is obtained by the addition of an ethereal solution of magnesium p-dimethoxyphenyl bromide to a solution of Michler's ketone in ether and benzene, and subsequent reduction of the dye formed by means of sodium hyposulphite, whilst the same substance can also be prepared by the condensation of Michler's hydrol and quinol dimethyl ether in the presence of hydrochloric acid and alcohol. When oxidised by chloranil, it yields a green dye, stable towards alkalis.

Michler's ketone may be condensed with catechol in the presence of phosphoryl chloride, and the dye produced is readily reduced to dihydroxytetramethyldiaminotriphenylmethane, m. p. 162—163°. The substance is identical with that obtained from protocatechualdehyde and dimethylaniline, or from catechol and Michler's hydrol. Under similar conditions, resorcinol yields a green *dye*, which becomes violet on addition of alkali; the corresponding leuco-base has not been obtained in the crystalline state. Quinol does not condense with Michler's ketone under these conditions.

The behaviour of these leuco-bases as photographic developers has been investigated. Reducing power is only observed in those cases in which the hydroxyl groups are in the ortho- or para-position.

H. W.

Influence of the Halogens on Phototropy in Hydrazones.

II. FERDINANDO GRAZIANI (*Atti R. Accad. Lincei*, 1913, [v], 22, i, 623—629. Compare A., 1910, i, 777).—The paper describes the hydrazones derived from the three isomeric chlorophenylhydrazines.

None of the o-compounds is phototropic, all the m-derivatives are phototropic, whilst four of the eight p-derivatives prepared are phototropic.

Benzaldehyde-o-chlorophenylhydrazone, $C_6H_4Cl\cdot NH\cdot N\colon CHPh$, crystallises in minute, colourless needles, m. p. 73°.

Anisaldehyde-o-chlorophenylhydrazone, $C_6H_4Cl\cdot NH\cdot N\colon CH\cdot C_6H_4\cdot OMe$, is a white, crystalline powder, m. p. 67°.

Cuminaldehyde-o-chlorophenylhydrazone,
$C_6H_4Cl\cdot NH\cdot N\colon CH\cdot C_6H_4\cdot CHMe_2$,
forms slightly yellow needles, m. p. 67°.

Cinnamaldehyde-o-chlorophenylhydrazone,
$C_6H_4Cl\cdot NH\cdot N\colon CH\cdot CH\colon CHPh$,
crystallises in flat, sulphur-yellow needles, m. p. 99°.

Piperonaldehyde-o-chlorophenylhydrazone,
$C_6H_4Cl\cdot NH\cdot N\colon CH\cdot C_6H_3\colon O_2\colon CH_2$,
forms slightly yellow, flat needles, m. p. 96°.

Anisaldehyde-m-chlorophenylhydrazone,
$C_6H_4Cl\cdot NH\cdot N\colon CH\cdot C_6H_4\cdot OMe$,
crystallises in flat, colourless needles, m. p. 135°.

Cuminaldehyde-m-chlorophenylhydrazone,
$C_6H_4Cl\cdot NH\cdot N\colon CH\cdot C_6H_4\cdot CHMe_2$,
forms flat, colourless needles, m. p. 131°, and is very phototropic.

Cinnamaldehyde-m-chlorophenylhydrazone,
$C_6H_4Cl\cdot NH\cdot N\colon CH\cdot CH\colon CHPh$,
is a yellow, crystalline powder, m. p. 120°.

Piperonaldehyde-m-*chlorophenylhydrazone*,

$$C_6H_4Cl\cdot NH\cdot N:CH\cdot C_6H_3:O_2:CH_2,$$
forms minute, colourless needles, m. p. 95°; it is very strongly phototropic.

Salicylaldehyde-*m*-chlorophenylhydrazone is very feebly phototropic.

p-*Tolualdehyde*-m-*chlorophenylhydrazone*,

$$C_6H_4Cl\cdot NH\cdot N:CH\cdot C_6H_4\cdot Me,$$
is a white, crystalline powder, m. p. 112°.

Benzaldehyde-*p* chlorophenylhydrazone has been prepared by Hewitt (T., 1893, **63**, 873), who gave m. p. 127°; the present author finds m. p. 132°. The substance is phototropic.

Anisaldehyde-p-*chlorophenylhydrazone*, $C_6H_4Cl\cdot NH\cdot N:CH\cdot C_6H_4\cdot OMe$, forms colourless leaflets, m. p. 150°, and is not phototropic.

Cuminaldehyde-p-*chlorophenylhydrazone*,

$$C_6H_4Cl\cdot NH\cdot N:CH\cdot C_6H_4\cdot CHMe_2,$$
forms slightly yellow needles, m. p. 131°, and is very phototropic.

Cinnamaldehyde-p-*chlorophenylhydrazone*,

$$C_6H_4Cl\cdot NH\cdot N:CH\cdot CH:CHPb,$$

crystallises in yellowish-green needles, m. p. 136°; it is phototropic.

Piperonaldehyde-p-*chlorophenylhydrazone*,

$$C_6H_4Cl\cdot NH\cdot N:CH\cdot C_6H_3:O_2:CH_2,$$
forms slightly yellow leaflets, m. p. 143°, and is not phototropic.

Salicylaldehyde-*p*-chlorophenylhydrazone has m. p. 173° (Auwers, A., 1909, i, 440, gave 169—170°). It is not phototropic.

p-*Tolualdehyde*-ɣ-*chlorophenylhydrazone*,

$$C_6H_4Cl\cdot NH\cdot N:CH\cdot C_6H_4Me,$$
crystallises in slightly yellow needles, and is feebly phototropic.

Vanillin-p-*chlorophenylhydrazone*,

$$C_6H_4Cl\cdot NH\cdot N:CH\cdot C_6H_3(OH)\cdot OMe,$$

forms flat, slightly yellow needles, m. p. 135°. It is not phototropic.

R. V. S.

The Formation of Dipiperidyls in the Electrolytic Reduction of Pyridine. BRUNO EMMERT (*Ber.*, 1913, **46**, 1716—1719).—From the formation of azobenzene and pinacone respectively in the reduction of nitrobenzene and acetone, and of phenylmethylpyrrolidone (Emmert, A., 1907, i, 339) in the reduction of a mixture of nitrobenzene and lævulic acid, it would appear that the first stage of the reduction is the production of free radicles which subsequently couple together. The electrolytic reduction of pyridine (Ahrens, A., 1897, i, 368), which has been believed to yield only piperidine, might therefore be expected to give rise to at least a small quantity of some binuclear product.

The reduction of pyridine at lead cathodes with a current density of 17·1 amps. per sq. dm. in diluted sulphuric acid is found to give actually much piperidine accompanied by less volatile products including 4 : 4′-dipiperidyl, m. p. 158—160°, 2 : 2′-dipiperidyl, b. p. 258—260° (corr.), and a high boiling resinous substance the molecule of which probably includes a higher number of piperidine nuclei; these less volatile products amounted to more than 10% of the pyridine taken.

D. F. T.

[Preparation of a Condensation Product from 5 : 7-Dichloro-isatin and 6-Chloroindoxyl.] FARBENFABRIKEN VORM. FRIEDR. BAYER & Co. (D.R.-P. 258258).—When a hot acetic acid solution of 5 : 7-dichloroisatin (220 parts) is treated with a similar solution of 6-chloroindoxyl (167 parts), some concentrated sulphuric acid added and the mixture warmed, it furnishes a *compound* crystallising in glistening, brown metallic needles. Differently substituted indoxyls and isatins can be employed for this reaction.   F. M. G. M.

Preparation of New Condensation Products from Indigotin and its Halogen Derivatives. GESELLSCHAFT FUR CHEMISCHE INDUSTRIE IN BASEL (D.R.-P. 259145).—When indigotin derivatives are treated with aromatic acid haloids in the presence of a condensing agent, they furnish compounds which dye wool in yellow shades.

The *compound* obtained by the action of benzoyl chloride on indigotin in the presence of copper powder forms yellowish-green needles, m. p. 275—276°.   F. M. G. M.

Synthetic Bases Closely Related to the Cinchona Alkaloids. ADOLF KAUFMANN (*Ber.*, 1913, 46, 1823—1837).—The difference in toxicity between quinine and quinotoxine is not due to the rearrangement of the nitrogen in the quinuclidine ring into a secondary amino-group with a free hydrogen atom, for methylcinchotoxine is just as active as cinchotoxine. Experiments by A. Warschawski have now shown that 4-quinolyl ketone (A., 1912, i, 1017), although it is chemically related to quinotoxine, is antipyretic, and only very slightly poisonous, from which it appears that the ketone group is not responsible for the toxicity. On the other hand, the ethyl ester of meroquinenine and especially the reduction product, ethyl cincholeuponate, are very powerful poisons. However, the author maintains his former hypothesis (*ibid.*) that the specific action of quinine is connected with the presence of an adrenaline-like grouping, and has now prepared derivatives of the annexed type.
It was found that 6-alkyloxy-4-quinolyl ketones with methyl or methylene attached to the carbonyl group react with halogens, giving derivatives which condense with primary amines, and that the new substances could be reduced to hydroxy-compounds of the above type. They all have the same physiological effect as quinine, and give the same fluorescence and respond to the thalleoquinine test. The process is easily carried through, and it thus becomes possible to prepare numerous analogues of quinine.

I. [With MAX HUBER and A. STETTBACHER.]—The cinchotoxine obtained by boiling 10 grams of cinchonine hydrochloride with 400 c.c. of 0·001% hydrochloric acid for fifty hours was extremely small in amount (compare Biddle, A., 1912, i, 296), but was characterised as the *phenylhydrazone-picrate*, which separated in microscopic, red needles, m. p. 200°, when phenylhydrazine and picric acid were added

to the alkaline, ethereal extract. The reaction is sensitive in a dilution of 1 in 2500.

II. [With OTTO ZELLER and MAX HUBER.]—Meroquinenine was prepared by the hydrolysis of quinenine with 25% phosphoric acid at 180° (Koenigs, A., 1894, i, 392). The *p*-methoxylepidine *phosphate* separated on cooling in large, grey, lanceolate crystals, m. p. 208—210°, and the filtrate was fractionally precipitated with phosphotungstic acid. The meroquinenine obtained from the precipitate by means of baryta was esterified, and the hydrochloride Fof the ethyl ester (I) (Koenigs, A., 1906, i, 762), reduced by hydrogen and colloidal palladium to the hydrochloride of ethyl cincholeuponate, which formed beautiful white needles, m. p. 158°, $[a]_D^{20}$ +5·71° (compare Skraup, A., 1895, i, 484). The free *ester* (II) is a colourless liquid, b. p. 140°/ 14 mm., $[a]_D^{18}$ −17 2°, which reacts violently with methyl iodide, giving *ethyl* N-*methylcincholeuponate*, $C_{12}H_{23}O_2N$, as a colourless oil, b. p. 139°/21 mm.
III. [With AUGUST POLL and HEINRICH PEYER.]—6-Ethoxy-4-quinolyl methyl ketone (this vol., i, 294) was warmed with bromine in hydrobromic acid, when the *hydrobromide* of 6-*ethoxy*-4-*quinolyl bromo-methyl ketone* separated in lemon-yellow crystals, m. p. 207°. The *hydrochloride*, m. p. 190°, crystallised when hydrochloric acid was used. The free *base* (III) forms yellow needles, m. p.104—105°, but is not so stable as the salts. When the hydrobromide is added to piperidine, diethylamine or dimethylamine in benzene or ether, the salt of the primary base is precipitated, and the new amino-ketone is obtained by evaporating the filtrate or by precipitation in the form of a salt.
6-*Ethoxy*-4-*quinolyl piperidinomethyl ketone* (IV) crystallises in light yellow, sparkling leaflets, m. p. 158°, and the *hydrobromide* forms long, white needles, m. p. 189—190°. 6-*Ethoxy*-4-*quinolyl diethylamino-methyl ketone* (VI) is a yellow, crystalline powder, m. p. 131°, which yields a neutral *monobromide* in white needles and a yellow *dibromide*, m. p. 193—194°, which reacts acidic. The *dimethylamino-ketone*, $C_{15}H_{18}O_2N_2$, forms yellow, prismatic columns, m. p. 132°.

(VI.) → (VII.)
The ketones are readily reduced by hydrogen in presence of palladium. 6-*Ethoxy 4-β-piperidino-a-hydroxyethylquinoline* (V) crystallises in white needles and plates, m. p. 85°, and the 6-*ethoxy-4-β-diethylamino-a-hydroxyethylquinoline* (VII) forms a very soluble *hydrochloride* in soft, white needles, m. p. 171°. J. C. W.

Hydantoins. XXII. History of 2-Thiohydantoin. TREAT B. JOHNSON (*J. Amer. Chem. Soc.*, 1913, **35**, 780—784).—2-Thiohydantoin was first synthesised by Klason (A., 1891, 179) by heating ethyl aminoacetate hydrochloride with potassium thiocyanate at 140—150°, but this work seems to have been overlooked by subsequent workers. Klason's observation has now been confirmed, but it has been found that the method gives too small a yield to be of practical value for preparing the compound. The reaction involves the intermediate formation of ethyl thiohydantoate. An attempt was therefore made to obtain 2-thiohydantoin by warming ethyl thiohydantoate with hydrochloric acid, but without success, hydrogen sulphide, ammonium chloride, and glycine hydrochloride being produced. E. G.

Preparation of ω-Methyl Sulphites [and ω-Alkyl Sulphites] of Substituted Aminoarylpyrazolones. FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D. R.-P. 259503—259577).—An account of the preparation of compounds previously described (this vol., i, 401), by the action of formaldehyde and sodium hydrogen sulphite on substituted aminopyrazolones. The second patent states that the formaldehyde can be replaced by other aldehydes, and describes the *compounds* obtained from 4-amino-1-phenyl-2 : 3-dimethyl-5-pyrazolone with acetaldehyde, and with propaldehyde, both of which have m. p. 124—125°, the latter decomposing at 130°. F. M. G. M.

Reactions of αβ-Diketonic Esters. ANDRÉ WAHL and M. DOLL (*Bull. Soc. chim.*, 1913, [iv], **13**, 468—485. Compare A., 1905, i, 474; 1907, i, 217; 1911, i, 108; 1912, i, 536, 625; this vol., i, 473).—The interaction of these esters with various reagents is described, and a number of the compounds obtained have been characterised. Some of this work has been recorded already (*loc. cit.*). The following observations and compounds are new :

Action of o-diamines (A., 1912, i, 536, 625).—*Ethyl 2-methylquinoxaline-3-carboxylate*, m. p. 74°, forms colourless needles. *Ethyl 2-methyl-1 : 4-naphthaquinoxaline-3-carboxylate*, m. p. 113—114°, forms slender, colourless needles. *Ethyl 2-propyl-1 : 4-naphthaquinoxaline-3-carboxylate*, m. p. 83—84°, crystallises in long, colourless needles. *Ethyl 2-n-butylquinoxaline-3-carboxylate* is an oil, but the corresponding acid, m. p. 86°, is crystalline. *Ethyl 2-phenylquinoxaline-3-carboxylate*,

m. p. 62—63°, forms silky needles; the *propyl* ester, m. p. 72—73°, and the iso*butyl* ester, m. p. 71°, are both crystalline. *Ethyl 2-phenyl-1 : 4-naphthaquinoxaline-3-carboxylate*, m. p. 116°, forms colourless needles.

Action of cyclic amines (A., 1912, i, 536, 625).—The aromatic esters condense with 2 mols. of the cyclic amines with the loss of $1H_2O$. The resulting compounds are probably best represented by the general formula $R \cdot CO \cdot C(NHPh)_2 \cdot CO_2Ph$ or

$$R \cdot C(:NPh) \cdot C(NHPh)(OH) \cdot CO_2Et.$$
Methyl benzoylglyoxalate yields a *dianilide*, m. p. 144—145°, crystallising in yellow needles from warm benzene, and a *di*-p-*toluilide*, m. p. 115—116°, forming lemon-yellow crystals. The propyl ester gives a *dianilide*, m. p. 88—89°, and the *iso*butyl ester a *dianilide*, m. p. 108—109°.

Action of hydroxylamine (A., 1907, i, 217; 1912, i, 536, 626).—With the exception of ethyl acetylglyoxalate, which yields a dioxime, all the esters yield monoximes when treated with hydroxylamine; thus methyl *p*-methoxybenzoylglyoxalate furnishes methyl oximinoanisoylacetate (this vol., i, 214, 532).

Action of phenylhydrazine (A., 1905, i, 474; 1912, i, 213, 536, 626; this vol., i, 532).—Ethyl *n*-valeroylglyoxalate yields *4-phenylhydrazino-1-phenyl-3-n-butyl-5-pyrazolone*, m. p. 119—120°, crystallising in orange needles. Methyl anisoylglyoxalate in addition to the two compounds already described (A., 1912, i, 626) when boiled in acetic acid with 2 mols. phenylhydrazine yields 4-phenylhydrazino-1-phenyl-3-*p*-methoxyphenyl-5-pyrazolone (A., 1912, i, 213). Methyl benzoylglyoxalate may yield (1) the *additive product*, $COPh \cdot C(OH)(NH \cdot NHPh) \cdot CO_2Me$, m. p. 144—145°, or (2) a mixture of phenylhydrazinopyrazolone with the *monophenylhydrazone*, m. p. 76° (identical with methyl benzeneazobenzoylacetate) depending on the conditions of the reaction. iso*Butyl benzoylglyoxalatephenylhydrazone*, m. p. 62—63°, forms hexagonal tablets. Unlike phenylhydrazine, *p*-nitrophenylhydrazine does not give rise to additive products, but yields either α-mono-*p*-nitrophenylhydrazones or *p*-nitrophenylhydrazinopyrazolones (*loc. cit.*).

Action of semicarbazide (A., 1907, i, 217; 1912, i, 536, 626).—The acyclic esters yield normal disemicarbazones, whilst the cyclic esters furnish compounds which have the composition of disemicarbazones with 1 mol. H_2O in addition. Probably 1 mol. of semicarbazide is added to the α-carbonyl, whilst the second condenses normally with the β-carbonyl group. Methyl benzoylglyoxalate yields a *compound*, m. p. 215°, of this type, which on recrystallisation is partly converted into a yellow *compound*, m. p. 292°, which may be a true disemicarbazone.

Action of hydrazine hydrate (A., 1912, i, 536, 626; this vol., i, 532).—Ethyl valeroylglyoxalate yields *dibutyl-3 : 3'-rubazonic acid*, and ethyl hexoylglyoxalate gives *dihexyl-3 : 3'-rubazonic acid*. With cyclic esters additive products are formed consisting of 2 mols. of the ester and one of hydrazine hydrate when the reaction takes place in acetic acid. Such a product has been described for methyl anisoylglyoxalate, $N_2H_2[C(OH)(CO \cdot C_6H_4 \cdot OMe) \cdot CO_2Me]_2$ (A., 1912, i, 626); that yielded by methyl benzoylglyoxalate has m. p. 137°, and crystallises in yellow

spangles. In alcoholic solution the benzoylglyoxalates yield 3 : 3'-diphenylrubazonic acid (*loc. cit.*).

The benzoylglyoxalates condense with the benzoylacetates in presence of piperidine, forming compounds in which condensation has probably been effected by interaction of the β-ketonic ester with the α-carbonyl. The following *products* of this kind are described; they crystallise in colourless needles : methyl benzoylacetate with methyl benzoylglyoxalate, $CO_2Me \cdot CBz(OH) \cdot CHBz \cdot CO_2Me$ (?), m. p. 120°; ethyl benzoylacetate with methyl benzoylglyoxalate, m. p. 117—118°; methyl benzoylacetate with ethyl benzoylglyoxalate, m. p. 124—125°; methyl o-methoxybenzoylacetate with methyl benzoylglyoxalate, m. p. 136—137° (compare A., 1907, i, 217). T. A. H.

Behaviour of Diphenyltriketone with Amino-compounds. I. CARLO GASTALDI and F. CHERCHI (*Gazzetta*, 1913, **43**, i, 299—303).—When alcoholic solutions of diphenyltriketone and o-phenylenediamine are mixed and cooled, *benzoylphenylquinoxaline*,

$$\begin{array}{c} CPh\text{———}C\cdot COPh \\ N\cdot C_6H_4\cdot N \end{array}$$

separates in slightly yellow scales, m. p. 153°. Its constitution follows from the fact that it can also be obtained from bromodibenzoylcarbinyl acetate. When the solution from which the crystals of m. p. 153° separate is diluted with water, *diphenyltriketone o-phenylenediamine*, $COPh \cdot C(OH)_2 \cdot CPh:N \cdot C_6H_4 \cdot NH_2$, is obtained in colourless rosettes, m. p. 155°. When this compound is heated on the water-bath for ten hours in aqueous-alcoholic solution with hydrochloric acid, phenylbenziminazole hydrochloride, m. p. 343°, is produced. The phenylbenziminazole liberated from it has m. p. 294° (compare Japp and Meldrum, T., 1890, **57**, 1043). R. V. S.

Tetramethylpyrrindoquinone and Some Other Derivatives of 2 : 3-Dimethylpyrrole. OSCAR PILOTY and K. WILKE (*Ber.*, 1913, **46**, 1597—1603. Compare Piloty, A., 1910, i, 277).—The paper deals with the preparation of a quinone, tetramethylpyrrindoquinone, from 2 : 3-dimethylpyrrole-4-carboxylic acid. The authors have also prepared 2 : 3-dimethyl-1-ethylpyrrole for comparison with their "hæmopyrrole-*e*," but have not yet been able to prepare "hæmopyrrole-*e*" picrate from it. They have found further that trisubstituted *C*-derivatives of pyrrole can yield bispyrrole picrates, so that the power to form bispyrrole derivatives and their picrates does not seem to follow any law.

The preparation of 4-ethyl hydrogen 2 : 3-dimethylpyrrole-4 : 5-dicarboxylate (A., 1912, i, 899) is simplified by using the tin double salt of β-aminobutan-γ-one, instead of that substance itself. The employment of ethyl hydrogen oxalacetate, instead of ethyl oxalacetate, presents no advantage, but it leads to the formation of a by-product, termed *aphaninester acid*, probably of the
$$\begin{array}{c} CO_2Et \\ | \\ MeC\text{———}C\text{-}C\cdot(OH)\cdot CH_2\cdot CO_2Et \\ \| \quad\quad | \quad CO_2H \\ MeC \quad C\cdot CO_2H \\ \diagdown\diagup \\ N \end{array}$$

annexed formula. This substance crystallises in hair-like needles, m. p. 156°. *Tetramethylpyrrindoquinone* (annexed formula) is obtained by boiling 2 : 3-dimethylpyrrole-4-carboxylic acid (*loc. cit.*) with acetic anhydride for several hours; it crystallises in rhombic tablets, which are yellow by transmitted, red by reflected, light; at a high temperature the substance sublimes.
$$CO \quad NH$$
$$MeC—C \diagdown \diagup C \diagdown OMe$$
$$MeC \diagup C—C \diagup—OMe$$
$$NH \quad CO$$

2 : 3-*Dimethyl*-1-*ethylpyrrole*-4-*carboxylic acid*, $C_9H_{13}O_2N$, is obtained by acting on 4-ethyl potassium 2 : 3-dimethylpyrrole-4 : 5-dicarboxylate (*loc. cit.*) with ethyl sulphate in benzene solution, and saponifying the ester by means of boiling concentrated aqueous alkali; it forms thin rods, m. p. 156°. When compressed tablets of this acid are subjected to dry distillation, 2 : 3-*dimethyl*-1-*ethylpyrrole*, $C_8H_{13}N$, b. p. 59°/11 mm., is produced. If hydrogen chloride is passed into a dry ethereal solution of the substance, the bis-compound is obtained; it crystallises in a freezing mixture in long needles which melt at room-temperature.

Ethyl 1 : 2 : 3-*trimethylpyrrole*-4-*carboxylate*, $C_{10}H_{15}O_2N$ (prepared similarly, using methyl sulphate), forms flat, rhombic prisms, m. p. 52°. The *acid*, $C_8H_{11}O_2N$, forms stellar aggregates of small crystals, m. p. 229° (previously sintering and becoming slightly brown).

Ethyl 2 : 3-*dimethylpyrrole*-4 : 5-*dicarboxylate*, $C_{12}H_{17}O_4N$ (prepared by the action of ethyl sulphate on the potassium salt), forms rhombic leaflets, m. p. 110°. Its *picrate*, $C_{18}H_{20}O_{11}N_4$, crystallises in bright orange rods, m. p. 112—113°. The *picrate* of the methyl ethyl ester of the same acid (*loc. cit.*) forms straw-yellow needles, which sinter at 122°, and are completely melted at 140°; analysis gave the formula $C_{28}H_{38}O_{15}N_5$, indicating a bis-compound.

2 : 3-Dimethylpyrrole-4-carboxylic acid yields a *picrate*, $C_{20}H_{21}O_{11}N_5$, which forms compact, red rods, m. p. 143°.   R. V. S.

Existence of Phenyldi-imide. STEFAN GOLDSCHMIDT (*Ber.*, 1913 **46**, 1529—1532. Compare Vaubel, A., 1900, i, 522; this vol., i, 519 ;' Forster and Withers, T., 1913, **103**, 266).—Vaubel's supposed phenyldi-imide has been characterised by Forster and Withers as a mixture of aniline and phenylazoimide. The author has repeated Vaubel's experiments, and, employing conditions somewhat different from those used by Forster and Withers, finds that the product is pure phenylazoimide, b. p. 65—68°/12 mm., the identity of which is confirmed by the formation of a condensation product, m. p. 178—179°, with phenylacetonitrile (compare Dimroth, A., 1903, i, 129).

The author has further attempted to prepare di-imines by the oxidation of phenylhydrazine and *p*-bromophenylhydrazine. At the ordinary temperature, the action of oxidising agents, such as lead peroxide, silver oxide, or *p*-benzoquinone, etc., is accompanied by the evolution of nitrogen. Since the action of all these agents with the exception of *p*-benzoquinone ceases at 0°, the latter substance has alone been used.

When an ethereal solution of *p*-benzoquinone is gradually added to a

solution of *p*-bromophenylhydrazine in ether cooled to −60° with careful exclusion of moisture and carbon dioxide, a copious separation of quinhydrone occurs and a yellow filtrate is obtained from which nitrogen is evolved on warming. Addition of a solution of stannous chloride in ether causes regeneration of *p*-bromophenylhydrazine. Attempts to isolate the di-imine in the pure state were, however, unsuccessful. It appears to possess no tendency to form salts or double salts, and does not react with substances such as anhydrous hydrocyanic acid, diphenylketen, etc., at the low temperature necessitated by the unstability of the substance. Tribromophenyl-hydrazine, which might be expected to yield a more stable oxidation product, is unaffected by *p*-benzoquinone. H. W.

Iminoindigotin. ARTHUR BINZ and K. R. LANGE (*Ber.*, 1913, **46**, 1691—1695).—When indigotin is shaken for two hours with alcoholic sodium ethoxide solution and the resultant additive product (compare Binz and Schädel, A., 1912, i, 317) shaken with a solution of zinc hydroxide in ammonia together with an excess of saturated alcoholic solution of ammonia, the resulting blue liquid after acidification with dilute hydrochloric acid deposits *iminoindigotin hydrochloride*; the *sulphate* is also sparingly soluble. The parent substance is evidently more reactive than indigotin, for the blue solution obtained before acidification can be completely oxidised by air to a brown *substance*, whilst hydrogen sulphide reduces the solution to a vat which on re-oxidation yields, not the imine, but a new *substance* which dissolves in alkali to a red, and in alcohol to a brown, solution. The iminoindigo-tin hydrochloride can be reduced by gentle warming with sodium hyposulphite, giving a greyish-white leuco-*compound*. The aqueous solution of the hydrochloride itself dyes wool and mordanted cotton, producing similar shades to indigotin.

If the blue solution obtained by the interaction of the additive compound of sodium ethoxide and indigotin with zinc hydroxide and ammonia is treated with much water instead of with acid, a *zinc* salt, $(C_{16}H_{10}ON_3)_2Zn$, a bluish-green, amorphous substance, soluble in chloroform and acetone, is obtained. This acid character of imino-indigotin is different from the power by which indigotin forms additive compounds because the colour is relatively unaffected.

The free *iminoindigotin*, $C_{16}H_{11}ON_2$ (compare Thiele and Pickard, A., 1898, i, 493), was obtained most satisfactorily by reducing the sulphate with aqueous sodium hydroxide and hyposulphite and re-oxidising the yellow solution; the deep blue product is obtained crystalline with difficulty, and decomposes without melting; it is probably not a pure substance, but possibly a mixture of isomerides, so

that the formula $C_6H_4{<}{\begin{smallmatrix}C(:NH)\\NH\end{smallmatrix}}{>}C{:}C{<}{\begin{smallmatrix}CO\\NH\end{smallmatrix}}{>}C_6H_4$ must be accepted

with reserve. The formation of the substance however, seems to supply further evidence in favour of the view that one-half of the indigotin molecule is more reactive than the second (compare Claasz, A., 1912, i, 513).

The halogen-indigotins, also indigo-red and "thioindigo," likewise form imino-derivatives, whilst by applying methylamine in the original

reaction a methylimino-product can be obtained. These substances also are possibly not homogeneous, and like iminoindigotin, exhibit both acidic and basic tendency.   D. F. T.

Syntheses in the Fatty Aromatic Series. X. Derivatives of Diaryl Paraffins. JULIUS VON BRAUN, H. DEUTSCH, and O. KOSCIELSKI (*Ber.*, 1913, 46, 1511—1526).—Attempts to prepare definite substitution products of diaryl paraffins by sulphonation, chlorination, or nitration have been only partly successful, the compounds obtained showing little tendency to crystallise or to distil without decomposition ; 4 : 4′-dicarboxylic acids have been prepared by the use of oxalyl chloride, but the corresponding amides do not yield any considerable quantity of amines when subjected to Hofmann's reaction. Further attempts to prepare symmetrically substituted dinitro-derivatives have met with slight success, but well characterised tetranitro-derivatives, $C_6H_3(NO_2)_2 \cdot [CH_2]_x \cdot C_6H_3(NO_2)_2$, have been obtained.

A method of obtaining mono-substituted derivatives of diaryl paraffins consists in the condensation of acyl derivatives of chlorinated bases with benzene in the presence of aluminium chloride (compare A., 1912, i, 688), a reaction which is remarkable, since the corresponding nitro-derivatives appear to be unsuitable for the Friedel-Crafts reaction. If, however, the chlorine atom is in the δ- or ε-position with respect to the benzene nucleus, hydrogen chloride is almost entirely eliminated from within the molecule.

4-Benzoylaminodibenzyl, m. p. 170—171°, is obtained in almost theoretical yield by the condensation of *p*-benzoylaminophenylethyl chloride with benzene in the presence of aluminium chloride, and is readily transformed into p-*aminodibenzyl*, colourless leaflets, which are stable to light, m. p. 48°. The latter forms a *hydrochloride*, leaflets, m. p. 210° after darkening at 205°, a *platinichloride*, m. p. 286—289° according to the rate of heating and after darkening from 200°, a *carbamide*,

$$CH_2Ph \cdot CH_2 \cdot C_6H_4 \cdot NH \cdot CO \cdot NH_2,$$
m. p. 155°, and a *phenylthiocarbamide*, m. p. 154°. The constitution of *p*-aminodibenzyl follows from its transformation into dibenzyl by the successive action of nitrous acid and stannous chloride. *4-Iododibenzyl*, m. p. 44—45°, b. p. 210°/10 mm. (slight decomp.), reacts with sodium in much the same manner as does iodobenzene, but more slowly than the latter with copper powder or magnesium. *4-Hydroxydibenzyl* forms yellow leaflets, m. p. 90°, and yields a yellow *sodium* salt with concentrated sodium hydroxide and a *benzoyl* derivative, m. p. 99°. *Dibenzyl-4-carboxylonitrile* is an oil which slowly solidifies when preserved, and is transformed by hydrochloric acid at 120° into *dibenzyl-4-carboxylic acid*, leaflets, m. p. 165°. The azo-dyes obtained from amino- and hydroxydibenzyl closely resemble those obtained from *p*-toluidine and *p*-cresol, so that the authors are led to the conclusion that the number of groups present is of greater importance for the alteration of colour than is the increase in weight of a group already present.

p-Nitrophenylethyl chloride, even after protracted treatment with benzene and aluminium chloride, yields oily products which still contain chlorine, and from which a uniform, chlorine-free nitro-

compound cannot be isolated. *p*-Nitrophenylpropyl chloride behaves in a similar manner.

p-Benzoylaminophenylpropyl chloride condenses with benzene in the presence of aluminium chloride to yield an oily *product*, which, when hydrolysed by hydrochloric acid at 150°, gives a colourless, mobile *base*, b. p. 95—110°/17 mm., which is probably aminohydrindene, $NH_2 \cdot C_6H_3 <^{CH_2}_{CH_2}> CH_2$ (*benzoyl* derivative, m. p. 161°), and p-*amino-diphenylpropane*, b. p. 210—225°/18 mm. (slight decomp.). The latter does not solidify when preserved during several months. It forms a *picrate, benzoyl* and m-*nitrobenzoyl* derivative, all of which are oily. The hydrochloride has m. p. 195°. When heated with methyl iodide (about 4 mols.) and sodium hydroxide, *p*-aminodiphenylpropane yields the corresponding quaternary *iodide*, $Ph \cdot [CH_2]_2 \cdot C_6H_4 \cdot NMe_3I$, colourless needles, m. p. 179—180°, and p-*dimethylaminodiphenylpropane*, b. p. 221—222°/17 mm. The latter is best obtained in the pure state by decomposition of the quaternary iodide in a vacuum. p-*Hydroxy-diphenylpropane* has b. p. 215—220°/18 mm.

o-Aminodiphenylpropane, in contrast to the corresponding *p*-compound, yields a solid m-*nitrobenzoyl* derivative, m. p. 137°. Even with a large excess of methyl iodide it gives solely the tertiary *amine*, b. p. 177—183°/17 mm. (slight decomp.), which, although viscous, does not solidify.

p-*Benzoylaminophenylamyl chloride*, m. p. 210—212°, reacts with benzene and aluminium chloride to yield a *product*, the nitrogen content of which is too high for a normal condensation product (see above).

Only minimal amounts of substance could be obtained by the condensation of acyl derivatives of chloro-bases with thiophen.

The action of oxalyl chloride on a solution of *aζ*-diphenylhexane in carbon disulphide in the presence of aluminium chloride results in the isolation of the *dicarboxylic acid*, $CO_2H \cdot C_6H_4 \cdot [CH_2]_6 \cdot C_6H_4 \cdot CO_2H$, m. p. 303—304°, the *potassium* salt of which is sparingly soluble in water, whilst the *sodium* and *ammonium* salts are more soluble. The corresponding *amide*, m. p. 178°, like the diamide of diphenyloctane-dicarboxylic acid, is converted by bromine and alkali into a dark amorphous mass from which practically nothing can be extracted by acids.

Reduction of the oily product obtained by the nitration of diphenyl-hexane leads to a basic substance, which, when benzoylated, yields a *benzoyl* derivative of indefinite m. p. The latter may be resolved by alcohol into two isomeric portions, the less soluble of which, m. p. 212°, is probably mainly *pp′*-dibenzoylaminodiphenylhexane, and is converted by hydrochloric acid at 140° into a *hydrochloride*, $C_{18}H_{28}N_2Cl_2$, which melts indefinitely at about 205°. The more soluble portion has m. p. 174°.

It is noteworthy, that although the homologues of benzyl chloride readily condense in the presence of sodium with formation of diaryl paraffins, a similar reaction does not occur when the benzene nucleus contains a nitro- or benzoylamino-group.

The preparation of tetranitro-derivatives of diarylparaffins (compare Borsche and Wollemann, this vol., i, 171) is best effected by gradual addition of the hydrocarbon to nitric acid (D 1·52) at −15°. The

mixture is allowed to remain for half an hour in ice and then during two hours at the ordinary temperature, after which it is heated for a few minutes on the water-bath and then poured into water. In this manner diphenylhexane yields $2:4:2':4'$-*tetranitro-aζ-diphenylhexane*, colourless needles, m. p. 90°, which, on oxidation with chromic acid, is converted into 2 : 4-dinitrobenzoic acid. Similarly, *tetranitro-βη-diphenyloctane*, m. p. 145—146°, and *tetranitro-aζ-diphenyl-β : ε-dimethylhexane*, m. p. 112°, are obtained from the corresponding hydrocarbons. Reduction of $2:4:2':4'$-tetranitro-aζ-diphenylhexane in ammoniacal alcoholic solution by means of hydrogen sulphide yields mainly *dinitrodiaminodiphenylhexane*, in which the two amino-groups are probably in the para-position to the hexamethylene chain. (Its *hydrochloride* was also examined.) Smaller quantities of *trinitroaminodiphenylhexane*, m. p. 126—127°, and of an isomeric *dinitrodiaminodiphenylhexane*, m. p. 150—151°, in which the amino-groups are probably in the ortho-position to the hexamethylene chain, are also formed. $2:4:2':4'$-*Tetra-aminodiphenylhexane*, needles, m. p. 138°, is obtained by the reduction of $2:4:2':4'$-tetranitrodiphenylhexane by tin and hydrochloric acid. The *hydrochloride*, m. p. 275°, *picrate*, needles, m. p. 213—215°, *benzoyl* derivative, which is not melted at 280°, and *tetrabenzylidene* derivative, m. p. 151°, were investigated. The base is converted by an excess of boiling acetic anhydride into its *tetra-acetyl* derivative, m. p. 270°; acetylation by glacial acetic acid, in the presence of a few drops of water, gives a *diacetyl* compound, leaflets, m. p. 167°.

Tetra-amino-βη-diphenyloctane,

$$C_6H_3(NH_2)_2 \cdot CHMe \cdot [CH_2]_4 \cdot CHMe \cdot C_6H_3(NH_2)_2,$$
colourless leaflets, m. p. 131°, is obtained in a similar manner from the corresponding tetranitro-compound.   H. W.

Syntheses in the Fatty-Aromatic Series. XI. Double Dye-stuffs from Diarylparaffins. Julius von Braun and O. Koscielski (*Ber.*, 1913, **46**, 1526—1529).—The authors have investigated the effect of the repetition of one and the same chromophore in an organic molecule on the intensity and nature of the colour [compare preceding abstract]. They have prepared double dyes in the azo-, triphenyl-methane-, indamine, and azine series, and do not find any noticeable difference between them and the corresponding mono-dyes.

$2:4:2':4'$-Tetra-amino-aζ-diphenylhexane and tetra-amino-βη-di-phenyloctane when dissolved in dilute acid and treated with sodium nitrite yield reddish-brown colorations exactly similar to that given by 2 : 4-tolylenediamine under similar conditions. On keeping, or immediately in concentrated solution, the "Vesuvines" separate as amorphous, dark brown powders which were not further investigated. When $2:4:2':4'$-tetra-amino-aζ-diphenylhexane is treated with benzenediazonium chloride (2 mols.), the *bis-chrysoidine* separates as a red precipitate. The free *base*,

$$C_6H_{12}[C_6H_2(NH_2)_2 \cdot N_2Ph]_2,$$
is a yellow, crystalline powder, m. p. 148—150°. The shades given by bis-chrysoidine and by the products derived from tolylenediamine

and tetra-aminodiphenyloctane are scarcely distinguishable from one another.

Tolylenediamine condenses with Michler's hydrol in acetic acid solution to yield the *base*, $CH(C_6H_4 \cdot NMe_2)_2 \cdot C_6H_3Me(NH_2)_2$, m. p. 156—158°. The corresponding *acetyl* derivative has m. p. 200°, and is oxidised by lead peroxide to a product which dyes cotton a pure green. The similar leuco-*base*, obtained from 2 : 4 : 2′ : 4′-tetra-amino-*aζ*-diphenylhexane and Michler's hydrol (2 mols.),

$$C_6H_{12}[C_6H_2(NH_2)_2 \cdot CH(C_6H_3 \cdot NMe_2)_2]_2,$$
has m. p. 222°. With acetic anhydride it yields a *tetra-acetyl* derivative, m. p. 255—256°, which is oxidised by lead peroxide. The dye so obtained has precisely the same colour as that obtained from tolylenediamine in solutions of similar concentration, and yields precisely the same shades on cotton.

Amorphous *dyes* are obtained by the condensation of 2 : 4 : 2′ : 4′-tetra-amino-*aζ*-diphenylhexane or tetra-aminodiphenyloctane with nitrosodimethylaniline hydrochloride. These give blue colours on the fibres indistinguishable from those obtained with tolylene-blue. When an aqueous solution of these dyes is boiled, the colour changes to red. The "double-reds" so obtained dye the fibres in practically the same shades as tolylene red. H. W.

Amines Derived from Proteins: The Peptamines Glycyl-*p*-hydroxyphenylethylamine, Alanyl-*p*-hydroxyphenylethylamine, and 4-Glycyl-β-aminoethylglyoxaline. MARKUS GUGGENHEIM (*Biochem. Zeitsch.*, 1913, **51**, 369—387).—It is known that by the scission of carbon dioxide from certain amino-acids, such as tyrosine and histidine, bases of pharmacological interest are obtained. The author has consequently undertaken the investigation of similar products from peptides, and with this object has prepared synthetically the substances named above. By the action of chloroacetyl chloride on *p*-hydroxyphenylethylamine, *chloroacetyl-p-hydroxyphenylethylamine*, $C_{10}H_{12}O_2NCl$, m. p. 109°, is obtained, which by the action of aqueous ammonia yields glycyl-*p*-hydroxyphenylethylamine, $C_{10}H_{14}O_2N_2$, m. p. 136°. By the action of bromopropionyl chloride on *p*-hydroxyphenylethylamine, dl-*bromopropionyl-p-hydroxyphenylethylamine*,

$$C_{11}H_{14}O_2NBr,$$

m. p. 98°, was obtained, which yields on treatment with ammonia dl-*alanyl-p-hydroxyphenylethylamine*, $C_{11}H_{16}O_2N_2$, m. p. 116°. By a similar series of reactions, 4-*glycyl-β-aminoethylglyoxaline*,

$$\begin{array}{c} CH{=}N \\ NH \cdot CH \end{array}\!\!\!\!\!>\!\!C \cdot CH_2 \cdot CH_2 \cdot NH \cdot CO \cdot CH_2 \cdot NH_2,$$
was obtained, the hydrochloride of which melted with decomposition at 250°. The pharmacological action of these substances was investigated and compared with the actions of *p*-hydroxyphenylethylamine and 4-β-aminoethylglyoxaline. The conjugated products have a similar peripheral action on smooth muscle as the simple bases, but the effect is much weaker. The actions were investigated on the uterus, surviving small intestine, the frog's heart, etc., and on the blood-pressures, and the effects are illustrated by numerous tracings. S. B. S.

Purines. X. 6 : 8-Dioxy-2-methylthiolpurine and 8-Amino-6-oxy-2-methylthiolpurine. CARL O. JOHNS and EMIL J. BAUMANN (*J. Biol. Chem.*, 1913, 14, 381—388).—The first orthodiaminoalkyl-thiolpyrimidine has been prepared and condensed to a purine. The presence of the methylthiol group instead of sulphur modified the properties of the new compound, 4 : 5-diamino-6-methylthiol-6-pyrimidone (I). Instead of combining with thiocarbamide to form a thiopurine, as 4 : 5-diamino-2-thio-6-pyrimidone does (this vol., i, 657), it gave an aminopurine (II), which is accounted for by assuming that the thiocarbamide is first transformed into guanidine thiocyanate. The latter substance is, indeed, the best reagent to use for the preparation of the aminopurine, which may even be obtained by employing ammonium thiocyanate. This is remarkable in view of the fact that a similar condensation between other diaminopyrimidines and guanidine salts could not be realised.

$$\underset{\text{(III.)}}{\begin{array}{c} \text{NH}\text{——}\text{CO} \\ \text{C·SMe} \quad \text{C·NH} \\ \text{N}\text{——}\text{C·NH} \end{array}\Big\rangle\text{CO}} \quad \longleftarrow \quad \underset{\text{(I.)}}{\begin{array}{c} \text{NH}\text{——}\text{CO} \\ \text{C·SMe} \quad \text{C·NH}_2 \\ \text{N}\text{——}\text{C·NH}_2 \end{array}} \quad \longrightarrow \quad \underset{\text{(II.)}}{\begin{array}{c} \text{NH}\text{——}\text{CO} \\ \text{C·SMe} \quad \text{C·NH} \\ \text{N}\text{——}\text{C}\text{—}\text{N} \end{array}\Big\rangle\text{C·NH}_2}$$
4-Amino-2-methylthiol-6-pyrimidone (A., 1905, i, 836) is best obtained by using methyl sulphate instead of methyl iodide. When it is dissolved in water with sodium nitrite and then acidified with acetic acid, 5-*nitroso-4-amino-2-methylthiol-6-pyrimidone*, $C_5H_6O_2N_4S$, is precipitated as a white solid, which gives a blue solution in acids and a red in alkalis, and decomposes at 255°. It was reduced to 4 : 5-*diamino-2-methylthiol-6-pyrimidone* (I), by means of ammonium sulphide, only just sufficient to discharge the red colour due to the nitroso-compound being added. The substance was dried at 30—40°, and formed colourless crystals, m. p. 211°, which condense with carbamide to form 6 : 8-*dioxy-2-methylthiolpurine* (III) as a granular powder which gives the murexide reaction, is unaltered at 320°, and hydrolyses with difficulty to uric acid. 8-*Amino-6-oxy-2-methylthiolpurine* (II) is also stable at 320°, gives the murexide reaction, and is hydrolysed by acids but not by alkalis, to uric acid.   J. C. W.

Action of Azoimide on Thiocarbimides and Carbimides. Constitution of Azoimide. V. E. OLIVERI-MANDALÀ and F. NOTO (*Gazzetta*, 1913, 43, i, 304—315).—By the action of azoimide on ethylcarbimide the authors have obtained ethylcarbamazide, and from phenylcarbimide, phenylcarbamazoimide, identical with that of Curtius and Hofmann (A., 1896, i, 648). From these results the authors consider it probable that azoimide and the azoimides should have the same structure, and they give reasons for preferring the cyclic formula

$\text{HN}\!\!<\!\!\overset{\text{N}}{\underset{\text{N}}{\|}}$, for azoimide to the chain formula which has been suggested.

By the action of azoimide on phenylthiocarbimide, one of two substances is obtained according to the temperature of reaction; at 40°, one molecule of azoimide reacts, yielding 4-phenyl-3-thiotetrazoline of Freund and Hempel (A., 1895, i, 193), whilst at 60—70° two molecules of azoimide are involved.

Ethylcarbamazoimide, $NHEt \cdot CO \cdot N_3$, prepared in ethereal solution, has b. p. $90°/28$ mm., m. p. 10—$14°$; it forms large, tabular crystals. Its reactions are similar to those of other azoimides containing the group $\cdot NH \cdot CO \cdot N_3$. The action of water yields ethylamine azoimide, whilst alkalis yield ethylamine; the action of aniline on the substance leads to the formation of s-phenylethylcarbamide and aniline azoimide.

The action of azoimide on phenylthiocarbimide in ethereal solution is only complete at 40—$50°$ (under pressure). When the phenylthiotetrazoline produced is dissolved in warm xylene, a decomposition occurs and triphenyli*so*melamine, m. p. $190°$, is obtained. Hofmann (A., 1886, 233) gave m. p. $185°$. Triphenyli*so*melamine platinichloride, $C_{21}H_{18}N_6 \cdot H_2PtCl_6$, was also prepared.

When an ethereal solution of azoimide and phenylthiocarbimide is heated under pressure at 60—$70°$ for twenty-four hours, a *substance*, $C_7H_7N_7S$, is produced, which crystallises in soft, shining scales, m. p. 158—$159°$. When it is boiled with 50% potassium hydroxide, it yields azoimide and the thiocarbimide. Alcoholic sodium hydroxide eliminates 1 molecule of azoimide, yielding thiolphenyltetrazole, m. p. $150°$. In view of these reactions the annexed structural formula is probable for the new substance.   R. V. S.

Supposed Isomerism of Benzeneazoresorcinol. ARTHUR HANTZSCH (*Ber.*, 1913, **46**, 1556—1557).—Two isomeric forms of benzeneazoresorcinol have been described by Will and Pukall (A., 1887, 660). The product, m. p. $161°$, is, in reality, a hydrate containing $\frac{1}{3}H_2O$, which can only be removed with difficulty. The dehydrated product has m. p. 169—$170°$, in agreement with that ($170°$) of the supposed isomeride. A very unstable *monohydrate* is obtained when acetic acid is added to a cooled alkaline solution of benzeneazoresorcinol.   H. W.

[Preparation of Aminoazo-derivatives of Aromatic *m*-Diamines.] BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 258653).— It is found that $2:4$-diaminophenetole, $2:4$-diaminoanisole, or other ethers of $2:4$-diaminophenols readily undergo bisdiazotisation by the ordinary methods, and when coupled with 2 mols. of a *m*-diamine- (substituted or otherwise) furnish brownish-red *compounds*. $2:4$-*Diaminoanisole* and $2:4$-*diaminophenetole* form colourless needles with m. p. 67—$68°$.

The nitro-ethers can be prepared as described by Willgerodt (A., 1879, ii, 716), and are readily reduced by the ordinary methods.

F. M. G. M.

Nature of the Yellow and Red Helianthine Solutions and Chromoisomerism of Aminoazo-salts. ARTHUR HANTZSCH (*Ber.*, 1913, **46**, 1537—1556).—The solid, red helianthine is dissolved, not only by alkalis, but by all indifferent solvents in the form of yellow helianthine. Red helianthine solutions are only formed in the

presence of hydrogen ions. Yellow helianthine solutions are there-
fore obtained in the absence of hydrogen ions and not merely in the
presence of hydroxyl ions.

Yellow helianthines and red helianthines, as internal sulphonates, are
optically very similar to the yellow and red chromoisomeric salts of
aminoazobenzenes with acids. The generally very unstable, yellow
acid salts are optically quite distinct from the yellow salts of the type
$N_2Ph \cdot C_6H_4 \cdot NMe_2X$, the absorption of which resembles that of azobenzene,
and cannot therefore possess the analogous constitution

$$N_2Ph \cdot C_6H_4 \cdot NMe_2, HX.$$
Since the quinonoid character of the red salts, $NHPh \cdot N:C_6H_4:NR_2X$,
is established by the analogy of their absorption with that of
magenta the yellow salts must have the formula

$$C_6H_5 \cdot NHX:N \cdot C_6H_4 \cdot NR_2$$
if structural isomerism is assumed. More probably, however, the
yellow salts are themselves quinonoid, since they show a quinonoid
band similar to that of the red salts and the aniline dyes, and hence
must be regarded as valency isomerides of the red salts, thus :
This conception leads to the adoption of a quinonoid structure for
the corresponding aminoazobenzenes, $C_6H_5 \cdot N \cdot N:C_6H_4:NR_2$, since the
latter yield spectra closely analogous to those of the yellow acid
salts.

In a similar manner, the transformation of yellow methyl-orange
into red helianthine probably takes place in the following stages : The
yellow sodium salt present in the alkaline solution is transformed by
neutralisation of the alkali into the corresponding free acid (1) which
immediately passes into the yellow internal salt (2) by wandering of
the hydrogen atom ; this yellow helianthine is converted by acid into
the red valency isomeride (3), which, in the presence of a large excess of
acid, passes into the analogously constituted red hydrochloride (4).
Whilst the dialkylaminobenzenes, including the halogenalkylates,
which are incapable of isomerisation yield three series of salts, the

simple aminoazobenzenes can yield also a fourth graphite-black series which are possibly constituted according to the formula

$$C_6H_5 \cdot NH(HX) \colon N \colon C_6H_4 \cdot NH.$$
Red helianthines are best obtained in the pure condition by means of their *pyridine* salts, which, when dried at $100°$, lose pyridine, leaving the pure helianthine.

Ethyl dimethylanilineazobenzoate, $NMe_2 \cdot C_6H_4 \cdot N_2 \cdot C_6H_4 \cdot CO_2Et$, forms leaflets of a reddish-golden colour, m. p. $160°$. H. W.

[Preparation of Compounds Containing 3 : 4-Dihydro-1 : 4-oxazine-3-one Ring.] AKTIEN-GESELLSCHAFT FUR ANILIN-FABRIKATION (D.R.-P. 259700).—When the azo-compounds obtained from 1-amino-2-naphthoxyacetic acids or 2-aminophenoxyacetic acids which contain an alkyl or alkyloxy-group in the meta-position are treated with acids, they lose water and furnish cyclic compounds according to the following scheme; and dyes in which X is represented by benzidine and other amino-compounds are described in the original. F. M. G. M.
Amount of *l*-Tyrosine in Proteins and the Accuracy of the Estimation of this Amino-acid. EMIL ABDERHALDEN (*Zeitsch. Physiol. Chem.*, 1913, 85, 91. Compare this vol., i, 409).—*l*-Hydroxyproline, like tyrosine, shows a blue coloration with the Folin-Denis reagent. The preparation used had $[\alpha]_D^{20} -72.37°$. A synthetic product made by Leuchs has $[\alpha]_D^{20} -76°$, whereas the value usually given is $[\alpha]_D^{20} -81°$. Since tryptophan and hydroxytryptophan also react with the Folin-Denis reagent, their method for estimating tyrosine is of no value. E. F. A.

The Oxidative Degradation of the Proteins. OTTO EISLER (*Biochem. Zeitsch.*, 1913, 51, 26—44).—On oxidation of proteins with calcium permanganate, "peroxyprotic" acids are produced, which, according to von Furth, undergo hydrolysis with barium hydroxide with scission of oxalic acid, yielding deaminoprotic acids, which on further oxidation with permanganate yield "kyroprotic" acids. These, on treatment with barium hydroxide yield deaminokyroprotic acids. The deaminokyroprotic acid from caseinogen was prepared and described. The mercury salt contained 18.35% C, 2.62% H, 5.04% N, 0.4% S, 59.3% Hg, 1.7% amino-acid nitrogen (estimated by van Slyke's method), and 0.44% basic nitrogen. The probable constitution of this acid is discussed by the author. Sericoin was also prepared from silk-waste by Weyl's method. This also was submitted to oxidation by calcium permanganate, and the product hydrolysed by barium hydroxide. The substance thus obtained could not be oxidised further by permanganate in the cold. The mercury salt contained 8.02% C, 1.06% H, 3.40% N, 12.85% O, and 74.67% Hg. The amino-acid nitrogen was 2.21%, and the basic nitrogen 1.72%. The high

percentages of the latter and of the mercury are remarkable. They indicate that the simpler amino-acid groups are removed by oxidation, leaving the more basic groups intact, which seems to show that the protein is built up by branched chains from a more stable residue of diamino-acids.   S. B. S.

The Amounts of Indole Produced by the Artificial Digestion or Putrefaction of Various Proteins. WACLAW VON MORACZEWSKI (*Biochem. Zeitsch.*, 1913, **51**, 340—354).—The amount of indole obtainable from various proteins by successive digestion with pepsin, trypsin, and putrefactive bacteria, both under the simplest conditions and in the presence of various foreign substances, such as fats, sugars, bile, etc., was estimated. The results are tabulated.   S. B. S.

Hæmoglobin. The Magnesium Derivative of Mesoporphyrin. JEAN ZALESKI (*Ber.*, 1913, **46**, 1687—1691).—In order to introduce magnesium into mesoporphyrin (compare Willstätter and Forsén, this vol., i, 499), the substance is treated with magnesium, methyl or ethyl iodide, and a trace of iodine in ethereal solution ; the product is a *compound*, $C_{38}H_{46}O_8N_4Mg$, or $C_{39}H_{48}O_8N_4Mg$, m. p. 335°, which in its absorption bands and easy scission of magnesium on treatment with dilute acid closely resembles rhodophyllin (Willstätter, A., 1908, i, 198) ; the *substance*, m. p. near 288°, obtained by elimination of magnesium, is distinct from the ethyl ester of mesoporphyrin originally taken.   D. F. T.

Methæmoglobin. BÉLA VON REINBOLD (*Zeitsch. physiol. Chem.*, 1913, **85**, 250—285).—It is regarded as established that methæmoglobin takes a middle position between hydroxyhæmoglobin, $Hb{<}^O_{()}$, and reduced hæmoglobin, Hb. It is uncertain whether it has Zeynek's formula $Hb(OH)_2$ or Küster's formula Hb–OH.

It is now proved by spectrophotometric and gasometric measurements that the reaction between potassium ferricyanide and hydroxyhæmoglobin is quantitative, one molecule of the cyanide being required to displace a molecule of oxygen as shown by the equation

$$Hb{<}^O_O + K_3FeCy_6 + H_2O = Hb·OH + K_4HFeCy_6 + O_2,$$
which is in agreement with Küster's formula.   E. F. A.

Keratin of White Human Hair. HANS BUCHTALA (*Zeitsch. physiol. Chem.*, 1913, **85**, 246—249).—The result of hydrolysing white human hair is as follows : Glycine, 9·12 ; alanine, 6·88 ; leucine, 12·12 ; glutamic acid, 8·0 ; phenylalanine, 0·62 ; tyrosine, 3·3, and cystine, 11·55%. The amounts of cystine, glycine, and alanine are abnormally large. Hair keratin closely resembles that from sheep's wool.
        E. F. A.

Keratin of the Scales of Manis japonica. HANS BUCHTALA (*Zeitsch. physiol. Chem.*, 1913, **85**, 241—245).—The keratin of *Manis japonica* yields amino-acids on hydrolysis, namely, glycine 1·33%,

alanine 120%, valine 4%, leucine 10 25%, 'proline 3·5%, glutamic acid, 3·5%, phenylalanine 2·67%, tyrosine 13%, and cystine 4·5%. The amount of alanine is abnormal, other keratins yielding 1·2%—1·8%. The proportion of tyrosine is likewise unusually large.   E. F. A.

Keratin of Snake Skins (Boa Constrictor and Python). HANS BUCHTALA (*Zeitsch. physiol. Chem.*, 1913, **85**, 335—340).—The distribution of the nitrogen and the percentage of certain monoamino-acids is determined in the keratin of snake skins, and compared with that in other keratins. The distribution of the nitrogen is much the same in all keratins, but they differ widely in the proportions of the individual amino-acids which they contain. Snake-skin keratin contains a high proportion of tyrosine and leucine.   E. F. A.

Action of Quinones on Wool and Other Protein Substances. WILHELM FAHRION (*Zeitsch. angew. Chem.*, 1913, **26**, 328. Compare *ibid.*, 1909, **22**, 2138).—A claim for priority against Scharvin (this vol., i, 661).   H. W.

Reactions on Dyeing Animal Fibres. WILHELM SUIDA (*Zeitsch. physiol. Chem.*, 1913, **85**, 308—323).—Wool loses more of its substance in a faintly acid bath than in a neutral bath when heated under the conditions usual for dyeing. The difference is especially marked on subsequent treatment with an alkaline bath. Wool in both cases mainly gives up basic substances to the bath, so that, normally, during dyeing the wool itself becomes acid.

When wool is heated with phenols and acetic acid, the presence of the phenol on the fabric cannot be established, using ferric chloride. The substituted nitrophenols dye the wool, the intensity increasing with the acidity of the phenol. These colours are readily removed by faintly alkaline washes.

Wool fixes phenolcarboxylic acids, but no ferric chloride reaction is shown, indicating that the phenylhydroxyl group has combined with some constituent of the wool.

Whereas *p*-benzoquinone, toluquinone, *o*-3 : 6-xyloquinone, etc., in a weak acetic acid bath dye wool intensely, *p*-2 : 5- and *m*-2 : 5-xyloquinone, also thymoquinone, anthraquinone, and phenanthraquinone have no such action. The active para-quinones all contain the grouping –CO·CH:CH·CO–, which is absent from the inactive quinones.

Naphthazarin, a dihydroxy-α-naphthaquinone, dyes wool a deep violet-brown. The colour is not removed even by strong ammonia.

The quinones are supposed to give rise to quinoneanilide-like compounds with the amino-substances of the wool. Silk is not dyed so quickly by quinones as wool.   E. F. A.

Precipitation of Enzymes from their Solutions by Moist Aluminium Hydroxide. WILLIAM H. WELKER and JOHN MARSHALL (*J. Amer. Chem. Soc.*, 1913, **35**, 822).—When solutions of the following enzymes were shaken with moist aluminium hydroxide, the enzymes were quantitatively removed: peroxydase and oxydase (aqueous extract of potato), pepsin (aqueous or 0·2% HCl solution), rennin

(aqueous solution), trypsin (0·5% Na_2CO_3 solution, 30% alcoholic extract of pancreas, or 30% alcoholic extract of pancreas containing an equal volume of 1% Na_3CO_3), and amylase and lipase (30% alcoholic extract of pancreas). The amylase of saliva was not completely removed by this treatment; the filtrate was capable of converting starch paste into soluble starch, but could not effect further hydrolysis. Pepsinogen could be precipitated quantitatively, but only with great difficulty.   E. G.

Action of Hydrogen Chloride and Ammonia Gas on Invertase. VI. THEODOR PANZER (*Zeitsch.physiol. Chem.*, 1913, 85, 225—230. Compare this vol., i, 113, 541, 662).—Invertase, when treated in turn with dry hydrogen chloride and dry ammonia, does not recover its hydrolytic activity. The groups destroyed by the acid are not restored when this is neutralised as is the case with diastase. This behaviour is regarded as further evidence in favour of the formation of anhydride by the action of the acid.   E. F. A.

Action of Nitrous Oxide on Invertase. VIII. THEODOR PANZER (*Zeitsch. physiol. Chem.*, 1913, 85, 392—398).—On subjecting invertase to the action of dry nitrous oxide, oxidation takes place, and subsequently a little nitrous oxide is fixed by the enzyme. The hydrolytic activity of the enzyme is not affected. The treatment increases the acidity of the enzyme, although in one instance the acidity decreased. The amount of amide and amino-nitrogen is less after treatment. The experiments again emphasise the difference between invertase and diastase.   E. F. A.

Action of Hydrogen Chloride and Ammonia on Diastase. V. THEODOR PANZER (*Zeitsch. physiol. Chem.*, 1913, 85, 97—111).—The action of dry hydrogen chloride and ammonia separately on diastase has already been studied (compare this vol., i, 113, 541). The enzyme has now been treated first with hydrogen chloride, and then with an excess of dry ammonia gas. The resulting increase in weight, acidity and nitrogen, shown by means of formaldehyde, was the same as when the enzyme was acted on by ammonia alone. The treatment with ammonia restores the hydrolytic activity of the diastase, whereas if the enzyme, after treatment with hydrogen chloride, is neutralised with aqueous ammonia, it remains inactive.
                                                         E. F. A.

Action of Nitrous Oxide on Diastase. VII. THEODOR PANZER (*Zeitsch. physiol. Chem.*, 1913, 85, 292—307).—Dry nitrous oxide gas was passed over diastase in the manner described for hydrogen chloride or ammonia. Whereas an enzyme preparation containing milk sugar absorbed about 3% of the gas, a purified enzyme material absorbed three times this amount. Only a small quantity of the gas can be pumped off in a vacuum. The nitrous oxide does not cause either hydrolytic decomposition or anhydride formation. The hydrolytic activity of the purified enzyme is largely destroyed by the treatment, but the presence of the milk sugar protects the enzyme from harm.
                                                         E. F. A.

Action of Salts of Metals on the Saccharification of Starch by Amylolytic Ferments. C. GERBER (*Bied. Zentr.*, 1913, **42**, 265—268; from *Compt. Rend. Soc. Biol. Paris*, 1911, **70**, 139, 391, 547, 724, 726, 728).—Alkali salts of monobasic acids increase the rate of saccharification when present in small amounts, whilst large amounts have a retarding effect; acid salts act similarly to the corresponding acids. The salts of monobasic organic acids act similarly; the retarding effect increases with the mol. wt.

Magnesium salts in small amounts have no action, and larger amounts have a retarding effect. Manganese, ferric and aluminium salts have a quickening effect in small amounts, and a retarding effect when present in large quantities. Ferrous salts retard or inhibit saccharification according to the amount.

Cadmium and zinc in very small amounts have a retarding effect, whilst moderate amounts inhibit saccharification. Still larger amounts, up to a certain point, are, however, favourable. Similar results were obtained with copper and gold salts.

Salts of platinum and palladium in very small amounts are favourable; the action is very suddenly reversed as the amounts increase.　　　　　　　　　　　　　　　　　　　　　　　　　N. H. J. M.

Synthesis of Glucosides of the Alcohols by means of Emulsin; Reversibility of Ferment Actions. ÉMILE BOURQUELOT and MARC BRIDEL (*Ann. Chim. Phys.*, 1913, [viii], **28**, 145—218).— A résumé and discussion of results already recorded in the following abstracts: 1906, ii, 386; 1911, i, 1053; 1912, i, 522, 592, 593, 672, 738, 790, 928, 946; this vol., i, 212, 303.　　　　　　　　　　　T. A. H.

Behaviour of Emulsin in Presence of Pyridine. GÉZA ZEMPLÉN (*Zeitsch. physiol. Chem.*, 1913, **85**, 415—426).—β-Glucosides are hydrolysed by emulsin in presence of 12% of pyridine. When the proportion of pyridine is increased, hydrolysis is retarded, and ceases in 20% solution. In presence of pyridine, amygdalin is converted into *iso*amygdalin.　　　　　　　　　　　　　　　　　　　　　　　　　E. F. A.

Use of Increasing Proportions of Dextrose in the Bio-chemical Synthesis of β-Methylglucoside. Influence of the Glucoside Formed on the Arrest of the Reaction. ÉMILE BOURQUELOT and ÉM. VERDON. (*Compt. rend.*, 1913, **156**, 1638—1640; *J. Pharm. Chim.*, 1913, [vii], **7**, 575—579).—In methyl alcohol (70%) the quantity of glucoside formed increases proportionately as the quantity of dextrose in solution increases up to 12%, above which the amount of glucoside formed diminishes slightly. The presence of methylglucoside in the solution has a marked inhibiting effect on the amount of glucoside synthesised. The quantity of glucoside necessary to check the reaction is proportional to the amount of dextrose in the solution.　　　　　　　　　　　　　　　　　　　　　　　　　W. G.

Enzyme Action. XIX. Urease. II. Observations on Accelerative and Inhibitive Agents. HENRY E. ARMSTRONG, M. S. BENJAMIN, and EDWARD HORTON (*Proc. Roy. Soc.*, 1913, *B*, **86**, 328—343. Compare A., 1912, i, 594).—The manner in which the

activity of urease is affected by the presence of various substances together with the urea has been studied throughout the whole course of the change with considerable accuracy. The results are expressed graphically.

Both strong acids and carboxylic acids such as $M/50$ aspartic and salicylic acids prevent action. Boric acid in all strength retards action. Guaiacol and resorcinol at first retard and subsequently accelerate hydrolysis. p-Benzoquinone is poisonous, and quinol and quinol monomethyl ether, both of which are easily oxidised to p-benzoquinone, soon stop action. Glycine, asparagine, and carbonic acid all accelerate action.

It is emphasised that in presence of carbonic acid the rate of change approximates to a "linear" character.

Hydrogen cyanide accelerates action.

Saligenin, acetaldehyde, benzaldehyde and salicylaldehyde are moderately active depressants.

It is considered that enzymic changes would be found to take place at approximately constant rates were it not that they are subject directly and indirectly to considerable retardation by the products of change; probably the products of change have an affinity for the enzyme which is actually greater than that which obtains between the hydrolyte and the enzyme.

Enzyme action takes place entirely at the surfaces of colloid particles suspended in the solution of the hydrolyte, and not between substances which are all in true solution.   E. F. A.

Fermentations with Yeast in the Absence of Sugar. XI. Carboxylase. CARL NEUBERG and P. ROSENTHAL (*Biochem. Zeitsch.*, 1913, 51, 128—142).—The carboxylase from yeast, which causes the decomposition of pyruvic acid, can be distinguished from the sugar ferment (zymase) by various reactions. The latter does not act in the presence of chloroform, whilst the former retains its full activity, especially in the presence of "buffers," which prevent great changes in the reaction of the fermenting liquid. For this latter purpose, solutions of either alkali salts of pyruvic acid in the presence of free arsenious or boric acids or free pyruvic acid in the presence of borates or arsenites can be used. Similar results were obtained both with fresh and dried yeasts of pure culture. The carboxylase acts in a much shorter time than the zymase. Furthermore, if maceration juices are preserved at room temperature, the zymase activity is readily lost, whereas the carboxylase remains active over comparatively long periods. Furthermore, the zymase is readily destroyed by heating to 50°, whereas the carboxylase activity remains intact. There is a further difference in that the zymase loses its activity on dialysis, whereas the carboxylase does not, especially if the dialysed solution is kept for some time. Attention is called to the fact that the fermentation of sugar must precede in stages, the C_6-sugar being apparently broken down into C_3-substances, such as pyruvic acid. The ferment causing the evolution of carbon dioxide from the latter can remain intact, even after the zymase is destroyed.   S. B. S.

Paralysis and Activation of Zymase and Catalase. HENRI VAN LAER (*Centr. Bakt. Par.*, 1913, ii, **37**, 529—534. Compare A., 1912, i, 1043).—In an earlier paper it was stated that the addition of papain depresses, and malt extract increases, the activity of zymase and catalase. The former is attributed to impurities in the juice of the *Carica papaya* which digest the two enzymes.

The activation of the enzymes by extract of malt may be due, firstly, to direct stimulation of the zymase and catalase by impurities in the extract of malt; secondly, by inhibition of the antagonistic enzyme (protease) by impurities, or else to the existence of pro-enzymes—prozymase and procatalase—combinations of the enzymes with a carbohydrate, such compounds being saccharifiable by amylase.

Experiments with a Munich bottom yeast and a Mons top yeast have been made, and again show a depressing action of the papain on the catalase and zymase in the yeast juice. Tests with extract of malt exhibit activation of the enzymes during the initial stages of the experiment with a pronounced depres-ion later on. This action is ascribed to the presence of proenzymes in the yeast-juice. At the moment of fission a positive effect is produced, and this is followed by their digestion by impurities in the malt extract.   H. B. H.

Arseno-compounds. AUGUST MICHAELIS and ARTHUR SCHÄFER (*Ber.*, 1913, **46**, 1742—1743).—Since arsenic compounds frequently have a higher molecular weight than the corresponding nitrogen compounds, the authors have determined the molecular weight of arsenobenzene and *p*-arsenotoluene respectively.

Arsenobenzene, slender, white needles, has m. p. 212°, not 196° as previously given (A., 1881, 722). It is readily oxidised in solution to phenylarsine oxide, which, even in small quantities, greatly depresses the m. p. A solution of arsenobenzene in benzene, when allowed to evaporate spontaneously in contact with air, leaves a resinous product consisting solely of phenylarsine oxide. In boiling benzene solution, arsenobenzene has mol. wt. at 399·8 (calc. 304).

p-Arsenotoluene separates from benzene in small plates, m. p. 202° (from chloroform, however, in needles, m. p. 184°; compare A., 1902, i, 411). In solution, it is readily oxidised to *p*-tolylarsine oxide. It has a normal molecular weight when dissolved in dry phenol. In the presence of a trace of moisture, on the other hand, a constant freezing point of the solution is not observed.   H. W.

The Displacement of Metals from their Phenyl Compounds. SIEGFRIED HILPERT and GERHARD GRUTTNER (*Ber.*, 1913, **46**, 1675—1691).—Although the action of various metals on the organo-metallic compounds has been fairly well investigated in the aliphatic series, the corresponding behaviour with the compounds of the phenyl series has been less well studied (compare Hilpert and Grüttner, A., 1912, i, 939). It is now discovered that at the temperature of the experiment (200—350°) the metals of comparatively low m. p. generally react with the organo-metallic compounds causing a displacement of the other metal, and that it the two metals do not affect one

another the reaction may proceed quantitatively. If the m. p. of the resulting mixture of metals lies below the temperature of the experiment the extent of the interaction appears to be dependant on the relative quantities of the two metals in the mixture.

Magnesium and aluminium react with mercury diphenyl so readily that no external heating is necessary; magnesium diphenyl (compare Fleck, A., 1893, i, 622) does not inflame in the air unless breathed upon; it forms feathery needles (from ether), which melt at the temperature of the hand, almost immediately afterwards passing into the ether-free, amorphous substance. For the reaction between zinc and mercury diphenyl (in a hydrogen atmosphere), heat has to be applied when the chemical change occurs with quantitative displacement of mercury; zinc diphenyl, needles, m. p. 105—106°, b. p. 280—285°, both in hydrogen, is very sensitive to air and moisture, the former converting it into zinc oxide and diphenyl, and the latter into zinc hydroxide and benzene; it is inflamed by fuming nitric acid, and reacts with chloroform, producing triphenylmethane; with iodine in benzene solution it produces zinc phenyl iodide, which is slowly converted further into zinc iodide; with mercury it reacts to a small extent, giving a trace of mercury diphenyl.

Contrary to expectation, aluminium reacts scarcely at all with zinc diphenyl, possibly on account of the protecting film of oxide; in order to determine the relative reactivity of these two metals towards the metallic phenyl compounds, the two metals were allowed to react simultaneously with the same quantity of mercury diphenyl under such conditions that the zinc if alone would form zinc diphenyl; it was found that the relative amounts of aluminium triphenyl and zinc diphenyl were 99 : 1. Magnesium decomposes completely the phenyl derivatives of aluminium and zinc, whilst mercury has no effect on them; the metals magnesium, aluminium, zinc, and mercury, therefore, stand in the same relative order of activity as in the ordinary potential series.

Cadmium exhibits but little tendency to form organo-metallic compounds and with the mercury alkyls gives rise only to hydrocarbons; with mercury diphenyl it is found that cadmium reacts, forming cadmium diphenyl, but the extent of the reaction depends on the composition of the liquid cadmium amalgam produced, and therefore on the relative amount of cadmium applied; by using an apparatus in which the liquid reaction product could be repeatedly treated in a hydrogen atmosphere with fresh cadmium until more than ten atomic proportions had been applied, a specimen of *cadmium diphenyl*, colourless prisms containing 25% of mercury diphenyl, was obtained; it is stable when dry, but in benzene solution it undergoes atmospheric oxidation. From the amount of cadmium necessary in the above experiment and the fact that the product when heated with excess of mercury quantitatively regenerates mercury diphenyl, it is evident that cadmium falls after mercury in the series, showing the relative activity of the metals towards the formation of phenyl compounds.

The behaviour of bismuth is somewhat analogous to that of cadmium; mercury diphenyl heated with an excess of bismuth and bismuth triphenyl heated with an excess of mercury both yield a mixture of

the phenyl derivatives of the two metals ; the relative proportions in the mixed products indicate that bismuth falls before mercury in the series indicating relative activity in these compounds. With the six metals investigated above, therefore, cadmium alone falls into a position different from that occupied in the ordinary potential series.

The quadrivalent metals lead and tin appear to form a special class, for they fail to react with mercury diphenyl, whilst their tetraphenyl derivatives are entirely unaffected by magnesium.

The behaviour of the metallic haloids towards metallic phenyl compounds is very different from that of the corresponding free metal. Mercuric bromide reacts quantitatively with an ethereal solution of magnesium phenyl bromide producing *mercury phenyl bromide*, leaflets, m. p. 275°, if the original reagents are in approximately equimolecular proportions; with an excess of the organo-magnesium compound, mercury diphenyl is formed, but in only 40% yield. In a similar manner, mercury a-naphthyl bromide, m. p. 203°, can be produced, which even with a large excess of magnesium a-naphthyl bromide gives only a small quantity of the diphenyl compound. Cadmium chloride also reacts with magnesium phenyl bromide and magnesium a-naphthyl bromide, but the products were not isolated.

It is remarked that the sensitiveness of the phenyl compounds towards air and water diminishes with increasing atomic weight and electro-negative character of the metal.

The action of the alkali metals on mercury diphenyl or zinc diphenyl, with or without a solvent, was never found to yield a deposit of mercury until water was added (compare Acree, A., 1903, i, 724), and it is believed that an additive product is first produced.

In agreement with the earlier negative results (Smith, Barnett and Hall, A., 1900, i, 89) on the existence of a tungsten methyl iodide (Cahours, 1862), the authors were unable to isolate any compound of such nature. D. F. T.

Physiological Chemistry

Narcosis. I. The Relationship between Narcosis and Oxygen Respiration. HANS WINTERSTEIN (*Biochem. Zeitsch.*, 1913, **51**, 143—170).—The author gives a critical review of the various experiments which indicate a relationship between narcosis and diminution of oxygen respiration. He draws the conclusion that narcosis cannot be explained simply as a result of diminished oxidation, citing amongst other experiments the fact that certain ascarids, which are anoxybiotic, are particularly susceptible to narcosis. It seems more probable that narcosis and inhibition of oxidation are concomitant results of some more general action.

S. B. S.

The Chlorine Content of Blood and its Division between the Corpuscles and Serum. The Permeability of Corpuscles for Inorganic Substances. J. SNAPPER (*Biochem Zeitsch.*, 1911, 51, 53—61).—The chlorine was estimated in the total blood, and in the serum and corpuscles separately. It was found that the ratio of the chlorine in the corpuscles to that in the serum was approximately constant both in the dog and in man, being about 40%. As this is very nearly the ratio of the intraglobular fluid to the total volume of the erythrocytes as found by Hamburger, the conclusion is drawn that there is an even distribution of the inorganic contents of blood between the serum and the formed elements.   S. B. S.

Formation of Methæmoglobin. WOLFGANG HEUBNER (*Arch. expt. Path. Pharm.*, 1913, 72, 241—281).—Whereas the injection of phenacetin into the blood of carnivora causes the formation of methæmoglobin, dimethylphenacetin is without effect. Phenacetin outside the body has no action on blood, indicating that the active substance is formed from it in the organism.

Parallel experiments with derivatives of o-, m-, and p-aminophenols show the meta-derivatives to be barely poisonous, and, whereas the ortho- and para-derivatives are equally poisonous for dogs, the ortho-compound is the stronger in the case of cats, which are extremely sensitive to both aminophenols. Rabbits are resistant to these poisons.

Since each aminophenol molecule reacts several times with hæmoglobin molecules, the reaction is explained on the hypothesis that the o- and p-aminophenols are oxidised to o- or p-benzoquinone-imine, and that this actually reacts with hæmoglobin, $2(Hb\dot{:}Fe)$, forming aminophenol and methæmoglobin, $2(Hb\dot{:}Fe\cdot OH)$. The change involves conversion of bivalent into tervalent iron, the active agent being the quinone. This is in agreement with the formation of hæmoglobin by the agency both of oxidising and reducing agents.

Quinol acts similarly, but has no effect in the absence of oxygen. p-Benzoquinone works energetically in the absence of oxygen.

Quinol and catechol readily produce methæmoglobin in test-tube experiments, whereas resorcinol is without effect. Similarly, pyrogallol is active, chloroglucinol inactive.

Aniline is active, dimethylaniline has no effect, although the isomeric m-xylidine is also active in producing methæmoglobin.

The substitution of the para- and of both ortho-positions in aniline by chlorine does not alter its activity. Apparently the aniline nitrogen is oxidisable without oxidation previously taking place at the ortho- or para-positions in the nucleus to form a quinone. Acetylation of the nitrogen in trichloroaniline has little effect; in dichloroaniline some lessening of the activity is brought about on acetylating.

Hæmoglobin is oxidised by hydroxylamine even in the absence of oxygen. The introduction into aniline derivatives of two methyl groups occupying the one the ortho-position to nitrogen, and the other either the ortho- or para-position lowers the oxidising

activity. Phenetidine, for example, has hardly any action in producing methæmoglobin.

Emphasis is laid on the difference between rabbits, dogs, and cats in the reactions between the blood and aromatic oxidising agents.

The spectrum of pure methæmoglobin does not show the two oxyhæmoglobin bands in the yellow and green. When these are seen, oxyhæmoglobin is present as impurity. E F. A.

The Change in the Permeability of Blood Corpuscles on Addition of Acid. J. SNAPPER (*Biochem. Zeitsch.*, 1913, 51, 62—88).—The results of Hamburger are confirmed, according to which the addition of acid causes a swelling of the corpuscles and a passage of chlorine from the serum into the corpuscles. The influence of the addition of acids to the blood both *in vivo* and *in vitro* was investigated. The diffusible and non-diffusible alkali was estimated. For this purpose, the total serum was titrated with $N/25$-tartaric acid, and also the filtrate after precipitation with alcohol, which throws down the proteins with the alkali combined with proteins (non-diffusible alkali). Congo-red paper was used as indicator. Both *in vivo* and *in vitro*, there was found to be a relative increase of the diffusible as compared with the non-diffusible alkali as a result of the action of acids. A possible explanation of the action of acids as regards the distribution of chlorine between serum and corpuscles seemed therefore to be the relative increase of ·SO_4 ions in the corpuscles when sulphuric acid was employed, as compared with the serum, due to the larger amount of alkali set free from proteins in a diffusible form and a subsequent interchange of ·SO_4 and Cl ions between serum and corpuscles. As, however, a change in distribution of chlorine could not be brought about by addition of neutral sulphates alone without addition of acids, this explanation is inadequate. It is assumed, therefore, that the acids act on the proteins and so alter the permeability of the cells to ions. A similar change of distribution could not be brought about by lipoid solvents, such as chloroform, even when the latter is present in sufficient quantities to cause a small amount of hæmolysis. S. B. S.

The Biological Significance and Metabolism of the Proteins. VII. The Amino-Nitrogen Titratable in the Presence of Formalin in the Blood Corpuscles of Various Animals. A. COSTANTINO (*Biochem. Zeitsch.*, 1913, 51, 91—96).— The proteins were separated by barium salts by the method of Buglia and Costantino. In both the serum and corpuscles, nitrogenous substances titratable in the presence of formalin were found. The quantity found was small in the case of serum, but relatively large in that of corpuscles. In non-nucleated, the quantity is only about half that existing in nucleated corpuscles. In the case of mammals and turkey, the amount found in the serum is about the same. The author calls attention to the importance of examining chemically the corpuscles when investigating various problems of metabolism. S. B. S.

Hæmolysis by Chemical Agents. PHILIPP EISENBERG (*Centr. Bakt. Par.*, 1913, **1**, 69, 173—225).—The author has carried out a long series of experiments on the action of salts, acids, alkalis, and various organic substances (including tetanolysin and vibriolysin) on blood corpuscles. He has investigated, amongst other factors, the influence of hypertonicity, synergism, and antagonism. He summarises his results, from which, however, no extensive generalisations can be made.   S. B. S.

Blood Lipoids and Phagocytosis. B. STUBER (*Biochem. Zeitsch.*, 1913, **51**, 211—233).—A method is described by means of which the phagocytic index of leucocytes can be determined, thrush spores being employed as the foreign object, as they can be readily stained by Leishmann's method. For *in vitro* experiments human blood was employed, and for *in vivo* experiments cats and sometimes rabbits were used. It was found that cholesterol by itself greatly diminishes the phagocytic index, whereas lecithin has no action. On the other hand, lecithin greatly diminishes, and even obliterates when in sufficient quantity, the power of cholesterol to reduce the phagocytic index, provided that it has not been previously heated. If the cholesterol and lecithin are heated after mixing, they do not together diminish the phagocytic index. Similar results were obtained by both the *in vivo* and *in vitro* experiments. It appears, therefore, that cholesterol acts directly on the phagocytes, and destroys their phagocytic action, but in the presence of lecithin a lecithin-cholesterol compound is formed. This cannot, however, be produced if lecithin is heated before the two substances are mixed.   S. B. S.

The Acetonitrile Reaction. FR. PORT (*Biochem. Zeitsch.*, 1913, **51**, 224—228. Compare Reid Hunt, A., 1905, ii, 847; 1910, ii, 736; Trendelenburg, A., 1911, ii, 50).—The author throws doubt on Reid Hunt's acetonitrile reaction with mice for detection of thyreogenic substances in the blood on the ground that the susceptibility of the animals to the poison is so very variable that it is impossible to determine the limiting dose.   S. B. S.

Influence of Fatigue on the Amount of Dialysable Compounds, which React with Triketohydrindenhydrate, in the Serum. EMIL ABDERHALDEN and ARNO ED. LAMPÉ (*Zeitsch. physiol. Chem.*, 1913, **85**, 136—142).—After severe fatigue in the dog, the blood-serum contains less of the substances referred to in the title. Admixture of the serum either of normal or fatigued dogs with cooked muscle produced no change. A similar result was obtained with other tissues.   W. D. H.

The Fermentative Properties of Blood. I. A Peptolytic Ferment of Normal Dog's Serum. LUDWIG PINCUSSOHN (*Biochem. Zeitsch.*, 1913, **51**, 107—115).—It is known that by injection of various proteins into animals, the blood acquires peptolytic properties. The author shows that normal dog's serum

possesses a ferment capable of hydrolysing the peptone of dog's muscle, prepared by treating the muscular tissue with 70% sulphuric acid in the cold, and precipitating by alcohol, after the removal of the sulphuric acid with barium hydroxide. The serum does not, however, digest a similar peptone prepared in the same way from cat's muscle, or other peptones from foreign substances.

S. B. S.

The Influence of Diet on the Activity of Ptyalin. H. VAN TRIGT (*Zeitsch. physiol. Chem.*, 1913, **85**, 156—160).—The author examined his saliva at frequent intervals; each meal increased its diastatic activity; the increased action was greatest after a carbohydrate meal, and least after a protein meal. W. D. H.

Fluorine in the Animal Organism. II. Skeleton, Cartilages, and Tendons. ARMAND GAUTIER and PAUL CLAUSMANN (*Compt. rend.*, 1913, **156**, 1425—1430. Compare this vol., i, 677).—An examination of bones, teeth, cartilage, and tendons for fluorine. Bones and teeth, either human or animal, are comparatively rich in fluorine, the content of the diaphyse portion of the bones being about four times as great as that of the epiphyse, in the case both of an elderly man and a new-born infant. The teeth approach the diaphyse in fluorine content. The skeleton of fish contains practically the same amount of fluorine as the scales, and a complete analysis of these organs shows a marked analogy. Cartilage and tendons are very low in fluorine content. W. G.

Is it Possible Artificially to Increase the Amount of Phosphatides in Brain? ERNST SALKOWSKI (*Biochem. Zeitsch.*, 1913, **51**, 407—422).—Commercial preparations of kephalin, when administered by the mouth, are well tolerated, and all but a small percentage is resorbed. Its ingestion causes an increased phosphoric acid output in the urine, both absolute and relative as compared with the nitrogen. In contrast to egg-yolk lecithin, kephalin does not accumulate in the liver, but appears to accumulate in the brain. Rabbits were used for the experiments, and the quantities of phosphatides in the organs were estimated by the following method. The organ (brain) was first extracted with hot alcohol, and the residue was then extracted with a mixture of equal volumes of absolute alcohol and benzene. The residues from both extracts were then dissolved in benzene, the extract thus made was filtered, and the phosphorus was estimated in the filtrate after the solvent had been evaporated off. S. B. S.

Normal and Pathological Alteration in the Lens of the Eye. ADOLF JESS (*Zeitsch. Biol*, 1913, **61**, 93—142).—During life there is an increase in the weight, the protein, and the water of the crystalline lens, and to a smaller degree in the substances which are soluble in ether. The increase in protein is greater than that in water. Among the proteins, an "albumoid" is more abundant in old age than crystallin, which is the more important in youth.

In senile cataract, the weight, the water, and the protein all decrease, and the loss of water is greater than that of protein; among the proteins crystallin is most diminished; the amount of albumoid is high; the amount of fat, cholesterol, and lecithin are not increased. In traumatic cataract there is no decrease in weight, but both the proteins decrease in amount; fat, cholesterol, and lecithin do not increase, but the relative and occasionally the absolute amount of water usually rises. In senile cataract, the cystine reaction lessens owing to the disappearance of crystallin; the albumoid has no cystine group in its molecule. In old traumatic cataracts the cystine reaction is also negative, owing to the total absorption of crystallin.   W. D. H.

Chemical Investigation of Calcified Aortæ. Franz Ameseder (*Zeitsch. physiol. Chem.*, 1913, **85**, 324—334. Compare A., 1911, ii, 219).—A further series of analyses of calcified aortæ are given with full details of the experimental methods.   E. F. A.

A Pigment in Melanosis of the Mucous Membrane of the Large Intestine. Emil Abderhalden (*Zeitsch. physiol. Chem.*, 1913, **85**, 92—95).—A brown pigment was separated from a melanotic large intestine. An elementary analysis is given, which agreed closely with that of a pigment obtained from tryptophan (A., 1912, i, 521).   W. D. H.

Ferments of the Pancreas. Cesare Serono and Antoniette Palozzi (*Chem. Zentr.*, 1913, i, 1212—1213; from *Arch. Farmacol. sperim.*, 1913, **14**, 501—508).—All the ferments of the pancreas are contained in the glycerol extract, expressed under high pressure, and their activity remains for a long time unimpaired. The proteoclastic activity increases on keeping, that is, with the conversion of trypsinogen into trypsin. In addition to diastase, there is a ferment capable of acting on maltose. The tryptic power is not destroyed by digestion with pepsin. Only the proteoclastic ferment is precipitated by a mixture of sodium chloride and magnesium sulphate.   S. B. S.

Autolysis of the Thymus. M. Kashiwabara (*Zeitsch. physiol. Chem.*, 1913, **85**, 161—172).—Kutscher considered that during autolysis the thymus underwent characteristic changes, especially in the amount of lysine and ammonia formed; the present research does not support this view. The course of autolysis in this organ does not materially differ from that of the liver, and there is no increase in the amount of ammonia formed; in both organs its nitrogen is about 10% of that in the soluble nitrogenous substances. Among the decomposition products, lysine was found, also leucine and tyrosine in small quantities. There are certain differences between liver and thymus in the partition of nitrogen; the mono-amino-acids and proteoses are only about half as abundant in the thymus as in the liver, but the group diamino-acids + peptone + ammonia is twice as great, and the purine bases three times as great.   W. D. H.

Extractive [Mytilitol] in the Valve Muscles of Mytilus edulis. BAREND C. P. JANSEN (*Zeitsch. physiol. Chem.*, 1913, 85, 231—232).—On extraction of the valve muscles of *Mytilus edulis* with water and precipitation of certain impurities with colloidal ferric hydroxide, a substance, $C_6H_{12}O_5,2H_2O$, crystallises from the filtrate; the name *mytilitol* is applied to it. It forms an *acetate*, m. p. 182°, crystallising in microscopic needles, which gives up five acetyl groups on hydrolysis. Mytilitol contains a six-carbon ring, and is regarded as an isomeride of quercitol. The muscles also contain histidine, betaine, taurine, and about 1·5% of glycogen.

E. F. A.

The Influence of Nutrition on the Secretion of Indole and Indican by Healthy Individuals. WACLAW VON MORACZEWSKI and E. HERZFELD (*Biochem. Zeitsch.*, 1913, 51, 314—339).—The amount of substance giving the indole reaction, which is obtained by the distillation of urine, was determined under different conditions of nutrition, and it was found that the amount increased on a diet of fats, of vegetables, and of gelatin, but diminished on a carbohydrate or sugar diet. The addition of proteins caused an increased output as compared with sugars, but a diminished output as compared with fats. No relationship could be found between the indole of the fæces and the indican of urine. The indole of the fæces was estimated both directly as excreted, and after submission to a secondary putrefaction. Fat was found to increase both the indole directly excreted and the amount obtained after secondary putrefaction. The same was found with proteins, whereas carbohydrates had the opposite effect. Vegetables protect proteins from putrefaction, so that the indole directly excreted is diminished, and that obtained by secondary putrefaction is increased to the same extent. The nitrogen and chloride of the fæces are affected in a similar way. At times a relationship between the indican of the urine and the indole of the fæces is to be found, the two rising and falling together; in the case of gelatin, sugar, and fat nutrition, the general metabolism exerts some influence on the amount of indole resorbed from the intestine; but the amount of indican of the urine is regulated by another factor in addition to its resorption from the alimentary tract, namely, the capacity of the organism to destroy the absorbed substance.

S. B. S.

Tryptic Digestion by the Urine. FILIP JOHANSSON (*Zeitsch. physiol. Chem.*, 1913, 85, 72—90).—In the normal urine of man, ox, and horse, no proteolytic enzyme precipitable by caseinogen in an alkaline solution was obtained. In albuminous urine, it is sometimes present. From the urine of the ox, and to a small degree of the horse, the caseinogen precipitate contains an enzyme which favours the proteolytic action of fibrin prepared from ox blood, but has no such action on ox-serum. Trypsinogen is absent from the urine. The substance in question is possibly a kinase.

W. D. H.

Excretion of Glycuronic Acid Mistaken for Glycosuria.
EMIL ABDERHALDEN (*Zeitsch. physiol Chem.*, 1913, **85**, 95—96).—A
case of apparent glycosuria in a child turned out on further
examination to have no sugar in the urine. The reducing pro-
perties were due to free and combined glycuronic acid. The urine
also contained abundant phenol and indoxyl.   W. D. H.

Changes in Voluntary Muscles in Disease R. C. JEWESBURY
and W. W. C. TOPLEY (*J. Path. Bact.*, 1913, **17**, 432—453).—In
wasting diseases the voluntary muscles show varying degrees of
wasting. In acute general diseases there is a hyaline or granular
change, and in a few cases fatty degeneration. In cases of abnormal
carbohydrate metabolism the interstitial fat is increased. Marked
fatty degeneration occurs in diphtheritic toxæmia, certain blood
disorders, and phosphorus poisoning. Glycogen was strikingly
present in all the cases (three in number) of diabetes examined.
Amyloid degeneration was not found at all.   W. D. H.

**Biochemistry of Growth. The Glycogen-content of the
Liver of Rats Bearing Malignant New Growths.** WILHELM
CRAMER and JAMES LOCHHEAD (*Proc. Roy. Soc.*, 1913, B, **86**,
302—307).—Glycogen disappears more rapidly from the liver of
tumour-bearing rats than from that of normal rats. There is no
increased oxidation of carbohydrate material in tumour-bearing
animals, so the result confirms the conclusion arrived at on pregnant
animals, that in growth carbohydrate is used in the synthesis of
protoplasm.   W. D. H.

Nitrogen Content of Malignant Tumours in Man. ROBERT
G. CHISHOLM (*J. Path. Bact*, 1913, **17**, 606—608).—Ten tumours
were investigated; in all cases the nitrogen percentage is lower
in the fresh tumour than in the somatic tissues of the host, with
the exception of the kidney. But reckoned for the dried tissue,
the percentage was lower in four cases only. Cramer and Pringle
found that the percentage of nitrogen coagulable by alcohol was
low in tumour tissue; the variable results on this point obtained
in the present research appear to be due to post-mortem changes.
                                                     W. D. H.

. **Action of Diuretics in Experimental Nephritis.** ARTHUR
E BOYCOTT and JOHN H. RYFFEL (*J. Path. Bact.*, 1913, 17, 458—501).
—After the convoluted tubules are put out of action by uranium
nitrate, secretory diuretics, such as caffeine, fail to produce
diuresis; so also do mechanical diuretics, such as Ringer's fluid. In
the early stages of uranium nephritis, the urine produced is small
in amount, and contains less chlorides than normal. Caffeine urine
contains less chlorides than that produced by Ringer's solution or
5% sodium chloride solution. Uranium causes glycosuria.
                                                     W. D. H.

**Action of Radium Emanations on the Respiratory
Exchange.** J. VON BENCZÚR and DIONYS FUCHS (*Chem. Zentr.*, 1913,
i, 1444; from *Zeitsch. exp. Path. Ther.*, 1913, 12, 564—567).—Doses,

even one hundred times greater than the ordinary therapeutic dose of radium emanation, have only a slight effect in increasing the gaseous exchange, and do not affect the combustion processes taking place in the organism.   S. B. S.

Behaviour of Lecithin towards Radium Emanation and Thorium-X. CARL NEUBERG and LÁSZLO KARCZAG (*Chem. Zentr.*, 1913, i, 1356 ; from *Radium in Biol. Heilkunde*, 1913, **2**, 116—122) —Different authors have assumed that the hæmolytic action of radium emanation and thorium-X is to be referred to a lecithin scission in the red corpuscles. It is found, however, that no hydrolysis takes place when solutions of the active substances are mixed with lecithin emulsions. The acidity does not rise, neither do the solutions differ in colour, odour, or consistence from the ordinary aqueous solutions.   J. C. W.

Burgi's Law of the Combined Action of Drugs. BÉLA VON ISSEKUTZ (*Pflüger's Archiv*, 1913, **151**, 456—478. Compare A., 1912, ii, 667).—When two narcotics are introduced into the organism at the same time, or within a short interval, the combined effect is often greater than the sum of the effects of each individual drug. This increased effect is, according to Burgi, greatest when the drugs have different cell receptors. This theory is adversely criticised in some detail by the author, who illustrates his arguments by numerous examples, both from his own experience and by quotations from the results of other workers. He draws the conclusion that it is difficult, if not impossible, to formulate any law which will explain the combined action of two drugs administered simultaneously.   S. B. S.

Action of Adrenalin on the Respiration. DIONYS FUCHS and NIKOLAUS RÓTH (*Chem. Zentr.*, 1913, i, 1443 ; from *Zeitsch. exp. Path. Ther.*, 1913, **12**, 568—571).—In experiments on men, similar results were obtained to those in the case of animals, namely, an increase in the volume in respiration. In man, however, there was no increase of frequency, as was observed in the case of animals.   S. B. S.

Colchicine and its Derivatives. HERMANN FUHNER (*Arch expt. Path. Pharm.*, 1913, **72**, 228—238).—The activity of some of Windaus's derivatives of colchicine was compared with that of the parent substance. Colchiceine, in which only one of the enolic methoxy-groups of colchicine is saponified, is much less active than the methyl ether, colchicine. If the hydroxyl group is methylated, the original toxic value of colchicine is reached, or nearly so. Replacement of the acetyl group in this by benzoyl reduces the activity to one-tenth of that of colchicine. Oxycolchicine, obtained by oxidation with chromic acid, has on frogs an action resembling that of veratrine, but has no action when given to mammals.
                                                W. D. H.

The Influence of Cholesterol on Hæmolysis. G. JAHNSON-BLOHM (*Zeitsch. physiol. Chem*, 1913, **85**, 59—67).—The inhibitory

influence of cholesterol on the hæmolytic action of saponin, which was discovered by Ransom, was attributed by Windaus to the hydroxyl group of the former substance, and other views have been advanced to explain it. In the present experiments saponin and soaps were employed as hæmolytics, and the inhibiting action of cholesterol was confirmed; it is specially great if the temperature is raised, and increases with the time cholesterol is allowed to act. In saponin-hæmolysis an irreversible process between the red corpuscles and cholesterol occurs. In soap hæmolysis the action is less marked, and the explanation not so clear.

W. D. H.

The Influence of Cyanogen Gas on the Organism. JEAN LOUIS BURCKHARDT (*Arch. Hygiene*, 1913, **79**, 1—24).—When cyanogen, in concentrations much below 0·1 mg. per litre of air, is inhaled by cats, it has no ill effects; in concentrations of 0·1 mg. per litre, it can be inhaled for half an hour without danger. When the concentration reaches 0·2 mg. per litre, it acts toxically within a few hours. Rabbits are less susceptible, and can tolerate concentrations of 0·4 mg. per litre; for these animals the toxic concentration lies between 0·6 and 0·8 mg. per litre. The symptoms are irritation of the mucous membrane, difficulty in respiration, and convulsions; death results from paralysis of the respiratory centre. The symptoms are apparently those of hydrogen cyanide poisoning, the cyanogen reacting in the organism according to the equation $(CN)_2 + 2KOH = KCN + KCNO + H_2O$. If this takes place, 1 mg. cyanogen must have the same toxic action as 1 mg. hydrocyanic acid; the latter is, however, according to Lehmann and his pupils, much more toxic. It is probable, therefore, that other secondary reactions take place.   S. B. S.

The Physiological Action of Fraxin and its Behaviour in the Organism. GIOVANNI B. ZANDA (*Chem. Zentr.*, 1913. i, 1779; from *Arch. Farmacol. sperim.*, 1913, **15**, 117—121).—Fraxin has small physiological action, and a dog can tolerate 2 grams per kilo. of body-weight without ill effects. It has no appreciable influence on blood-pressure or temperature, and the greater part is excreted unchanged within twenty-four hours. To the mouse, it is relatively non-toxic, but it shows a slight action on the activity of a frog's heart.   S. B. S.

Anæmia Produced by the Hæmolysin from Streptococci. J. W. McLEOD and J. W. McNEE (*J. Path. Bact.*, 1913, **17**, 524—537). —Rabbits vary in their susceptibility to streptolysin. Hæmoglobinæmia and hæmoglobinuria are produced, and the hæmolytic property of the filtrate is closely related to its toxicity. Incubation at 37° destroys toxic and hæmolytic properties. The bone marrow hypertrophies in long experiments, and changes were also noted in liver, kidneys, and spleen. Repeated injections produce increased susceptibility and no immunity. The hæmolysis *in vivo* is much less than *in vitro*.

W. D. H.

Degradation of β-Ketonic Acids in the Animal Organism. LEO HERMANNS (*Zeitsch. physiol. Chem.*, 1913, **85**, 233—240).— It is uncertain whether, on decomposition of aliphatic acids in the organism, ketonic or acid intermediate compounds are formed. It is shown that ethyl phenylacetoacetate is decomposed into benzyl methyl ketone and hippuric acid. The ketone at first formed is converted into benzoic acid. When the ketone is administered to dogs, hippuric acid is recovered.

On subcutaneous injection of ethyl benzylacetoacetate, hippuric acid is formed in quantity, and only traces of phenylethyl methyl ketone. This ketone, when administered alone, yields exclusively phenaceturic acid. In this case, therefore, there is acid decomposition in contrast with the ketonic decomposition in the case of the phenyl ester.

Ethyl phenylpropylacetoacetate under similar conditions gives a good deal of hippuric acid, and traces of phenylbutyl methyl ketone.

When phenylbutyl methyl ketone is administered, only phenaceturic acid is obtained in the urine. The ketone is decomposed between the carbonyl and the methylene carbon, and phenylbutyric acid is formed : $C_6H_5 \cdot [CH_2]_4 \cdot CO \cdot CH_3 \rightarrow C_6H_5 \cdot [CH_2]_3 \cdot CO_2H$. The ester, on the contrary, forms phenylvaleric acid :

$$CH_3 \cdot CO \cdot CH \cdot CH_2 \cdot CH_2 \cdot C_6H_4 \cdot CO_2Et \rightarrow C_6H_5 \cdot [CH_2]_4 \cdot CO_2H.$$
The phenyl group in ethyl phenylacetoacetate has thus an abnormal influence.

The normal formation of acetone in the body is due to similar secondary reactions. Normally, acetoacetic acid is degraded to acetic acid, but under pathological conditions the secondary reaction predominates and acetone is formed. The degradation of the fatty acids accordingly does not take place with the formation of ketones, but there is an elimination of two carbon atoms.

<div align="right">E. F. A.</div>

The Influence of Salvarsan and Neosalvarsan on the Circulation and on the Kidneys of Healthy and Diseased Animals. ALWENS (*Arch. expt. Path. Pharm.*, 1913, **72**, 177—223). —Intravenous injection of salvarsan causes nephritis. Its toxicity increases not only with the dose given, but with the concentration; the histological appearances of the kidneys are described in detail; the nephritis is a vascular one, analogous to that produced by arsenic and cantharides. An immediate result of the injection, if made rapidly, is a fall in blood-pressure. Neosalvarsan produces clinically no nephritis, and in animals the nephritis produced by long-continued use of the drug is less marked; so also is the fall in blood-pressure. In animals which already have nephritis from other causes, the condition is intensified by very small doses of salvarsan, and in cases where the heart is diseased, the action of salvarsan on the circulation is most unfavourable.   W. D. H.

The Relationship of Strophanthin Action and the Intensity of the Heart's Action. VIKTOR WEIZSACKER (*Arch. expt. Path.*, 1913, **72**, 282—294).—It was proved in experiments

on the frog's heart that the action of strophanthin takes place more rapidly the more quickly the heart is beating. In the resting heart, the drug is not completely inactive. The rate of beat being constant, rise of temperature increases the velocity of the action of strophanthin.   W. D. H.

The Resistance of Different Animals Towards Arsenic. M. WILLBERG (*Biochem. Zeitsch.*, 1913, **51**, 231—252) —The following are the tolerated doses of potassium arsenite, expressed in mg. per kilo. of body-weight. For pigeons, less than 0·012 (subcutaneous); mice, 0·0156—0·0176 (subcutaneous); hedgehog, 0·01—0·014 (subcutaneous); rabbits, 0·008—0·01 (subcutaneous); dogs, 0·007 (subcutaneous or intravenous); guinea-pigs, 0·009 (subcutaneous); cats, 0·005—0·006 (subcutaneous); hares, more than 0·005 and less than 0·008 (subcutaneous); snakes, 0·012. The corresponding doses for arsenious acid are: For pigeons, 1·786 (per os); rabbits, 0·015 (per os); dogs, 0·03 (per os); hens, less than 0·06 (per os). It is noteworthy that the tolerance by man is less than by any of the above animals, which is probably due to the more highly developed nervous system. When arsenic is administered by the mouth, animals are to a large extent protected from the poisonous action by vomiting.   S. B. S.

Lipoids which Resemble Lecithin in Forming Hæmolysins along with Cobra-venom. JOHN CRUICKSHANK (*J. Path. Bact.*, 1913, **17**, 619—622).—A number of substances were obtained from the alcoholic extracts of egg-yolk, heart, liver, and kidney, which differ from lecithin. They are all soluble in water, and with one exception in ether. They are precipitated from the ethereal solution by acetone. They all form hæmolysins along with cobra-venom.   W. D. H.

Action of the Lecithins on the Processes of Poisoning in Higher Animals. E. HANSCHMIDT (*Biochem. Zeitsch.*, 1913, **51**, 171—192).—Lecithin by itself exerts no toxic action on animals, which can tolerate large doses, whatever method of administration is adopted. If injected together with curare, strychnine nitrate, ethyl alcohol, chloral hydrate, veronal, or morphine, it inhibited the action of these drugs. It increased, however, the toxic action of ricin. In the case of phosphorus poisoning, the effect of the lecithin appears to depend on the weight of the substance administered, smaller doses having apparently a beneficial, and larger doses a harmful, effect. The general condition of the animal and its body content in lipoids appears also to have some effect in this case.   S. B. S.

Poisoning by Methyl Alcohol. FRANCESCO OLIVARI (*Chem. Zentr*, 1913, i, 1780; from *Arch. Farmacol. sperim*, 1913, **15**, 83—96).—The toxicity of crude and pure methyl alcohol for frogs, mice, and guinea-pigs was investigated. In the case of the pure products, the minimal lethal doses were: for frogs, $16\cdot2^0/_{00}$; for

mice, $11\cdot5^0/_{00}$; and for guinea-pigs, $9\cdot5^0/_{00}$ of the body weight; the corresponding numbers for the crude acid product were 10·0, 7·5, and $6^0/_{00}$; and for the crude basic product, 8·6, 6·8, and $5\cdot5^0/_{00}$. A scheme is given for the forensic examination of drinks, and animal organs in which wood-spirit is suspected. The liquid is acidified with phosphoric acid, and the volatile acids, etc., are distilled off, whilst the bases, pyridine, amines, etc., remain in the residue. The distillate containing the acids is neutralised, and again distilled, the salts of the acids remaining behind, the aldehydes, etc., distilling over. These are fixed by m-phenylenediamine hydrochloride, and the mixture is distilled, when acetone and methyl alcohol distil over, and are estimated in the distillate. If the mixture is saponified before these treatments, a conception can be formed as to the quantity of esters present from the amount of alcohol in this distillate. Finally, ethereal oils can be extracted by mineral oils (b. p. 140—230°), and separated from the higher alcohols by fractional distillation. S. B. S.

Chemistry of Vegetable Physiology and Agriculture.

Formation of γ Aminobutyric Acid from α-Glutamic Acid by Micro-organisms. EMIL ABDERHALDEN, GEORG FROMME and PAUL HIRSCH (*Zeitsch. physiol. Chem.*, 1913, 85, 131—135).—Whereas Ackermann (A., 1910, ii, 1089) identified γ-aminobutyric acid amongst the bacterial decomposition products of d-glutamic acid, Abderhalden and Kautzsch (A., 1912, i, 952) were unable to confirm this. It is now found that γ-aminobutyric acid is formed when a mixture of glutamic acid, dextrose, Witte's peptone, and inorganic salts is incubated with decomposing pancreatic tissue. Success depends on the presence of the proper micro-organism; the mixture contained various yeasts, together with Diplococci and Staphylococci. E. F. A.

Methods in Soil Bacteriology. VI. Ammonification in Soil and in Solution. FELIX LÖHNIS and HENRY HAMILTON GREEN (*Centr. Bakt. Par.*, 1913, ii, 37, 534—562).— A critical study of the factors affecting ammonification and nitrification of blood meal, flesh meal, and horn meal under laboratory conditions. Where the tests are carried out in solution and under aerobic conditions, the quantity of material does not appear to influence the rate of ammonification. Under anaerobic conditions there is a marked retardation of the process, due possibly to an accumulation of bacterial metabolic products. It is suggested that in the initial decomposition of flesh meal and horn meal in shallow layers of liquid, aerobic and anaerobic organisms play perhaps an equally

important part, but that aerobic organisms are concerned more actively with the later stages of ammonification Under aerobic conditions, and with larger quantities of material, considerable amounts of ammonia may volatilise from the cultures, or undergo assimilation by bacteria. The decomposition of horn meal and blood meal is much more rapid in soil than in solution. When, however, soil tests in deep layers at full saturation are compared with solution tests in shallow layers, ammonification is faster in solution than in soil, and this would seem to indicate aeration as being one of the chief factors in determining the rate of decomposition in soils. The three materials used show differences among themselves in the rate of decomposition, and this varies again according as to whether the tests are made in solution or in soil. The conclusion is drawn that solution tests seem to afford more information concerning the nature of the materials used as sources of nitrogen.

Nitrification is not registered in solution in the presence of any of the materials, but in soil tests it keeps pace with ammonification provided that aeration is liberal, and that the quantity of ammonia formed is not excessive.   H. B. H.

The Oxidation of Thiosulphates on Bacterial Filters. WILLIAM T. LOCKETT (*J. Soc. Chem. Ind.*, 1913, 32, 573—581).— It has already been observed that phenol and thiocyanate undergo oxidation on bacterial filters (Fowler, Ardern, and Lockett, A., 1911, ii, 139). In the present investigation, thiosulphate solutions were passed repeatedly through filters, consisting of stoneware pipes 24 in. long, cemented at one end and filled with clinkers. The amount of change in the solution was determined by an estimation of the oxygen absorbed from acid permanganate solution, and of the residual thiosulphate by $N/80$-iodine. It was found that solutions up to 0·5% concentration (expressed as $Na_2S_2O_3$) can be oxidised; the resulting solution is acid, and the addition of alkali accelerates the rate of oxidation. The thiosulphate is oxidised finally to sulphate, but tetrathionate and pentathionate, with occasional traces of trithionate, are intermediarily produced.

In an extension of the investigation to the thionic acids, it was first shown that the usual tests are applicable with but few exceptions to thionate solutions of 0·1 and 0·02% concentration. With the exception of the dithionates, all the thionates undergo oxidation in this manner; potassium trithionate is oxidised to sulphate with intermediate formation of a considerable quantity of tetrathionate; potassium tetrathionate gives sulphate with a little pentathionate, whilst potassium pentathionate is directly oxidised to sulphate.

The conclusion is drawn that the oxidation is due to bacterial agency assisted by the physical and chemical properties of the filtering medium.   D. F. T.

The Products of the Putrefaction of *l*-Aspartic Acid. New Method of Detecting β-Alanine EMIL ABDERHALDEN and ANDOR FODOR (*Zeitsch. physiol. Chem.*, 1913, 85, 112—130).—On putrefactive

decomposition of *l*-aspartic acid, succinic, propionic, and formic acids are formed (compare Neuberg and Cappezzuoli, A., 1909, ii, 691). These acids are easily separated by the ester method, as the acid esters may be extracted with ether from the ester hydrochlorides of the amino-acids.

Emphasis is laid on the necessity of carrying out putrefactive decomposition experiments with a single known organism or a mixture of known organisms. β-Alanine obtained by Ackermann (A., 1911, ii, 757) from aspartic acid could not now be identified. It is recognisable in the very smallest quantity by conversion into ethyl acrylate, which has a characteristic odour, and when added to a putrefaction experiment it is easily identified in this manner. Pure cultures of the five micro-organisms present were incubated separately with aspartic acid. In no case was β-alanine formed.

E. F. A.

Reaction Phases of Alcoholic Fermentation. HANS VON EULER and DAVID JOHANSSON (*Zeitsch. physiol. Chem.*, 1913, 85, 192—208).—It is shown generally that, when sugar is fermented in presence of phosphate, the relation between the amount of carbon dioxide liberated and the phosphate fixed throughout the whole course of the change is that expressed by Harden and Young's equation, namely, $2C_6H_{12}O_6 + 2PO_4HR_2 = 2CO_2 + 2C_2H_6O + 2H_2O + 2C_5H_{10}O_4(PO_4R_2)_2$. This expression by no means explains the mechanism of fermentation or the part played in it by the individual enzymes.

Fermentation begins with the conversion by means of an enzyme of the hexose sugars into a carbohydrate, which can be esterified with phosphate. The development of carbon dioxide which accompanies this esterification is checked by an excess of phosphate. The fermentation controlled by phosphate is accelerated by the presence of lævulose. Both hexose diphosphate and triosemonophosphate are formed. The enzymatic hydrolysis of the hexose phosphate ester studied by Harden and Young is materially retarded by the presence of toluene. All the foregoing facts must be taken into consideration in any explanation of the fermentative changes.

E. F. A.

Invertase Reaction of Mixed Yeast Cultures. ALBERT J. J. VANDEVELDE and A. VANDERSTRICHT (*Biochem. Zeitsch.*, 1913, 51, 388—397).—The invertase action of mixed cultures lies generally between that of the varieties forming the mixture, which is in contrast to the effect observed with certain mixed cultures, on the alcoholic fermentation, where a mixture exerts a favouring action.

S. B. S.

Reduction of Acetaldehyde by Yeast Juice. S. KOSTYTSCHEV and ELISE HÜBBENET (*Zeitsch. physiol. Chem.*, 1913, 85, 408—411. Compare A., 1912, ii, 860).—An extract of dried yeast (maceration juice) is proved to reduce methylene-blue to the colourless state, and also acetaldehyde to alcohol, both in the presence and in the

absence of sugar. The active hydrogen in this case is probably formed in the same way as during zymase fermentation. E. F. A.

Are Moulds Able to Form Volatile Substances from Antimony Compounds? ERICH VON KNAFFL-LENZ (*Arch. expt. Path. Pharm.*, 1913, 72, 224—227).—The moulds investigated are not able to form volatile antimony compounds. In this there is a difference between antimony and the similar elements arsenic, selenium, and tellurium. The possibility that chronic antimony poisoning is due to the formation of volatile substances is excluded.
W. D. H.

Nature of the Osmotic Optimum in Biological Processes. ALFRED GUILLEMARD (*Compt. rend.*, 1913, 156, 1552—1554).—A theoretical paper explaining results obtained in the culture of *Aspergillus niger* under various conditions. The living matter absorbs metallic compounds necessary for its physico-chemical constitution, the rate of formation of plant tissue following a curve which presents an optimum for a certain density with respect to the properties of the metal experimented with. The osmotic optimum occurs with most chemical substances in biological reactions. The amount of substance which favours it is the "excitation" dose, and precedes the "toxic" dose. W. G.

Replacement of Zinc by Copper in the Culture of Aspergillus niger CHARLES LEPIERRE (*Compt. rend.*, 1913, 156, 1489—1491. Compare this vol., i, 326, 327).—Like cadmium, glucinum, and uranium, copper can replace zinc in the culture of *Aspergillus niger*. Added in the form of its sulphate, the weight of crop is normal if the amount of copper does not exceed 1 in 500,000, but the growth is retarded. If the amount rises to 1 in 1000, growth ceases. Sporulation takes place only if the copper present does not exceed 1 in 10,000. W. G.

The Assimilation of Guanine and Guanidine by Moulds. ALEXANDER KOSSOWITZ (*Chem. Zentr.*, 1913, i, 1297; from *Zeitsch. Gahrungs physiologie allg. landw. techn. Mykologie,* 1912, 2, 84—86).— Guanine could be used by a large number of moulds as a source both of carbon and nitrogen. These include *Botrytis bassiana, Penicillium glaucum, Mucor γ-Boidin, Cladosporium herbarum, Phytophthora infestans, Penicillium brevicaule, Aspergillus glaucus* and *A. niger,* and *Isaria farinosa.* Guanidine, as carbonate, chloride, nitrate, or thiocyanate, could be used as a nitrogen source by all moulds. S. B. S.

Enzymatic Hydrolysis of Hippuric Acid by Mould Fungi. ARTHUR W. DOX and RAY E. NEIDIG (*Zeitsch. physiol. Chem.*, 1913, 85, 68—71. Compare A., 1909, i, 861; ii, 510).—Some characteristic mould fungi—three Aspergillus and three Penicillium species— were grown for periods of one, two, three, and four weeks in a nutrient solution consisting of sucrose, tartaric acid, and inorganic

salts. The mycelium was removed, ground with glass, the juice expressed, and its action on hippuric acid tested, the formation of glycine being detected by means of titration with formaldehyde. In most cases nearly complete hydrolysis was observed independently of the age of the culture. There is very little secondary action converting glycine into ammonia. Taka-diastase (made from *Aspergillus oryzae*) has a similar hydrolytic action on hippuric acid.
E. F. A.

The Penetration of Different Forms of Nitrogen in Plants; Phenomena of Adsorption. D. CHOUCHAK (*Compt. rend.*, 1913, **156**, 1696—1699. Compare Pouget and Chouchak, A., 1912, ii, 796, 975).—The roots of young wheat plants deprived of vitality by immersion in boiling water for thirty minutes retain the property of adsorbing and fixing nitrogen in diffeernt mineral and organic forms. This property is due to the presence of certain substances not removed by boiling water, but removed by boiling alcohol. This power of adsorbing different nitrogenous compounds, at the same molecular concentration, varies according to the nature of the compound, and for the same form of nitrogen, the amount of nitrogen adsorbed varies, within certain limits, directly with the concentration of the surrounding medium with respect to nitrogen. The ratio of the concentration of adsorbed nitrogen in the roots to that of the nitrogen remaining in the liquid is always greater than unity.
W. G.

The Absorption of Different Forms of Nitrogen by the Plant; Influence of the Medium. D. CHOUCHAK (*Compt. rend.*, 1913, **156**, 1784—1787. Compare preceding abstract).—The adsorbing power of the exterior layer of dead roots, and the rate of absorption or diffusion in the living plant, for the same concentration in nitrogen, is considerably modified by the presence of such salts as magnesium sulphate, sodium chloride, etc., and the effects produced by a number of these have been studied. They do not act in the same manner, but by their action on dead roots and on living plants they arrange themselves in the same order. In a mixture of two or more salts, they may help or be antagonistic to one another. In many cases the adsorption of nitrogen is very considerably increased, sodium chloride having a beneficial effect.
W. G.

The Significance of Lipoids for the Formation of Bio-electrical Differences of Potential in Certain Plant Organs. JACQUES LOEB and REINHARD BEUTNER (*Biochem. Zeitsch.*, 1913, **51**, 288—299).—The bio-electrical differences of potential already described by the authors at the undamaged surface of certain plant organs (apple, etc.) are qualitatively and quantitatively almost identical with that at the interface of an aqueous solution, and a solution of phosphatides in guaiacol, *m*-cresol, and amyl alcohol, and a guaiacol extract of apple behaves in this respect exactly like the undamaged organ itself. The solvents themselves without the

phosphatide have practically no action. Fatty acids which are insoluble in water, such as oleic and palmitic acids, show the same effect towards the varying concentrations of the aqueous salt solutions as the living organ. They behave, however, differently towards different concentrations of acids. The bio-electric action of the organs is not due therefore to fatty acids, neither is it due to cholesterol, the electromotor effects of which are quite different to those of the living organ. Solid proteins, such as coagulated egg-white or gelatin, also act in a different way. The bio-electric effects of the living organ are therefore ascribed to the presence of phosphatides or some similar insoluble substances. Cephalin and lecithin were used in the experiments in chains, which were constituted in the following way: Hg | HgClM/1KCl | Guaiacol solution | KCl in varying concentrations | M/KClHgCl | Hg.   S. B. S.

The Influence of Anæsthetics on the Potential Difference at the Surface of Living Animal and Vegetable Tissues. JACQUES LOEB and REINHARD BEUTNER (*Biochem. Zeitsch.*, 1913, **51**, 300—306).—The addition of alcohol or ether to the aqueous phase diminishes the difference of potential at the interface of a living organ and an aqueous solution. The action is a reversible one. The quantities necessary to produce an effect are considerably larger than those necessary for the production of narcosis. A similar diminution of difference of potential is produced by the addition of alcohol or ether to the aqueous phase at the interface of an aqueous solution and a solution of oleic acid or lecithin in guaiacol. The action is due to the entrance of some ether into the non-aqueous phase. A similar action was not observed on the addition of an indifferent non-electrolyte, such as dextrose, to the aqueous phase.   S. B. S.

The Part Played by the Surface Tension and by Lipoids in the Living Cell. HORACE M. VERNON (*Biochem. Zeitsch.*, 1913, **51**, 1—25).—Exosmosis of tannin from vegetable cells, caused by various narcotics, is apparently not a mere surface-tension phenomenon, as Czapek assumes. According to this observer, the substances cause exosmosis in those concentrations which reduce the surface tension of water/air to 0·685. Out of the twenty-nine substances investigated by Czapek, seven produce exosmosis in concentrations in which the surface tension varies between 0·82 and 0·998. The concentrations, according to the author, more nearly correspond with those which produce narcosis in tadpoles and hæmolysis of blood-corpuscles. The narcotics appear therefore to exert their action owing to their solubility in lipoids, according to the Overton theory. The part played by the lipoids in animal cells can be investigated by determining the concentration of the various substances which inhibit the action of indophenoloxydase, an insoluble ferment which only acts, according to the author, when the lipoids are intact. It is now found that the concentrations of narcotics which are just sufficient to inhibit this ferment action

are about twice as strong as those which cause exosmosis of tannin from *Echeveria* cells. The actual ratios vary between 0·9 and 2·8 for the seventeen substances investigated. As the concentrations varied between 1 and 720, the closeness of these ratios is striking. Colloidal sodium oleate acts in the same concentrations on *Echeveria* as on oxydase, whereas saponin acts on the oxydase in 1/40 of this concentration. Acids act on oxydase in concentrations corresponding more or less with the electrical conductivity of this solution, and there is a crude parallelism between these values and their hæmolytic action. S. B. S.

Carbohydrates of Vegetables ERNST BUSOLT (*J. Landw.*, 1913, **61**, 153—160).—The sap of French beans (3000 c.c.), when kept for a week, yielded 9·3 grams of pure mannitol. No mannitol was found in the sap when quite fresh, or in sap which was at once sterilised by boiling and then kept for a week.

Cauliflower (1300 grams), without the stalk, yielded 7·9 grams of pure mannitol, which is supposed to have been present originally. It is, however, possible that the mannitol was produced during the evaporation of the sap. N. H. J. M.

Simple Vegetable Bases. GEORG TRIER (*Zeitsch. physiol. Chem.*, 1913, **85**, 372—391).—Emphasis is laid on the fact that the plant betaines are to be regarded as the simplest alkaloids formed from the amino-acids by exhaustive methylation.

The presence of glycine betaine and of choline in the alcoholic extract of oat seeds is established. In the phosphatide from oats, colamine (aminoethyl alcohol) but no betaine is present.

Glycine betaine may be identified as platinichloride. This salt undergoes a characteristic change when left in contact with its mother liquors.

Aminoethyl alcohol reacts quantitatively with nitrous acid, and may be estimated in this way. Since choline does not react with nitrous acid, the presence in it of 1% of colamine may be detected. Colamine is incompletely precipitated by phosphor-tungstic acid.

An investigation of the bases in areca nuts leads to the following formulæ being suggested:

$$\text{Guvacine, } C_6H_9O_2N = CH_2 \! \! <^{CH_2 \cdot CH_2}_{N = CH} \! \! > \! CH \cdot CO_2H.$$

$$\textit{iso}\text{Guvacine, } C_6H_9O_2N = CH_2 \! \! <^{CH_2 \cdot CH_2}_{NH - CH} \! \! > \! C \cdot CO_2H.$$

$$\text{Arecaine, } C_7H_{11}O_2N = CH_3 \! \! <^{CH_2 - CH}_{CH_2 \cdot NMe} \! \! > \! CH \mid {}^{- \; - \; CO}_{\quad \; O}.$$
These differ from the formulæ suggested by Jahns. E. F. A.

Formation of the Anthocyan Pigments of Plants. IV. The Chromogens. FREDERICK KEEBLE, E. FRANKLAND ARMSTRONG, and W. NEILSON JONES (*Proc. Roy. Soc.*, 1913, *B*, **86**. 308—317. Compare A., 1912, ii, 673; this vol., i, 325).—Flowers of any colour

variety of Brompton stocks, when treated with alcohol, lose their colour rapidly. The original colour is regained when the decolorised petals are placed in water, the recovery being rapid when the water is heated. The phenomenon is a general one, and it is also shown by the vegetative parts of plants. The brown wall-flower, which contains a mixture of purple anthocyan and yellow plastid colour, recovers purple. The power of recovering the original colour serves as a means of distinguishing anthocyan from plastid pigments. The recovery of the pigment is shown to be due to the oxidation of a chromogen.

The decolorisation is due to the activity of a reducing agent, which is extracted by alcohol. This is resistant to high temperatures, as the alcohol may be evaporated to dryness, and the residue taken up in water; it then contains an active reducing agent. This agent prevents the action of ·bran peroxydase on benzidine, whilst, when added to the blue solution resulting from the interaction of bran peroxydase, hydrogen peroxide, and benzidine, it brings about the decolorisation of the blue. Quinol has a similar effect, but not formaldehyde.

The flower petals contain a much larger quantity of chromogen than is used in the natural flower, as the colour may be removed and recovered several times. The amount of active water present in the cells determines the direction in which the pigment producing reaction shall go; as the amount of water decreases, the reducing agents become active and the oxydases inert.

The activity of α-glucase ceases in 60% ethyl alcohol and in 40% methyl alcohol. The activity of emulsin falls rapidly in alcohols up to 40% strength; in solutions with from 40 to 90% of alcohol the activity is proportional roughly to the amount of water present. Oxydase action ceases in about 70% alcohol, but in the plant cell the chromogens may undergo oxidation, even in 95% alcohol.

E. F. A.

Formation of the Anthocyan Pigments of Plants. V. Chromogens of White Flowers. W. NEILSON JONES (*Proc. Roy. Soc.*, 1913, *B*, 86, 318—323. Compare Keeble and Armstrong, A., 1912, ii, 673).— Lack of colour in recessive white flowers may be the consequence, not of the absence of an essential constituent of the colour-producing mechanism, but of the failure of these constituents to come together and interact with one another. White flowers of *Lychnis coronaria* contain a chromogen which gives rise to a reddish-brown pigment on oxidation. The chromogen may be extracted by treatment with absolute alcohol; it reacts with the peroxydases in other plants in presence of hydrogen peroxide to form the brown pigment, and can thus be used in the same way as benzidine to demonstrate the distribution of oxydase. In *Lychnis* the natural conditions are never such as to allow any interaction between oxydase and chromogen. On treatment with alcohol or a similar hormone, the barrier is removed by the destruction of the plasmatic impermeability, and pigment is formed. The following types of white flowers have been demonstrated: (1) Those which contain

an oxydase and a chromogen, for example, *Lychnis coronaria.* (2) Those which contain a peroxydase and a chromogen, for example, *Dianthus,* sp. (3) Those which contain a peroxydase but no chromogen. These give no colour reaction after treatment with chloroform and hydrogen peroxide. (4) Those which contain no peroxydase.   E. F. A.

Variation in the Composition of Water-Trefoil (Menyanthes trifoliata, L.) during a Season's Growth. MARC BRIDEL (*J. Pharm. Chim.,* 1913, [vii], **7.** 529—535. Compare A., 1911, i, 659).—This investigation was carried out on the same lines as were adopted in the case of gentian root (A., 1911, ii, 426), with the exceptions that (1) the carbohydrates hydrolysed by invertase in the water-trefoil are unknown, and (2) that meliatin, unlike gentiopicrin, cannot be isolated and weighed. The proportion of meliatin was therefore estimated by the change in rotation induced by emulsin in an aqueous solution of a dry alcoholic extract of the plant, in which (1) the initial reducing sugar, and (2) the carbohydrates hydrolysed by invertase had already been determined.

The results, tabulated in the original, show that the plant contains most meliatin (0·891%) towards the end of May, and least (0·655%) at the beginning of October. The carbohydrates hydrolysed by invertase are at a minimum (0·950%) at the middle of June, and increase steadily to 2·761% at the beginning of October. As in the case of gentian, it appears that the percentage of glucoside shows little variation, so that this substance cannot be regarded as a reserve material. On the other hand, the carbohydrates are accumulated as reserve materials up to the period at which the fruit ripens, to be used at the resumption of vegetative activity.   T. A. H.

Husks of Buckwheat Seeds. KURT FESSLER (*Zeitsch. physiol. Chem.,* 1913, **85,** 148—155).—The :brown husks of buckwheat seeds are reputed to contain a green pigment not identical with chlorophyll. The poisonous action of the husks towards animals is attributed to the photodynamic action of this pigment. The green pigment has now been studied more in detail and its absorption spectrum recorded; it shows red or brownish-red fluorescence in organic solvents. On keeping, the green colour changes to a yellow or brownish-green.

A yellow xanthophyll pigment is also present, which is closely related to phytosterol. The brown pigment of the husks is identified as a phlobaphen.   E. F. A.

The Fruit of Crataegus macracantha. W. BRUCE ARMSTRONG (*Chem. News,* 1913, [iv], **13,** 280—281).—The fruits yielded 17·98% of sugars, 2·085% of ash, and contained 0·595% of nitrogen and 0·79% of oil. Protein was detected in all the fruits, and Wagner's reagent and the phenolphthalein test indicated that atropine may be present, although no other evidence of this could be obtained.

The ash had the following percentage composition: Al_2O_3 (trace of iron), 6·86; CaO, 13·93; MgO, 12·16; K_2O, 23·80; Na_2O, 37·63; SO_3, 3·09; Mn, 0·10; Cl, 0·15. The sugars present included dextrose and lævulose. Acetic and citric acids were also present, the former due to fermentation.   T. A. H.

The Pharmacognosy of the Manna Ash. GIOVANNI B. ZANDA (*Chem. Zentr.*, 1913, i, 1779; from *Arch. Farmacol. sperim.*, 1913, **15**, 66—82).—Details are given for the preparation of the manna. To separate mannitol from fraxin, the aqueous extract of *Fraxinus* bark is treated with neutral lead acetate, the mixture is filtered, and then basic lead acetate is added. The mannitol in the filtrate can be estimated gravimetrically or polarimetrically. The fraxin is precipitated as a lead compound, which is decomposed by hydrogen sulphide. The product thus obtained is freed from tannic acid by treatment with a small quantity of water and recrystallised from alcohol. The fraxin can be estimated by titration with Fehling's solution after hydrolysis with dilute hydrochloric acid. The mannitol and fraxin contents of various species and of trees from different provinces and in different seasons were also investigated. When the quantity of mannitol is relatively large, that of fraxin is small and vice versa.   S. B. S.

Presence of Gentiopicrin in the Leaf-bearing Stems of Gentiana spp MARC BRIDEL (*J. Pharm. Chim*, 1913, [vii], **7**, 486—492. Compare this vol., i, 434).—The leaf-bearing stems of *Gentiana cruciata*, L., *G. lutea*, L., and *G. asclepiadea*, L., were first examined by Bourquelot's biochemical method, and gave indications of the presence of gentiopicrin. The latter was then extracted from each of these materials. The first-named plant yielded very little, in which respect it resembles *G. pneumonanthe*, the stems of which also contain only a small amount of the glucoside (A., 1910, ii, 887).   T. A. H.

Fruit of American Holly (Ilex opaca). F. F. CARHART and G. H. MILLER (*Chem. News*, 1913, **107**, 243—244).—The dry fruit contained 46·34% of reducing sugars, 8·31% of ash, 0·61% of nitrogen, and 1·5% of oil, as well as oxalic acid and proteins. The reducing sugars include dextrose and lævulose. The percentages of the constituents of the ash are as follows: SO_3, 4·59; Al_2O_3, 10·08; Fe_2O_3, 1·27; CaO, 15·91; MgO, 8·01; P_2O_5, 14·06; K_2O, 17·15; Na_2O, 24·32; MnO, 0·10; Cr, nil. The oil had D 0·9358 and saponification equivalent 303, and appeared to belong to the castor oil group.   T. A. H.

Comparison of the Hydrolysing Diastases of the Latex of Maclura aurantiaca with those of Ficus carica and Broussonetia papyrifera. C. GERBER (*Compt. rend.*, 1913, **156**, 1573—1575).—The latex of *Maclura aurantiaca*, like those of *Broussonetia papyrifera* and *Ficus carica*, merits the name of "vegetable pancreatic juice." Like them, and in the same way as

animal pancreatic juice, it hydrolyses and renders soluble carbohydrates, fat and protein substances, and plays a primary part in the nutrition of the plant. These properties are due to the existence of certain enzymes, the characteristics of which are intermediate between those of the enzymes of the *Broussonetia* and *Ficus*, and place the latex of the *Maclura aurantiaca* between those of these two plants, and nearer to the first than the second.

W. G.

Migration of the Constituents of Maize Grain in Water and Aqueous Solutions. EDMOND POPPE (*Bull. Soc. chim. Belg.*, 1913, 27, 103—109. Compare A., 1911, ii, 428).—Maize grains, when steeped in water or in dilute aqueous solutions of chlorides, nitrates, phosphates, or sulphates, or in saturated solutions of sucrose or sodium chloride, at the ordinary temperature for forty-eight hours, lose but very small amounts of their constituents. If, however, they are steeped in boiling solutions, a large amount of the nutritive substances is removed, and the grains diminish in alimentary value by 36·2%. Dilute solutions of the above-mentioned salts behave as distilled water with respect to the amount of nutrients removed. The ordinary temperature is not sufficiently high to kill the epidermic cells and so destroy their semi-permeability, but this occurs at the higher temperature, and the cell-walls become permeable to all the substances dissolved in the water. W. G.

Some Data on the Ripening of Florida Oranges. F. ALEX. McDERMOTT (*J. Amer. Chem. Soc.*, 1913, 35, 834—837).—A study has been made of the enzymes in the peel of Florida oranges with a view to ascertaining whether any change takes place in their nature or activity at the point at which the fruit becomes sufficiently ripe for consumption. The peel contains peroxydase, catalase, and invertase enzymes, but no oxydases. During ripening, the weight of the peel decreases in relation to the total weight, whilst that of the juice increases about equally in this relation. The total amount of acid in the juice decreases only slightly, but its concentration decreases considerably, whilst the sugar increases both in concentration and total amount. E. G.

Chemical Examination of the Roots of Phaseolus multiflorus, Lam. FREDERICK B. POWER and ARTHUR H. SALWAY (*Pharm. J.*, 1913, [iv], 36, 550—552).—The statement having been made that the roots of this plant (scarlet runner bean) are poisonous, the authors have submitted the roots to a systematic chemical examination, and have isolated a number of definite constituents. Physiological tests of certain of these constituents, and of extracts of the roots, furnished no evidence that the roots are toxic.

An aqueous extract of the roots on precipitation with alcohol furnished a preparation which hydrolysed amygdalin and gave the biuret reaction. No hydrocyanic acid was formed on macerating the ground roots in water.

An alcoholic extract of the roots was mixed with water and

steam distilled, and thus separated into (a) a small amount of brown essential oil, (b) resinous matter, and (c) matter soluble in water. From the last-mentioned portion furan-3-carboxylic acid (compare Rogerson, T., 1912, 101, 1044), allantoin (compare Ackroyd, A., 1911, ii, 308; Titherley and Coppin, A., 1912, ii, 289), an amorphous, glucosidic substance, and a reducing sugar which furnished d-phenylglucosazone were obtained.

The resinous matter was extracted successively with light petroleum, ether, chloroform, ethyl acetate, and alcohol. The material soluble in light petroleum was heated with alcoholic potassium hydroxide, and from the product of this reaction a *phytosterol*, $C_{27}H_{46}O$, m. p. 130°, pentatriacontane, and a *phytosterolin*, m. p. 275° (*acetyl* derivative, m. p. 162°), were isolated, as well as a mixture of solid fatty acids, which had m. p. 55°, and some liquid fatty acids, consisting of oleic, linoleic, and a third acid of lower molecular weight.

From the ether, ethyl acetate, and chloroform extracts nothing definite was isolated, but the second contained some glucosidic material.

The portion insoluble in the foregoing organic solvents, but soluble in alcohol, yielded a glucoside, *phaseosaponin*,

$$C_{50}H_{84}O_{20},7H_2O,$$
m. p. 238° (decomp.), crystallising in colourless leaflets, and having the properties of a saponin. On hydrolysis by hot dilute hydrochloric acid, this furnished rhamnose (4 mols.) and *phaseosapogenin*, $C_{26}H_{44}O_4$, m. p. 200° (dry, decomp.), which could not be obtained crystalline. A different saponin and sapogenin of the above empirical composition were found by van der Haar in *Polyscias nodosa*, Forst (A., 1912, i, 885).   T. A. H.

Pine Nut Oil. MAXWELL ADAMS and AUGUST HOLMES (*J. Ind. Eng. Chem.*, 1913, 5, 285—287).—The seeds obtained from the cones of the nut pine (*Pinus Monophylla* or *P. Fremontiana*), a tree growing on the Sierra Nevada Mountains, California, yield about 12% of oil having an aromatic odour and agreeable taste; it is light yellow in colour, but becomes colourless on exposure to light. The oil has m. p. −15°, b. p. 305°/60 mm., n_D^{40} 1·4543, saponification number 189·3, iodine number (Hübl) 108, and consists chiefly of olein, together with small quantities of stearin, palmitin, laurin, and linolein.   W. P. S.

Fruit of the "Snowberry" (Symphocarpus racemosus). C. B. SMITH (*Chem. News*, 1913, 107, 266).—The dried fruits contained 4·1% ash, 17·17% sugars, 1·1% of oil, 0·59% nitrogen (=3·68% protein) as well as tartaric and citric acids and a trace of malic acid. No alkaloids were found. The ash had the following percentage composition: SiO_2, 0·78; Fe_2O_3, 2·10; Al_2O_3, 3·15; CaO, 15·11; MgO, 6·30; Na_2O, 8·32; K_2O, 40·26; SO_3, 6·95; P_2O_5, 14·87; Mn, 0·94. The sugars probably included dextrose and lævulose. The oil had saponification value 212·3.   T. A. H.

Imbibition of Strychnos Seed. EDUARD VERSCHAFFELT (*Pharm Weekblad*, 1913, 50, 697—706).—The seed of *Strychnos Nux vomica* has a cuticular layer permeated very slowly by water. The presence of this layer greatly retards the imbibition of the seed, but addition of chloroform, ethyl acetate, and certain other organic substances produces a marked augmentation in the permeability to water, and hence in the velocity of imbibition.   A. J. W.

Occurrence of Barium in Tobacco and Other Plants. JAMES S McHARGUE (*J. Amer. Chem. Soc.*, 1913, 35, 826—834).—Crawford (*Bull.* No 129, *Bur. Plant Indust*, *U.S Dept Agric*) has shown that the poisonous effect of loco-weed (*Astragalus* spp) on cattle is due to the presence of barium, and further work has shown that barium is of common occurrence in plant tissues and soils.

Barium has now been found in tobacco in amounts varying from 0·009% to 0·074% (calculated as $BaSO_4$). Some of the barium can be extracted from the leaves by means of water, and is probably present in combination with organic acids   It is suggested that the occurrence of barium in living cells of the higher plants may indicate that the metal has some metabolic function.   E. G.

Constituents of the Leaves of Zygadenus intermedius.   III. FREDERICK W. HEYL and F. E. HEPNER (*J. Amer. Chem. Soc*, 1913, 35, 803—811) —In an earlier paper (this vol., i, 386) an account has been given of zygadenine, a crystalline alkaloid obtained from the leaves of *Zygadenus intermedius*.   Further investigation of the leaves has shown that in addition to the alkaloid, sucrose, reducing sugars, and dextrin (A , 1911, ii, 326), they also contain the following substances: Quercitin; cerotic acid; a *phytosterol*, m. p. 135°, $[\alpha]_D^{20} -29·5°$, which yields an *acetyl* derivative, m. p. 122—123°; hentriacontane, m. p. 68°; a fat, composed of the glycerides of stearic, palmitic, linolic, oleic, and *iso*linolenic acids; a polyhydric *alcohol*, m. p. 285—288°, of the ipuranol class; and a crystalline substance, m. p. 112—114°, which has not been identified.

The ash from (1) the leaves and tops and (2) the bulbs had the following composition, the first figure in each case referring to (1) and the second to (2): Moisture, 3·79, 2·04; Cl, 0·30, 0·19; CO_2, 18·05, 16·61; sand, 8·31, 7·01; C, 0·71, 0·48; soluble SiO_2, 4·39, 3·55; SO_3, 2·89, 3·33; P_2O_5, 5·03, 8·73; Fe_2O_3, 1 03, 1·08; Al_2O_3, 2·55, 1·08; Mn, traces; CaO, 25·37, 26·48; MgO, 5·34, 5·02; Na_2O, 5·58, 4·68; K_2O, 20·64, 20·35.   E. G.

Acidity in Silage : Method of Estimation   C O. SWANSON, J. W. CALVIN, and EDWIN HUNGERFORD (*J Amer. Chem. Soc.*, 1913, 35, 476—483).—The estimation of acidity in silage is usually carried out on an aqueous extract (compare Hart and Willaman, A , 1912, ii, 1205; Dox and Neidig, this vol., i, 236). A comparison has now been made of the efficiency of water and alcohol as extracting agents, and it has been found that equally uniform results are obtained by means of either solvent, but that the alcoholic extracts always contain a higher percentage of acids than the aqueous. It

therefore follows that some of the acids in silage are soluble in alcohol, but insoluble in water. The quantities insoluble in water vary with different kinds of silage, but are greatest in maize silage.

E. G.

Occurrence of Methyl Alcohol in Fruit Wines   HUGO BAUER and R. ENGLER (*Pharm Zentr.-h.*, 1913, **54**, 445—447. Compare Wolff, A., 1901, i, 110).—Methyl alcohol was found in currant wine; the amount was too small to be of practical importance.

N. H. J. M

The Part Played by Oxydases in the Curly Top Disease of Sugar Beet. HERBERT H. BUNZEL (*Biochem Zeitsch*, 1913, **50**, 185—208) —Leaves of plants with this disease contain two to three times as much oxydase as those of normal plants. No differences could be detected in the roots In beets in which the growth was impeded by other factors, no abnormally high content in oxydase could be detected. The difference in the oxydase content of leaves of different plants is not merely a function of their size, and young and healthy leaves are normal in this respect. Where a normal function of the plants is suppressed, such as the formation of seeds, there is a high oxydase content. The general conclusion is drawn that abnormal disturbances of growth lead to an increased oxydase content of the leaves. Attention is called to similar high oxydase contents in other plant diseases. The general distribution of the oxydases in the various juices of the plant was also investigated The expressed juice of seeds is richest in oxydase; then follow the leaves and roots.

S. B. S

Action of Flowers of Sulphur on the Growth of Sugar Beet. JOSEF URBAN (*Zeitsch. Zuckerind Bohm*, 1913, **37**, 441—444). —Application of flowers of sulphur slightly increased the yield of sugar beet. The sulphur was without effect on the colour of the leaves, and also had no effect on the amount of sugar and the quality of the juice.

N. H. J. M.

The Acids in Honey. ALFRED HEIDUSCHKA and G. KAUFMANN (*Chem. Zentr.*, 1913, i, 1221   from *Südd. Apoth. Zeit.*, 1913, **53**, 118—119).—About half of the volatile acids in honey is represented by formic acid, which was estimated in the steam-distillate and found to compose $0·0037$ to $0·0072\%$ of the substance The non-volatile acids were estimated by the method of Heiduschka and Quincke (A., 1908, ii, 73) with the result: Lactic acid, $0·0225\%$; malic acid, $0·0019\%$; traces of tartaric acid; the merest traces of higher fatty or wax acids; no succinic acid; phosphoric acid, $0·0286\%$ as P_2O_5. This accounts for about one-quarter of the total acidity as measured by $0·1N$-potassium hydroxide. The remainder is largely due to carbon dioxide and to amphoteric substances   J. C. W.

Behaviour of Nitrates in Soils IGNAZ VOGEL (*Landw. Versuchs-Stat.*, 1913, **82**, 158—159. Compare A , 1912, ii, 1200)- The high

and irregular losses of nitrogen previously observed are now shown to be due to absorption of nitrates by the glazed dishes in which the soils were kept. Subsequent experiments showed, however, that light humous soils, kept in thin layers, may lose, in a few days, 10—12% of the nitrates present. The loss of nitrates is now attributed to denitrification, and not to a chemical decomposition of nitrates, or to assimilation. N. H. J. M.

The Behaviour of Acid Amides in the Soil. Samuel L. Jodidi (*J. Franklin Inst.*, 1913, 175, 245—258. Compare A., 1910, ii, 339; 1911, ii, 820).—The author, having previously shown the different forms in which organic nitrogen exists in soils, now describes experiments on the ammonification of acetamide and propionamide when mixed with soil under different conditions; after varying intervals of time these mixtures were distilled with either magnesium oxide or barium carbonate, and the evolved ammonia carefully estimated.

It is found that acetamide and propionamide readily undergo ammonification when mixed with soil, that the rate of transformation is greatly influenced by the chemical structure of the amide, and that the maximum percentage of ammonia obtained from acetamide and propionamide is 83·43% and 75·14% respectively. F. M. G. M.

Fixation of Ammonia by Permutite and Clay Soils. Availability of Permutite Nitrogen for Plants. David J. Hissink (*Landw. Versuchs-Stat.*, 1913, 81, 377—432).—The results of pot experiments showed that oats assimilate nitrogen as ammonium sulphate and as permutite nitrogen about equally well, 70% of both being utilised. The solubility of the two forms of nitrogen in water saturated with carbon dioxide is, however, totally different, permutite nitrogen requiring 1300 to 1400 times as much water as the nitrogen of ammonium sulphate held by a clay soil.

The very slow liberation of ammonia from permutite indicates that the ammonia is partly chemically combined, and not merely held by adsorption. N. H. J. M.

Evolution of Sulphur in Soil; Study of its Oxidation. Ch. Brioux and Marcel Guerbet (*Compt. rend.*, 1913, 156, 1476—1479).—A study of the oxidation of sulphur when introduced into various kinds of soil, with or without the addition of certain other substances. The results show that the oxidation is almost entirely due to microbic action. With garden soil the oxidation is slow at first, but becomes very rapid after the tenth day, the introduction of carbohydrates, such as sucrose and starch, having a marked retarding influence on the rate of oxidation, whilst peptone produces very considerable increase in the oxidation after the fifteenth day. The addition of chalk to a soil poor in lime increases the rate of oxidation by fixing the sulphuric acid formed. The inoculation of sterilised soil by ordinary soil water increases the rate of oxidation by about twenty to sixty times. W. G.

Chemical Causes and Character of the Injurious Effect of Large Amounts of Lime on Peat Soil. GEORG A. RITTER (*Bied. Zentr.*, 1913, **42**, 239—242; from *Fuhling's Landw. Zeit.*, 1912, 593).—The losses of nitrogen which take place when lime and nitrates are applied to peat are attributed to chemical and not to biological action. A very small part of the loss may be due to the production of nitro-compounds from humus; the main cause of the destruction of nitrates is the reducing action of the humus.

The injury to vegetation observed when lime alone is applied in large amounts to peat cannot be due to the destruction of nitrates, since no nitrates are present, but to the increased oxidation of the organic matter and the production of substances, such as oxalic, formic, and acetic acids, etc., which are injurious to plants.
N. H. J. M.

Influence of Humus on the Weathering of Silicates. H. NIKLAS (*Bied Zentr.*, 1913, **42**, 231—232, from *Intern. Mitt. Bodenk.*, 1912, **2**, 214).—The results of experiments in which silicates were kept in contact with peat for seven years, showed that the silicates were only very slightly attacked.   N. H. J. M.

Zeolitic Properties of Ground Phonolite and Lime Trass Manure Compared with some Soil Varieties. ERICH BUSSMANN (*J. Landw.*, 1913, **61**, 97—134).—The ammonia of ammonium chloride is very strongly and chemically absorbed by lime trass; it is strongly absorbed by marsh soil, and well absorbed by phonolite, whilst red soils and loam have respectively only moderate and slight absorptive properties. All the substances adsorb potassium in dilute solutions, and absorb it in strong solutions. Calcium is only notably absorbed by lime trass. Nitrogen as nitrates is not absorbed by any of the substances, and magnesium only by lime trass and marsh soil. Phosphoric acid is 'fixed chemically, most by lime trass, and least by lime.

Under certain conditions the addition of phonolite and lime trass is favourable to the activity of Azotobacter, and consequently induce increased fixation of nitrogen in the soil. The sum of factors which produce this result is, however, still unknown.
N. H. J. M.

Manure Analyses. EILHARD ALFRED MITSCHERLICH and WILH. SIMMERMACHER (*Landw. Jahrb.*, 1912, **43**, 405—435).—A continuation of the author's work on the law of minimum as a logarithmic function (compare A., 1911, ii, 760). Numerous analyses are described, and the results tabulated, from which the author deduces formulæ supporting his theory.   F. M. G. M.

Organic Chemistry.

Formation of Pure Methane from Aluminium Carbide.
ENRIQUE HAUSER (*Anal. Fis. Quim.*, 1913, **11**, 317—319).—The carbide may on treatment with water yield alkali hydroxides, which with metallic aluminium give hydrogen, which in one case amounted to 8% of the gas.   G. D. L.

The Inflammability of Acetylene Mixed with Approximately 30% of Air. MARCEL DELEPINE (*Eighth Inter. Cong. App. Chem.*, 1912, **4**, 25—28).—In a series of experiments on the inflammability of mixtures of acetylene and air in approximately the proportion 70 : 30, an ovoid globe of one litre capacity was used. Electric sparks 2 mm. in length failed to ignite the gas even when the pressure was increased to $1\frac{1}{2}$ atmospheres. An electrically heated platinum wire is more effective than one of iron, for a wire of the latter metal, 2 cm. in length, caused ignition only when the additional pressure was 3·5 cm. and the wire was actually fused. The effect of the extent of the heated surface is indicated by the failure of a platinum wire 10 mm. long and 0·1 mm. in diameter to inflame a mixture under 11·3 cm. additional pressure although the wire fused, whilst a wire 0·2 mm. in diameter and 20—30 mm. long inflamed the gaseous mixture even when the pressure was slightly reduced; the latter wire failed to ignite a similar gaseous mixture enclosed in a lead tube 20 mm. in diameter and 1·4 mm. long. Mercury fulminate is very active in causing ignition, for although 0·005 gram failed to affect a mixture containing 29% of air, 0·01 gram caused inflammation in a mixture containing 28% of air under an additional pressure of 1 cm.; if the air is reduced to 23%, however, the pressure must be increased by more than 9 cms. before ignition is caused by this quantity of fulminate.

The initiation of the combustion is believed to be due to the primary decomposition of the acetylene giving hydrogen which forms a more combustible mixture with the air; the combustion of the new mixture then induces the inflammation of the remaining gas. It is suggested that the decrease in inflammability in the lead tube used above is due to the rapid mixing of the hydrogen and air being checked.   D. F. T.

Action of Acetylene on Some Copper Compounds: New Cupro-Acetylene Compounds. FELIPE LAVILLA LLORENS (*Anal. Fis. Quim.*, 1913, **11**, 320—327).—When pure acetylene is allowed to act on a 10% solution of copper sulphate, to which is added 3 volumes of a 20% solution of sodium sulphite, there is first precipitated the compound Cu_2SO_3, Cu_2C_2 of a clear red colour. When an excess of acetylene is employed, the dark red $Cu_2SO_3, 2Cu_2C_2$ is formed. When acetylene in excess acts for a long period on the well washed precipitates obtained from copper sulphate by means of sodium hydroxide or carbonate, or ammonium hydroxide, a black, explosive substance of the composition C_6Cu_3, H_2O is obtained.   G. D. L.

Action of Alkali Hydroxide and of Dry Silver Oxide on Trimethylene Bromide. B. F. FORTINSKI (*J. Russ. Phys. Chem. Soc.,* 1913, **45**, 568—580).—The author reviews the literature dealing with the formation of β-oxides, and describes attempts to prepare such an oxide from αγ-dibromopropane.

The action of aqueous potassium hydroxide on αγ-dibromopropane yields allyl alcohol and β-propylene glycol; the latter forms a *phenyl-urethane*, $C_{17}H_{18}O_4N_2$, m. p. 137—137·5°.

The reaction occurring between dry silver oxide and αγ-dibromo-propane is very energetic, but in presence of ether proceeds more smoothly, the products being β-propylene glycol and a compound of high boiling point which is converted into the same glycol by treatment with 10% sulphuric acid solution, and is hence probably a double β-oxide.   T. H. P.

Oxidation of Alcohols under the Influence of Heat. JEAN B. SENDERENS (*Compt. rend.,* 1913, **156**, 1909—1912).—As a pre-liminary to the investigation of the oxidation of alcohols in presence of various metals and metallic oxides, the action of hot air on various alcohols has been examined, and it is shown that oxidation occurs at lower temperatures than has previously been supposed.

The experiments were made by passing a mixture of dry air and the vapour of the alcohol into a vacuous glass tube, heated to the required temperature. The air was passed in at the rate of 100 c.c. per minute. Under these conditions, the oxidation of ethyl alcohol begins at 405°, and the issuing gas contains no oxygen, when the temperature is raised to 450°. The corresponding temperatures for *iso*butyl alcohol are 400° and 435°, and for *iso*amyl alcohol, 380° and 410°. The principal product is carbon monoxide, but some dioxide is also formed, and at the lower temperatures some aldehyde and acid are produced. In the case of ethyl alcohol the issuing gas contains also some ethylene, methane, and hydrogen. Magnesium turnings, finely-granulated zinc, aluminium powder, molybdic anhydride, blue tungstic oxide, thoria and silica only feebly assist or accelerate these reactions, whereas vanadic anhydride lowers the temperature at which oxidation begins, and accelerates the absorption of oxygen, and is therefore a true catalyst (compare Naumann, Moeser and Lindenbaum, A., 1907, ii, 273).
                                                            T. A. H.

The Hydrogenation of Some Secondary *d*-Ethylenic Alcohols in the Presence of Nickel. ROGER DOURIS (*Compt. rend.,* 1913, **157**, 55—57).—By the passage of secondary ethylenic alcohols of the type CHR:CHR'·OH over reduced nickel at 200°, they are converted, by isomerisation, into the corresponding ketones, $CH_2R·CH_2·COR'$, some of the saturated hydrocarbon $CH_2R·CH_2·CH_2R'$ being formed at the same time. The secondary ethylenic alcohols are readily obtained by the condensation of magnesium alkyl haloids with acraldehyde or crotonaldehyde (compare Grignard, A., 1901, i, 679). Thus *iso*amyl-propenylcarbinol is converted into *propyl isoamyl ketone*, $C_5H_{11}·COPr$, b. p. 177—179°, D_4^0 0·8362, D_4^{27} 0·8205, giving a *semicarbazone,* m. p. 107°. This ketone is also obtained by oxidation of *propylisoamyl-*

carbinol, $C_5H_{11}\cdot CHPr\cdot OH$, b. p. 184—186°/760 mm., D_4^0 0·8335, D_4^{16} 0·8199, prepared by the action of butaldehyde on magnesium *iso* amyl bromide.

*iso*Butylvinylcarbinol, when passed over reduced nickel at 200°, yields ethyl *iso*butyl ketone, b. p. 134—135°, giving an *oxime*, m. p. 129°. *cyclo*Hexylpropenylcarbinol yields cyclo*hexyl propyl ketone*, not yet obtained free from *butyl*cyclo*hexane*, b. p. 178—182°, D_4^0 0·8315 D_4^{20} 0·8178. The ketone gives a *semicarbazone*, m. p. 155°. W. G.

Action of Bromine on Ethyl Ether. ALEXANDER E. ARBUZOV (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 442—457).—In view of the divergent results obtained by McIntosh (T., 1905, **87**, 784; A., 1910, i, 808) and by Tschelinzev and Konovalov (A., 1909, i, 353; 1911, i, 415) the author has investigated the action of bromine on ethyl ether, with the following results.

At temperatures above 0°, this action yields no "oxonium dibromide," the sole product being Schutzenberger's perbromide (A., 1873, 487). If Tschelinzev's directions are followed closely, the same perbromide is obtained in an impure condition.

The value 9·13 Cal., given by Tschelinzev and Konovalov for the heat of formation of the dibromide, really represents the heat of formation of the perbromide, the value found by the author being 8·8 Cal. per gram-mol.

The interaction of ether and bromine in presence of solvents does not lend itself to calorimetric investigation, indefinite results being obtained.

At −80°, the action of bromine on ether yields the dibromide described by McIntosh (*loc. cit.*). T. H. P.

Vanadic Esters and Other Organic Vanadium Compounds WILHELM PRANDTL and LUDWIG HESS (*Zeitsch. anorg. Chem.*, 1913, **82**, 103—129).—The only previous preparation of vanadic esters is by Hall (T., 1887, **51**, 751). It is found that finely powdered vanadium pentoxide dissolves in many alcohols on boiling, and esters may be isolated from the solutions. Orthovanadic esters are readily prepared, with the exception of the methyl ester, and may be distilled without decomposition. Pyrovanadic esters have not been obtained. Meta-vanadic esters result from the action of small quantities of water on the ortho-esters, and form unstable solids, which decompose without melting. It is proposed to call the metavanadates, trivanadates. The further action of water gives the hexavanadates, which have not been obtained in a pure condition, as they are always mixed with trivanadates and colloidal vanadic acid.

The alcoholic solutions are of the colour of potassium dichromate when cold, but become lighter, and finally colourless, on heating, the colour change being completely reversible. This is due to the reaction in the case of the ethyl ester:

$$Et_4V_6O_{17} + 2Et\cdot OH \rightleftharpoons 2Et_2V_6O_9 + H_2O$$
<div style="text-align:center">Orange   Colourless.</div>
Any change tending to remove water should therefore cause a lightening of the colour. This is confirmed. The deeply coloured cold 1·5% solution of vanadium pentoxide in ethyl alcohol becomes colourless at 60—70°, but if diluted with an equal volume of absolute alcohol the change takes place at 50—60°, whilst the addition of a few drops of water raises the temperature of the change to above 70°. Anhydrous copper sulphate removes most of the colour at the ordinary temperature. An excess of alcohol in the cold does not alter the colour, but only affects the temperature at which the change takes place. The electrical conductivity diminishes at the same time as the colour, and only begins to increase with the temperature after decolorisation is complete. The conductivity also diminishes with increasing concentration of the alcohol. Pure ethyl orthovanadate has a very small conductivity. A solution of 1 mol. V_2O_5 in 1·09 mol. Na_2O exhibits similar colour changes to the ester.

The esters, especially *tert.*butyl orthovanadate, are very suitable for the preparation of clear colloidal solutions of vanadic acid, as the alcohol is easily removed by boiling.

Ethyl orthovanadate, Et_3VO_4, is a bright yellow liquid, b. p. 98·5°/16 mm., and 152°/145 mm., D^{15} 1·167, forming white crystals in liquid air. A greenish-black, crystalline *compound*, $V_4C_{16}H_{40}O_{18}$, is obtained by heating the ester at 160—170°, acetaldehyde and ether being evolved. Propyl orthovanadate, $Pr^a_3VO_4$, has b. p. 143°/24 mm., D^{15} 1·088, and forms an amber-coloured glass in liquid air. *n*-Butyl orthovanadate, $(C_4H_9)_3VO_4$, has b. p. 175°/22 mm., and the *iso*-propyl ester, b. p. 149°/16 mm., and D^{15} 1·033.

tert.Butyl orthovanadate, b. p. 117°/15 mm., forms colourless crystals, m. p. 45—47°. *iso*-Amyl orthovanadate forms yellow crystals, m. p. about 70°, b. p. 185—187°/18 mm. The tert.*amyl ester*, $(C_5H_{11})_3VO_4$, is a colourless liquid, b. p. 161°/19 mm., D^{17} 0·993, and is stable towards air and water.

Ethyl trivanadate (metavanadate), $Et_3V_3O_9$, is a light yellow powder, which readily decomposes. The molecular weight determination in phenol gives figures corresponding with the above formula. The n-*propyl* and iso-*amyl* esters have similar properties.

Vanadium oxychloride and sodium ethoxide react in benzene, forming *diethyl chloro-orthovanadate*, $VOCl(OEt)_2$, a dark red liquid, b. p. 103°/33 mm., D^{15} 1·366. By using suitable proportions, *ethyl dichloro-orthovanadate*, $VOCl_2\cdot OEt$, is obtained as a red liquid, b. p. 102°/49·5 mm.

The methyl esters have not been isolated, and glycerol and benzyl alcohol are oxidised by vanadium pentoxide.

Aniline hexavanadate, $(NH_3Ph)_4V_6O_{17},2H_2O$, forms reddish-brown, monoclinic prisms, $a:b:c = 0·4912:1:0·8511$, β 93°57'. Vanadium oxychloride forms an *additive product*, $VOCl_2,2Et_2O,2H_2O$.

<div align="right">C. H. D.</div>

The Methods for the Synthesis of Glycerides. Adolf Grün (*Ber.*, 1913, **46**, 2198—2200).—Polemical. A criticism of the results and conclusions of van Eldik Thieme (this vol., i, 701).   J. C. W.

The Preparation, Crystalline Structure, and Physical Properties of the Two Forms of Solid Nitroglycerin [Glyceryl Trinitrate]. HAROLD HIBBERT (*Eighth Inter. Cong. App. Chem.*, 1912, **4**, 37—57).—The statement of Kast (A., 1906, i, 922) as to the existence of two isomeric forms of glyceryl trinitrate, m. p. 2·8° and 13·5° respectively, has been considerably discounted by the failure of Nauckhoff (A., 1912, i, 63) to isolate the more fusible isomeride.

It is now found that if a mixture of wood pulp or powdered glass wool with glyceryl trinitrate (preferably a fresh specimen which has not been previously solidified) is cooled to − 40°, the latter crystallises in the new form described by Kast, for if glyceryl trinitrate at − 40° is inoculated with it the whole crystallises to a *labile* form, m. p. 2·0°. This labile isomeride passes readily into the stable form, m. p. 13·1°, for although when fused and cooled again to − 40° within one minute it spontaneously crystallises in the labile form, a longer period in the fused condition prevents any tendency to spontaneous crystallisation in any form. The solid labile form also passes rapidly into the stable one when inoculated with a trace of the latter or sometimes even on rubbing, the transformation being accompanied by a very appreciable development of heat ; the labile form also appears to be the more sensitive towards shock.

If the wood pulp used for the initial freezing contains powdered sodium nitrate, inoculation with this mixture causes more rapid crystallisation of glyceryl trinitrate, but in the more stable modification. Potassium nitrate has no such effect on the nature of the solid which separates, and it is possible that the separation of the less fusible isomeride is not due merely to the presence of the sodium nitrate, but depends on other conjoint factors of which the presence of moisture is one.

Microphotographs are given of the crystals of the two forms, of which the labile belongs to the triclinic and the stable to the rhombic system. Attention is drawn to the remarkable analogy between the isomeric forms of glyceryl trinitrate and those of benzophenone (Zincke, this Journ., 1871, **24**, 832 ; Auwers and Meyer, A., 1889, 611).

D. F. T.

Boiling Points of Solutions of Glyceryl Trinitrate. A. L. HYDE (*Eighth Inter. Cong. App. Chem*, 1912, **4**, 59—67).— Molecular-weight determinations have been effected by means of a modified form of the electrically heated Beckmann apparatus, with glyceryl trinitrate in various solvents ; as the concentrations attained in some cases over 75 grams of the nitrate to 100 of solvent, the results calculated from the usual law for dilute solutions can hardly be very trustworthy. With ether, methyl alcohol or chloroform as solvent, the results indicate an association which increases with the concentration, whilst with acetone the results are below the theoretical. Ethyl acetate gave, over a fairly wide range of concentrations, concordant results, which agreed well with the theoretical molecular weight and its application for such determinations should be useful, for example, in the estimation of diglycerol tetranitrate admixed with glyceryl trinitrate.

In a mathematical discussion of the results obtained with the three

solvents which give indications of association, it is shown that the rise in boiling point can be expressed by the equation $a = ch'$, where a is the rise in b. p., h the percentage composition of the solution, whilst c and n are constants.   D. F. T.

Separation of Glyceryl Trinitrate from Nitro-substitution Compounds. A. L. HYDE (*Eighth Inter. Cong. App. Chem.*, 1912, **4**, 69—76).—On shaking 1—3 grams of a mixture of glyceryl trinitrate and a nitro-derivative of toluene with 75 c.c. of carbon disulphide, four times with fresh portions (30 c.c.) of diluted acetic acid (65 acid : 35 water by volume), it is found that a fairly constant percentage of the nitrotoluene originally present in the mixture is left in the carbon disulphide, whilst the glyceryl nitrate is almost entirely to be found in the acetic acid. The quantity of nitrotoluene in the carbon disulphide is determined by careful evaporation after first washing the solution with water.

The following nitro-compounds were tried : *o*- and *p*-nitrotoluenes, liquid dinitrotoluene and its isomerides, m. p. 48° and 68° respectively, also liquid trinitrotoluene. Knowing the proportion of each of these to be found in the carbon disulphide after the above procedure, it is possible to apply this process to the rough estimation of any one of these nitro-compounds in a binary mixture with glyceryl trinitrate.
                                                              D. F. T.

Phytic Acid in Cottonseed Meal and Wheat Bran. J. B. RATHER (*J. Amer. Chem. Soc.*, 1913, **35**, 890—895).—The Patten and Hart modification of Posternak's method for the separation of inositolphosphoric acid, or so-called phytic acid, from wheat bran gives a product containing at least 5% of inorganic impurity mainly iron and aluminium phosphates, so that the formula $C_2H_8O_9P_2$ based on such results is probably erroneous (compare Posternak, A., 1903, ii, 679). Examination of the phosphorus compounds of wheat bran which are soluble in 0·2% hydrochloric acid and of cottonseed meal which are soluble in similar acid and also extracted by subsequent treatment with 0·2% ammonium hydroxide, indicates that by purification they yield an identical acid $C_{12}H_{41}O_{42}P_9$; this on heating with sulphuric acid undergoes scission into inositol and phosphoric acid and it is free from pentosans.   D. F. T.

Trimethylene Trisulphide and Its Oxidation Products. OSCAR HINSBERG (*J. pr. Chem.*, 1913, [ii], **88**, 49—58. Compare A., 1912, i, 546).—Trimethylene trisulphoxide dissolves in concentrated hydrochloric acid, yielding a compound which is resolved into its components on the addition of alcohol, and is considered to be a basic salt containing the group $CH_2 \cdot SCl \cdot OH$; when kept the solution deposits a colourless oil. In view of these results, the author is undertaking a study of the action of the halogen acids on the trisulphoxide, the present paper dealing particularly with the action of hydriodic acid.

Trimethylene trisulphoxide dissolves in warm dilute hydriodic acid and crystallises out again unchanged. When dissolved in concentrated

hydriodic acid (1 gram in 20—25 c.c., D = 1·96) and the solution maintained for twenty-four hours at the ordinary temperature, the trisulphoxide is reduced to a new labile (β) *trimethylene trisulphide*, which is obtained as yellow, crystalline precipitate on diluting the solution with water. The new trisulphide has m. p. 247° (decomp.), and passes into the stable (α) trisulphide of m. p. 216° on crystallisation from chloroform, acetic acid, benzene or alcohol. Attempts to effect the reverse transformation by the action of acetyl chloride, ethyl iodide or iodine proved successful.

The β-trisulphide may also be prepared by dissolving the α-compound in concentrated hydriodic acid, and maintaining the solution for several days at the ordinary temperature.

A solution of trimethylene trisulphoxide in seven times its weight of hydriodic acid (D 1·96) deposits after twelve hours stout, brown plates or prisms of *β-trimethylene trisulphide tri-iodide*, $CH_2 \underset{SI \cdot CH_2}{\overset{SI \cdot CH_2}{<}} > SI$, which melts indefinitely at 118—123° (decomp.), and loses its iodine completely when exposed to the air for eight days, or when heated at 60°, yielding β-trimethylene trisulphide. If the tri-iodide is crystallised from chloroform and then heated at 60° until the iodine is removed, either the pure α-trisulphide or a mixture of the α- and β- forms is obtained.

The tri-iodide combines with iodine in chloroform solution, yielding a *tetraiodide*, $C_3H_6S_3I_4$, which is derived from the α-trisulphide, and crystallises in elongated prisms, resembling iodine, m. p. 100° (decomp.), with previous sintering. The tetraiodide is more stable than the tri-iodide, but loses its iodine completely when heated for several hours at 60°, or when exposed to the air for several weeks yielding α-trimethylene trisulphide. If kept for several weeks in contact with aqueous sodium hydrogen carbonate, the tetraiodide loses only part of the iodine, with the formation of a brown substance which is probably the tri-iodide of α-trimethylene trisulphide.

The author has also investigated the action of hydrogen peroxide on the isomeric trisulphides, in the hope of obtaining the corresponding trisulphoxides, but no evidence of the existence of such isomerides was obtained.

When heated for two hours with 10—15% hydrogen peroxide on the water-bath, the trisulphides are converted into trimethylene trisulphoxide, which is accompanied by *trimethylenedisulphonesulphoxide*, $CH_2 \underset{SO_2 \cdot CH_2}{\overset{SO_2 \cdot CH_2}{<}} > SO$.

The latter compound is separated from the trisulphoxide by taking advantage of its sparing solubility in water and organic solvents. It crystallises in colourless needles, which become brown at 270° without melting.

The action of hydrogen peroxide on the trisulphide also leads to the formation of *trimethylenedisulphoxidesulphide*, $CH_2 \underset{SO \cdot CH_2}{\overset{SO \cdot CH_2}{<}} > S$, which is readily soluble in water and crystallises in slender, colourless needles; m. p. about 210° (decomp.).

With respect to the isomerism of the trimethylene trisulphides, it is

pointed out that the existence of the two forms cannot be explained by a *cis-trans*-isomerism as in the case of the trithiobenzaldehydes, for, owing to the symmetrical structure of the molecule, stereo-isomerism of this kind is excluded. The author inclines to the view that the isomerism is of a new type determined by spatial configuration of the sulphur atom, and suggests that the two modifications of tri-thiobenzaldehyde and of other substituted trithioformaldehydes may be sulphur isomerides of this type and not *cis-trans*-isomerides is usually imagined.   F. B.

Uranyl Formate. Reply to Courtois. WILLIAM ŒCHSNER DE CONINCK and ALBERT RAYNAUD (*Bull. Soc. chim.*, 1913, [iv], 13, 665—666. Compare this vol., i, 333).—A reply to Courtois (this vol., i, 585), in which the authors suggest that the salts used were different and that the experiments were conducted under different conditions.
                                                         W. G.

The Mechanism of the Hell-Volhard Reaction. II. OSSIAN ASCHAN [With (Frl.) ELLA EUROPAEUS] (*Ber.*, 1913, 46, 2162—2171. Compare A., 1912, i, 599).—Meyer (A., 1912, i, 941) expressed the opinion that the formation of a mixture of α-bromo-acid chloride and α-bromo-acid bromide by the action of bromine on acid chlorides is due, in the first place, to direct α-substitution, followed by a reaction between the liberated hydrogen bromide and the bromo-acid chloride, as in the equation : $CH_2Br\cdot COCl + HBr = CH_2Br\cdot COBr + HCl$.

The author now shows that anhydrous sulphuric acid does not react with acetyl chloride in the cold, and also describes the action of hydrogen chloride and bromide on the acid haloids. He finds that hydrogen bromide will convert acetyl chloride into acetyl bromide (compare Staudinger and Anthes, this vol., i, 616), but that, con-versely, hydrogen chloride will transform acetyl bromide into acetyl chloride. Such changes cannot both be due to direct substitution, but are best explained by assuming the formation of the intermediate compound, $CH_3\cdot C{<}^{Br}_{Cl}{-}OH$, which can part with either hydrogen chloride or bromide, according to the conditions. Thus, whether it is assumed that direct α-substitution is the first step in the action of bromine on acid chlorides, or that enolisation of the carboxyl group takes place, the formation of the same intermediate product must be assumed.

1. $CH_3\cdot COCl + Br_2 = CH_2Br\cdot COCl + HBr = CH_2Br\cdot C{<}^{Br}_{Cl}{-}OH.$

2. $CH_3\cdot COCl {\rightarrow} CH_3\cdot C(OH)Cl + Br_2 = CH_2Br\cdot C{<}^{Br}_{Cl}{-}OH.$
The following cases have been studied, and the amount of transforma-tion that takes place during definite intervals of time, calculated from halogen estimations which were controlled by density determinations : the action of hydrogen bromide on acetyl chloride, chloroacetyl chloride and bromoacetyl chloride, and the action of hydrogen chloride on acetyl bromide, chloroacetyl bromide and bromoacetyl bromide.   J. C. W.

Trichloroacrylic Acid and Certain of its Derivatives.
JACOB BOESEKEN and P. DUJARDIN (*Rec. trav. chim.*, 1913, 32, 97—111).—Heptachloropropane, b. p. 115°/12 mm., obtained according to Prins' method (A., 1911, i, 173) by the action of chloroform on pentachloroethane in the presence of aluminium chloride, is converted by alcoholic potassium hydroxide into hexachloropropylene, b. p. 209—210°/760 mm., 99°/15 mm. (compare Fritsch, A., 1898, i, 63). The latter is conveniently converted into trichloroacrylic acid, m. p. 76°, by the action of slightly diluted sulphuric acid at 135° or by a boiling aqueous suspension of barium carbonate. The *sodium*, *potassium*, and *magnesium* salts of this acid are readily soluble, whilst the *lead* salt crystallises in leaflets sparingly soluble in water. From measurement of the conductivity, the acid appears to be dissociated to about the same extent as oxalic acid, whilst it has approximately the same influence on the rate of inversion of sucrose as hydrochloric acid in $\frac{1}{5}N$-solution.

Trichloroacrylyl chloride, prepared by the action of an excess of thionyl chloride on the acid, has b. p. 158°/760 mm., n_D^{15} 1·52709, and when treated with ammonia in benzene solution is converted into the corresponding amide, m. p. 96° (compare Fritsch, *loc. cit.*). The latter is transformed by phosphoric oxide into trichloroacrylonitrile,
$$CCl_2{:}CCl{\cdot}CN,$$

m. p. 20°, n_D^{20} 1·5100.

A series of mixed aromatic ketones of the general formula
$$CCl_2{:}CCl{\cdot}CO{\cdot}R,$$

has been prepared either by gradual addition of the benzenoid derivatives to the stable molecular compound, $CCl_2{:}CCl{\cdot}COCl{\cdot}AlCl_3$ (compare Böseken and Hasselbach, this vol., i, 335), or by addition of the acid chloride to a mixture of benzenoid derivative and catalyst, reaction being continued only until one molecule of hydrogen chloride had been evolved. In this manner, the following ketones have been obtained : (i) *phenyl trichlorovinyl ketone*, b. p. 138°/2 mm., D_4^{15} 1·3902, n_D^{27} 1·5798, which unites with chlorine in sunlight to form pentachloropropiophenone, m. p. 82·5° (compare Böseken and Hasselbach, *loc. cit.*); (ii) *p-chlorophenyl trichlorovinyl ketone*, $C_6H_4Cl{\cdot}CO{\cdot}CCl{:}CCl_2$, b. p. 159°/17 mm., m. p. 19°, from trichloroacrylyl chloride and chlorobenzene. The isomeric *o* chloro derivative could not be isolated from the product. When acted on by chlorine in sunlight, *p*-chlorophenyl trichlorovinyl ketone yields p-*chlorophenyl pentachloroethyl ketone*, white crystals, m. p. 116°; (iii) p-*tolyl trichlorovinyl ketone*, $C_6H_4Me{\cdot}CO{\cdot}CCl{:}CCl_2$, b. p. 147·5°/10 mm., (iv) m-*xylyl trichlorovinyl ketone*, b. p. 165°/14 mm.; (v) p-*xylyl trichlorovinyl ketone*, b. p. 161°/13 mm.; (vi) sec.-*propylphenyl trichlorovinyl ketone*,

$$CHMe_2{\cdot}C_6H_4{\cdot}CO{\cdot}CCl{:}CCl_2,$$
b. p. 173°/12 mm. In the three latter cases, reaction is very vigorous, but seems also to proceed in another direction, since evolution of hydrogen chloride continues after the quantity corresponding to one molecule has been evolved. (vii) ψ-*Cumyl trichlorovinyl ketone*, $C_6H_2Me_3{\cdot}CO{\cdot}CCl{:}CCl_2$, m. p. 57°. (viii) p-*Anisyl trichlorovinyl ketone*, m. p. 26·5°. In this case, the action is far less rapid than with toluene. Reaction was carried out in carbon disulphide solution when

a certain amount of the ketone was simultaneously decomposed with formation of *p*-hydroxybenzoic acid. (ix) *Phenetyl trichlorovinyl ketone*, m. p. 58°, D_4^5 1·3202, n_D^{18} 1·5726.

The position of the sub-tituents in the above ketones is deduced from a study of their decomposition by alkali. When mixed with potassium alkoxides they are immediately decomposed with separation of the potassium salt of the aromatic acid according to the equation : $X \cdot C_6H_4 \cdot CO \cdot CCl \colon CCl_2 + KOH = X \cdot C_6H_4 \cdot CO_2K + HCCl \colon CCl_2$. In this manner, benzoic, *p*-toluic, anisic, *p*-ethoxybenzoic, and *p*-chlorobenzoic acids were obtained from phenyl trichlorovinyl ketone, *p*-tolyl trichlorovinyl ketone, *p*-anisyl trichlorovinyl ketone, *p*-phenetyl trichlorovinyl ketone, and *p*-chlorophenyl trichlorovinyl ketone respectively.

H. W.

Methylation of Aliphatic Compounds by means of Methyl Sulphate. EUGÈNE GRANDMOUGIN, EM. HAVAS and G. GUYOT (*Chem. Zeit.*, 1913, **37**, 812—813).—Although methyl sulphate has been extensively used in the methylation of aromatic substances, very few instances have been recorded of its use with aliphatic compounds. The authors have therefore investigated its applicability to the latter class and find that, in a series of typical methylations, this reagent can advantageously replace the customary methyl iodide under definite conditions of experiment.

Ethyl methylacetoacetate is obtained in 85% yield by the gradual addition of methyl sulphate to a solution of ethyl sodioacetoacetate in methyl alcohol under definite conditions of temperature which are fully described in the original, and, when again methylated under similar conditions, gives an 87% yield of ethyl dimethylacetoacetate.

In an analogous manner, ethyl methylmalonate and ethyl dimethylmalonate may be prepared, the yield of the former being 80—85%. The latter substance can also be obtained directly from ethyl malonate, the most favourable proportions being ester (1 mol.), sodium (3 atoms) and methyl sulphate (3 mols.). Employment of the theoretical quantities leads to the formation of a mixture of mono-methyl- and dimethyl-malonic esters.

Phenylmethylpyrazolone can also be readily methylated by means of methyl sulphate. When methyl sulphate is slowly added to a solution of sodium methoxide and phenylmethylpyrazolone in methyl alcohol,

5-methoxy-1-phenyl-3-methylpyrazole, $\begin{smallmatrix} N\text{---}NPh \\ CMe \cdot CH \end{smallmatrix} \!\!>\! C \cdot OMe$, is obtained

(compare Knorr, A., 1895, i, 397 ; von Pechmann, A., 1895, i, 494). When, on the other hand, methylation is accomplished by the addition of methyl sulphate to a boiling solution of sodium hydroxide in the minimum quantity of water and methylphenylpyrazolone in methyl alcohol, antipyrine is obtained in 80% yield.

The conversion of aminoantipyrine into pyramidone can also be readily effected by means of methyl sulphate.   H. W.

Aliphatic Nitrosocarboxylic Esters. JULIUS SCHMIDT and EMIL AECKERLE (*Annalen*, 1913, **398**, 251—256).—*Ethyl chloromethyl-acetoacetate*, $CH_3 \cdot CO \cdot CMeCl \cdot CO_2Et$, b. p. 116—117°/75 mm, D_4^{18} 1·157,

n_D^{15} 1·4382, obtained from ethyl methylacetoacetate and sulphuryl chloride, is not attacked by nitrous fumes at 0°. Ethyl a-benzoyl-propionate is converted by careful treatment with nitrous fumes at 0° into *ethyl a-nitroso-a-benzoylpropionate*, $C_6H_5 \cdot CO \cdot CMe(NO) \cdot CO_2Et$, a dark blue liquid, n_D^{19} 1·4902, which exhibits oxidising properties, and gradually decomposes into benzoic acid and ethyl a-nitrosopropionate.

These two experiments indicate that the formation of nitrosocarboxylic esters by the action of nitrous fumes on the esters of alkylated ketonic acids is represented by the scheme:

$$R \cdot CO \cdot CHR' \cdot CO_2Et \longrightarrow R \cdot CO \cdot CR'(NO) \cdot CO_2Et \xrightarrow{H_2O}$$
$$R \cdot CO_2H + NO \cdot CHR' \cdot CO_2Et. \quad C. S.$$
Ricinstearolic Acid. GEORG MÜHLE (*Ber.*, 1913, **46**, 2091—2098).— The presence of the triple linking in ricinstearolic acid is confirmed by the addition of iodine which occurs when the acid is treated with the calculated quantity of iodine and a trace of dried ferrous iodide in carbon disulphide or warmed with an acetic acid solution of iodine, the temperature being kept, however, below 40°; the resultant *ricinstearolic acid di-iodide*, $CH_3Me \cdot [CH_2]_4 \cdot CH(OH) \cdot CH_2 \cdot CI:CI \cdot [CH_2]_7 \cdot CO_2H$, forms colourless needles, m. p. 62°, decomp. at 175°; *sodium* and *barium* salts, colourless needles; *mercury* salt, yellow powder; *methyl* ester, pale yellow oil, decomp. at 150°.

Recinstearolic acid, needles, m. p. 51°, b. p. 260°/10 mm. without decomposition, obtained by successive treatment of castor oil with bromine and potassium hydroxide solution, is accompanied by a small quantity of *θιλ-trihydroxystearic acid*, m. p. 110—111°,

$$CH_3Me \cdot [CH_2]_4 \cdot CH(OH) \cdot CH_2 \cdot CH(OH) \cdot CH(OH) \cdot [CH_2]_7 \cdot CO_2H,$$

identical with the *a-isotrihydroxystearic* acid obtained earlier by oxidation of castor oil. A specimen of ricinstearolic acid kept for twenty years without any precautions for the exclusion of atmospheric moisture gave a deposit of a *dihydroxystearic acid*, leaflets, m. p. 140—141°. The author was unable to reproduce the results of earlier workers, who state that on distillation of ricinelaidic acid and of ricinoleic acid under reduced pressure, an acid, $C_{18}H_{32}O_2$, is produced.

Acetylricinelaidic acid, obtained by acetylation of ricinelaidic acid with acetic anhydride, is a bright yellow, viscid oil; *acetylricinstearolic acid* is very similar.

Methyl ricinstearolate, obtained by esterification with a methyl alcoholic solution of hydrogen chloride, or in alkaline solution with methyl sulphate, is a colourless oil, b. p. 225°/12 mm., D 0·9389; *ethyl* ester, b. p. 230°/12 mm., D 0·9371.

Glyceryl monoricinstearolate, obtained from a-monochlorohydrin and dried sodium ricinstearolate at 150°, is a pale yellow, viscid oil; *glyceryl triricinstearolate*, from trichlorohydrin and sodium ricinstearolate at 190—200° under pressure, is of similar appearance.

The action of phosphorus pentachloride on ricinstearolic acid in the cold, yields a chlorostearolic acid, $C_{18}H_{31}O_2Cl$, a pale yellow, viscid oil, which cannot be distilled without decomposition. D. F. T.

Thorium Chloro-oxalate. A. COLANI (*Compt. rend.*, 1913, **156**, 1907—1909. Compare A., 1913, i, 444; Hauser and Wirth, A., 1912, i, 827).—Hauser and Wirth's method is the most convenient for

the preparation of this salt, which has the composition assigned to it by Wyrouboff and Verneuil (A., 1899, ii, 598; compare Kohlschütter, A., 1902, i, 11). The behaviour of thorium oxalate with hydrochloric acid of various strengths at various temperatures is shown by lists of analytical results in the original. The chloro-oxalate loses from 0·5 to 1·00% of thorium by volatilisation of the chloride when heated rapidly, but no loss takes place when heat is gradually applied and the thoria, produced under the latter conditions, contains only 0·1 to 0·2% of chlorine. Similarly, thorium oxalate precipitated in solutions of moderately concentrated hydrochloric acid contains very little chlorine. In these two respects, thorium behaves differently from the rare earths   Determinations of the solubility of thorium chloro oxalate in hydrochloric acid are given in the original, and show that the solubility is much diminished in presence of oxalic acid, but that in the absence of the latter and with liquids containing 21·2% or less of hydrogen chloride, decomposition is rapid and complete into oxalate and chloride.   T. A. H.

Barium Malonate Jellies and their Micro structure. FRIEDRICH FLADE (*Zeitsch. anorg. Chem.*, 1913, **82**, 173—191).—The transformation of barium malonate jellies into powders takes place more slowly than with other barium salts (compare Neuberg and Neimann, A., 1906, ii, 753; Neuberg and Rewald, A., 1908, ii 39).

Equivalent quantities of solutions of malonic acid and barium hydroxide in methyl alcohol and glycerol are freed from air-bubbles by placing under an exhausted bell-jar and mixed. The greater the proportion of glycerol, the slower the formation of the jelly. If the glycerol is removed by means of methyl alcohol, it may be replaced by other liquids, such as chloroform or benzene, without destruction of the jelly, and with a great increase in its transparency. Much of the liquid may be removed by pressure between filter-paper, or by evaporation. The residue is barium malonate with $2H_2O$. Warming does does not liquefy the jelly.

Microscopical observations show that the jelly is made up of a network of fibres of barium malonate, in which the liquid is held as in a sponge. These fibres are stained deeply by methyl violet. The fibres are about 0 5 mm. long and 0 0001—0·0003 mm. thick, and are shown to be crystalline by their behaviour in polarised light.   C. H. D.

Stereochemistry of the Halogen Substituted Succinic Acids. BROR HOLMBERG (*J. pr. Chem.*, 1913, [ii], **87**, 456—479).—The author has shown previously (A., 1912, i, 603) that during the hydrolysis of the sodium salt of *l*-bromosuccinic acid, the elimination of bromine proceeds at a greater rate than the increase in the acidity of the solution, and from these results has drawn the conclusion that the formation of malic acid from the bromo-acid is preceded by the formation of propiolactonecarboxylic acid.

The present paper deals with conditions favourable to the formation of the lactone and also with the hydrolysis of the sodium salts of *l*-chlorosuccinic, *l*-iodosuccinic and *l*-bromosuccinamic acids. In the case of bromosuccinic acid, the addition of neutral salts of weak acids

(formate, acetate, succinate and malate) increases the velocity of bromine ion formation, but diminishes the rate of hydrolysis of the lactone. Further, the formation of the lactone proceeds less readily with chlorosuccinic and bromosuccinamic acid than with bromosuccinic acid.

It is also found that the hydrolysis of the lactone yields either a *l*- or *d*-malic acid accordingly as it is carried out in acid or alkaline solution. Thus, a solution of *l*-bromosuccinic acid after being exactly neutralised with sodium hydroxide was maintained for twenty-four days at 25°, and then contained 10% of unchanged bromo-acid, 25% of lactone and 65% of malic and fumaric acids; after the bromo-acid and lactone had been completely hydrolysed by heating the solution on the water-bath, the malic acid obtained from the product was lævorotatory. On the other hand, when the hydrolysis was effected by excess of sodium hydroxide, the resulting malic acid contained a preponderance of the dextrorotatory form.

Similar results were obtained in the case of silver oxide; the action of excess of the oxide on *l*-bromosuccinic acid yields a dextrorotatory malic acid, whilst the theoretical amount necessary to form the neutral silver salt gives rise to a lævorotatory acid. F. B.

Symmetric and Asymmetric Acid Dichlorides. II. ERWIN OTT (*Ber.*, 1913, **46**, 2172—2175. Compare A., 1912, i, 828).—A further difference in reactivity between symmetric and asymmetric chlorides is in their behaviour on treatment with hydrogen and platinum black. Whereas fumaryl and chlorofumaryl chlorides immediately "poison" the catalyst so that not even limonene can be reduced in their presence, chloromaleyl chloride may easily be reduced to *n*-butyric acid. The hydrogen chloride which is formed gradually impedes the reduction, but if it is removed from time to time by evacuation, the absorption of hydrogen can be carried almost to the theoretical value. The reduction of dibromomaleyl chloride, however, could only be carried to one-fifth before "poisoning" of the platinum took place, whilst *as-o*-phthalyl chloride and phthalyl tetrachloride could not be reduced at all. J. C. W.

Ethyl Cyanotartronate and its Reactions with Amines. RICHARD SYDNEY CURTISS and LLOYD F. NICKELL (*J. Amer. Chem. Soc.*, 1913, **35**, 885—890. Compare Curtiss and others, A., 1911, i, 353, 366; A., 1909, i, 763).—The reaction between anhydrous hydrogen. cyanide and ethyl oxomalonate is greatly influenced by small variations in temperature; at 30° it is complete in twenty-four hours, the product being *ethyl cyanotartronate*, $OH \cdot C(CN)(CO_2Et)_2$, an undistillable oily liquid, D_{20}^{10} 1·16; it is soluble in alkaline solutions to a yellow solution, and if treated in ether with sodium, deliquescent, colourless crystals of an unstable *substance* slowly separate.

Ethyl cyanotartronate in cooled ethereal solution reacts with many amines, producing compounds which in all probability have an amidine structure; thus dipropylamine yields a crystalline *substance*,

$$NPr_2 \cdot C(:NH) \cdot C(CO_2Et)_2 \cdot OH,$$
m. p. 72·5—73°. With diethylamine an analogous *compound*, m. p. 56°, was obtained, whilst benzylamine gave in a similar manner a

substance, m. p. 55—56°. These three substances on exposure to the atmosphere or when kept at 25°, undergo decomposition with formation of a tarry mass. Ethylamine, *iso*butylamine and benzylethylamine gave rise to uncrystallisable syrups, triethylamine slowly produced a red, tarry mass, whilst ammonia formed a very unstable, crystalline *substance*. With aromatic amines there was apparently no reaction.

<div align="right">D. F. T.</div>

Catalytic Decomposition of Aldehydes. M. I. Kuznecov (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 557—568).—In his earlier experiments on the oxidation of methyl alcohol by means of atmospheric oxygen with a view to preparing formaldehyde, the author found that the aldehyde was always accompanied by carbon monoxide and hydrogen in proportions depending on the temperature conditions and on the nature of the catalyst employed (*Bull. Charkov Technol. Inst.*, 1909). These two products result from the decomposition of aldehyde previously formed: $CH_2O = CO + H_2$.

Further experiments show that resolution of the aldehydic group with formation of carbon monoxide is a general reaction for all aldehydes.

The first series comprises measurements of the degree of decomposition of formaldehyde at various temperatures and under the influence of a number of different metals and of wood charcoal, asbestos and powdered Jena glass. The results show that the action depends not only on the chemical character of the catalyst but also on its physical condition. For instance, with copper turnings at 500° there is no decomposition, and at 600° only 4% of the aldehyde is attacked; with copper reduced from the oxide by the action of hydrogen, 9·2% of the aldehyde is decomposed at 500°; and with copper obtained by reduction of copper sulphate solution by means of alkaline formaldehyde, the action proceeds to the extent of 35·3, 84·2, 94·8 and 95·8% at 200°, 300°, 400° and 500° respectively. With different forms of other metals smaller variations are observed.

In the second series the products obtained by the decomposition of the following aldehydes by palladium black were investigated: formaldehyde, acetaldehyde, paracetaldehyde, propaldehyde, *n*-butaldehyde, *iso*butaldehyde, benzaldehyde and *p*-tolualdehyde. The results show that the aldehyde group is decomposed by palladium into carbon monoxide and hydrogen, the latter combining with the hydrocarbon radicle: $R \cdot CHO = RH + CO$. In the cases of propaldehyde and the butaldehydes, free hydrogen and unsaturated hydrocarbons are also obtained owing to the partial decomposition of the saturated hydrocarbons originally formed. T. H. P.

Stability of Paracetaldehyde. R. Richter (*Pharm. Zeit.*, 1913, **58**, 482—483).—A series of experiments has been performed on the stability of paracetaldehyde alone, in aqueous solution and in the presence of various pharmaceutical preparations. The author is led to the following conclusions: (1) pure paracetaldehyde, free from acid and acetaldehyde, can be kept for sixteen months without alteration; the presence of these substances even in small quantity,

however, induces a gradual decomposition of the paracetaldehyde; (2) in the presence of pure raspberry juice without addition of water, paraldehyde remains unchanged during two months; (3) when mixed with water and a syrup composed of sugar and citric acid, paracetaldehyde speedily undergoes conversion into acetaldehyde; after two months, 7·8% of the paracetaldehyde had undergone such conversion; (4) in aqueous solution, without addition of juice, formation of acetaldehyde occurs slowly but continuously. H. W.

Catalytic Actions. VII. Polymerisation of Chloral. JACOB BOESEKEN and A. SCHIMMEL (*Rec. trav. chim.*, 1913, **32**, 112—127).— The authors have studied the polymerisation of chloral in the presence of pyridine. For this purpose, known weights of dry chloral and pyridine have been preserved for a month at the ordinary temperature, at the end of which time a quasi-stable state had been reached. The contents of the flask were then treated with a large quantity of dilute hydrochloric acid, which combined with the pyridine and dissolved unchanged chloral. The metachloral which is insoluble in this reagent was estimated by decomposition with potassium hydroxide.

As the quantity of pyridine employed relatively to the amount of chloral increases, the latter becomes more completely transformed into metachloral, until, in the presence of about $\frac{1}{5}$ mol. pyridine, transformation is practically quantitative. Beyond this point, the amount of metachloral formed diminishes with increasing quantities of pyridine. The separation of metachloral is incomplete, whatever the quantity of catalyst employed. From determinations of the vapour tension of metachloral, obtained from chloral either by means of pyridine or fuming sulphuric acid, it appears that the true equilibrium of the system, chloral $\rightleftarrows$ metachloral, is situate practically entirely on the side of metachloral, and thus, that starting from chloral, this equilibrium is not obtained after a month even in the presence of considerable quantities of catalyst. This result is probably due to the absorption of pyridine by the polymeride which separates in the colloidal state.

When pyridine (4—5 mols.) is added to chloral (100 mols.) a rapid separation of a gelatinous mass occurs. After several weeks, a second change is observable in that the metachloral in contact with the walls of the vessel again becomes transparent, forming a membrane greatly resembling a collodion pellicle. This *transparent metachloral* does not appear to retain pyridine and has a vapour tension below that of the equilibrium mixture.

When pure metachloral is placed in an atmosphere of pyridine, it almost immediately becomes opaque, and then has the same vapour tension as the pseudo-binary system. Subsequently, it becomes gelatinous and then completely liquid.

In the presence of larger quantities of catalyst, less chloral is transformed into the polymeride, although equilibrium is more certain to be obtained in this case since a portion of the metachloral dissolves in the pyridine. The catalyst here exerts a marked influence on the

equilibrium, although it has not been found possible to isolate an additive compound of pyridine and chloral.

The phenomena here observed are analogous to those encountered in the polymerisation of chloral by means of fuming sulphuric acid (Boeseken, *Rec. trav. chim.*, 1910, **29**, 104) or aluminium chloride.

<div align="right">H. W.</div>

Modifications of Metachloral and Decomposition of Chloral by Aluminium Chloride. Perchlorobutanal, $CCl_3 \cdot CCl_2 \cdot CCl_2 \cdot CHO$. JACOB BOESEKEN and A. SCHIMMEL (*Rec. trav. chim.*, 1913, **32**, 128—133).—Metachloral is known in a gelatinous modification immediately obtained by the addition of pyridine to anhydrous chloral, an opaque modification formed by the action of different catalysts on chloral, and representing the equilibrium mixture of the system chloral⇌metachloral and as a transparent modification which is slowly produced when pyridine remains in contact with chloral. The latter is probably the only pure metachloral, the others being mixtures of it with unchanged chloral and catalyst. Attempts have been made to obtain the polymeride of chloral described by Combes (A., 1887, 127) as the product of the action of aluminium chloride on chloral. The authors have repeated his experiments, and have also somewhat modified the conditions, and find that the products are tetrachloroethylene, pentachloroethane and relatively very small amounts of perchlorobutanal, b. p. 145·5—147°/20—26 mm., m. p. 46·5—48°, molecular weight in benzene solution, 334. The latter is quantitatively decomposed by alkali according to the equation :

$$CCl_3 \cdot CCl_2 \cdot CCl_2 \cdot CHO + 2KOH = C_3Cl_6 + KCl + HCO_2K + H_2O.$$
When heated with excess of aluminium chloride, it is decomposed with evolution of carbon monoxide.

<div align="right">H. W.</div>

The Catalytic Preparation of Ketones. ALPHONSE MAILHE (*Bull. Soc. chim.*, 1913, [iv], **13**, 666—671).—A reply to Senderens (A., 1911, i, 134, 302 ; this vol., i, 342) in which the author maintains the utility of his method using zinc oxide, and more especially cadmium oxide, as a catalyst in the preparation of ketones from acids.

<div align="right">W. G.</div>

Cerium Acetylacetonates. ANDRÉ JOB and PAUL GOISSEDET (*Compt. rend.*, 1913, **157**, 50—52).—Urbain (compare A., 1897, i, 236) prepared a basic cerous acetylacetonate by the action of cerous hydroxide on acetylacetone, and Biltz (compare A., 1904, i, 715) obtained the crystalline, neutral cerous salt by the action of cerous nitrate on an ammoniacal solution of ammonium acetylacetonate. Adopting Urbain's method the author has now prepared the ceric compound in a crystalline state. An excess of acetylacetone is added to a suspension of ceric hydroxide in water and the mixture agitated, when it slowly turns brown, and at the end of several days deep red needles of *ceric acetylacetonate* separate, having the composition $Ce(CHAc_2)_4,11H_2O$. On drying this salt in a vacuum and crystallising it from carbon tetrachloride, it is obtained in the anhydrous state as black crystals, m. p. 171—172°, having a metallic lustre. It is slightly soluble in water, and in solution is readily hydrolysed except

in the presence of excess of acetylacetone. The anhydrous salt is soluble in most organic solvents to a deep red solution, the colour rapidly disappearing in sunlight in the case of oxidisable solvents.

W. G.

Syntheses by means of Sodamide. II. Alkylation of Aliphatic Ketones. ALBIN HALLER and EDOUARD BAUER (*Ann. Chim. Phys.*, 1913, [viii], **29**, 313—349).—The authors' work (A., 1909, i, 108) on the alkylation of acetophenone and analogous substances by the successive action of sodamide and alkyl haloids has been extended to aliphatic ketones.

When an ethereal solution of pinacoline is treated successively with sodamide (1 mol.) and methyl iodide (1·1 mol.), a mixture of unchanged material, methyl- and dimethyl-pinacoline is obtained from which $\beta\beta$-dimethylpentan-γ-one, $CMe_3 \cdot CO \cdot CH_2 \cdot CH_3$, b. p. 124—126°, can be isolated by repeated fractional distillation. This substance has already been described by Wischnegradsky (A., 1875, 878). The *oxime* has m. p. 79—80°. When the methylation is repeated until no further action occurs in ethereal solution, $\beta\beta\delta$-trimethylpentan-γ-one, $CMe_3 \cdot CO \cdot CHMe_2$, b. p. 133—135° (compare Nef, A., 1900, i, 349), is obtained. It has D_4^0 0·80536, n_α^{27} 1·40304, n_D^0 1·40513, n_β^{27} 1·41020, n_γ^{10} 1·41429. The oxime has m. p. 141°. When reduced by sodium and alcohol, the ketone yields $\beta\beta\delta$-*trimethylpentan-γ-ol*,

$$CMe_3 \cdot CH(OH) \cdot CHMe_2,$$

b. p. 145—148°, the *phenylurethane* of which has m. p. 79°. $\beta\beta\delta$-Trimethylpentan-γ-one can be further methylated by means of sodamide and methyl iodide in benzene solution, when $\beta\beta\delta\delta$-*tetramethylpentan-γ-one*, $CMe_3 \cdot CO \cdot CMe_3$, is obtained. It has b. p. 150—151°, D_1^{20} 0·81992, n_α^{23} 1·41485, n_D^{25} 1·41702, n_β^{10} 1·42224, n_γ^{27} 1·42643. It does not appear to form an oxime, a semicarbazone or a hydrazone. Its ketonic nature is, however, established by reducing it to $\beta\beta\delta\delta$ *tetramethylpentan-γ-ol*, b. p. 165—166°, m. p. 50°, the *phenylurethane* of which has m. p. 118—119°, whilst the *formate* has b. p. 185°. In a similar manner, pentamethylacetone can be converted into $\beta\beta\delta\delta$ *tetra methylhexan-γ-one*, $CMe_3 \cdot CO \cdot CMe_2Et$, b. p. 172—174°, by the successive action of sodamide and ethyl bromide or iodide in benzene solution. Like its lower homologue, this substance forms neither oxime, semicarbazone or hydrazone. Reduction converts it into $\beta\beta\delta\delta$-*tetramethylhexan-γ ol*, $CMe_3 \cdot CH(OH) \cdot CMe_2Et$, b. p. 187—188°, the *phenylurethane* of which forms slender needles, m. p. 94—95°.

The ethylation of pinacoline can be effected in a precisely similar manner. The successive action of sodamide and ethyl bromide or iodide on an ethereal solution of pinacoline leads to the isolation of $\beta\beta$-*dimethylhexan-γ-one*, $CMe_3 \cdot CO \cdot CH_2 \cdot CH_2Me$, b. p. 146—148°, D_4^{25} 0·81055, n_α^{25} 1·40740, n_D^{25} 1·40952, n_β^{27} 1·41465, n_γ^{10} 1·41888, and $\beta\beta$-*dimethyl-δ-ethylhexan-γ-one*, $CMe_3 \cdot CO \cdot CHEt_2$, b. p. 171—176°, D_4^{25} 0·82521, n_α^{25} 1·42007, n_D^{25} 1·42227, n_β^{10} 1·42738, n_γ^{27} 1·43173. The former yields an *oxime*, needles, m. p. 76—77°, and on reduction gives $\beta\beta$-*dimethylhexan-γ-ol*, b. p. 155—157° (*phenylurethane*, m. p. 70—71°). The latter does not combine with hydroxylamine or with semicarbazide, but, when reduced with sodium and absolute alcohol, forms

$\beta\beta$ *dimethyl-δ-ethylhexan-γ-ol.* b. p. 187°, the *phenylurethane* of which crystallises with $\frac{1}{2}H_2O$ and has m. p. 107°. In benzene, or better in toluene solution, complete ethylation of pinacoline can be effected, whereby *$\beta\beta$-dimethyl-$\delta\delta$-diethylhexan-γ-one*, b. p. 214—216°, is produced. It does not yield an oxime or a semicarbazone. Reduction converts it into *$\beta\beta$-dimethyl-$\delta\delta$-diethylhexan-γ-ol*, $CMe_3 \cdot CH(OH) \cdot CEt_3$, b. p. 226—228°, the *phenylurethane* of which has m. p. 110°.

$\beta\beta\delta$-Trimethylhexan-γ-one, $CMe_3 \cdot CO \cdot CHMeEt$, b. p. 155—156°, is obtained mixed with unchanged starting material by the methylation of ethylpinacoline in ethereal solution. Since a separation of the two could not be effected by distillation, the product was treated with an alcoholic solution of hydroxylamine hydrochloride with which only the latter reacted to form an oxime. The mother liquors, separated as completely as possible from the crystalline oxime, were acted on by phenylcarbimide, whereby the dissolved oxime was converted into carbanilidoxime, which remained on distilling the mixture under diminished pressure. The distillate was treated with water to decompose the excess of phenylcarbimide, and the ketone extracted with ether and distilled. When reduced, it is converted into *$\beta\beta\delta$ trimethylhexan-γ-ol*, $CMe_3 \cdot CH(OH) \cdot CHMeEt$, b. p. 169°, the *phenylurethane* of which has m. p. 78°.

$\beta\beta\epsilon$-Trimethylhexan-γ-one, $CMe_3 \cdot CO \cdot CH_2 \cdot CHMe_2$ (compare Nef, A., 1902, i. 6), is obtained in the usual manner as a liquid, b. p. 157·5—158 5°. Its oxime has m. p. 77—78°, whereas Nef gives 66—70°.

Although the action of allyl iodide on the sodium derivative of acetophenone yields only complex resinous products, allylpinacolines can be readily obtained by the successive action of sodamide and allyl iodide on an ethereal solution of pinacoline. In this manner, *allylpinacoline*, $CMe_3 \cdot CO \cdot CH_2 \cdot CH_2 \cdot CH:CH_2$, b. p. 61—64°/14 mm., and *diallylpinacoline*, $CMe_3 \cdot CO \cdot CH(CH_2 \cdot CH:CH_2)_2$, b. p. 83—86°/14 mm., are readily prepared.

δ-Benzyl-$\beta\beta$-dimethyl-δ-ethylhexane-γ-one, $CMe_3 \cdot CO \cdot CEt_2 \cdot CH_2Ph$, is obtained by the action of benzyl chloride on a boiling solution of the sodium derivative of diethylpinacoline in toluene. It has b. p. 152—154°/15 mm., and does not yield an oxime or a semicarbazone.

In the cases of pinacoline and of acetophenone, a tertiary carbon atom is attached to the carbonyl group. The authors have therefore extended their investigations to such ketones in which this is not the case, and find that alkylation can be similarly effected, substitution occurring at either of the secondary carbon atoms attached to the keto-group (compare Haller, A., 1905, i, 214; Haller and Bauer, A., 1912, i, 269).

An ethereal solution of diethyl ketone reacts vigorously with sodamide, and, after addition of methyl iodide, yields, on fractionation, *ethyl isopropyl ketone*, $COEt \cdot CHMe_2$, b. p. 115—119°, di-*isopropyl* ketone, $CO(CHMe_2)_2$, b. p. 123—124·5° (*semicarbazone*, m. p. 143—144°), and a *fraction*, b. p. 148—152°/18 mm., which is probably *$\delta\zeta$-dimethyl-$\gamma\eta$-diethyl-$\Delta^{\gamma\zeta}$-nonadien-ϵ-one*,

$$CEt_2 : CMe \cdot CO \cdot CMe : CEt_2.$$

$\beta\delta\delta$-Trimethylhexan-γ-one, b. p. 158—161°, is prepared by the

ethylation of di-*iso*propyl ketone in ethereal solution. It does not yield an oxime or a semicarbazone. On reduction it gives $\beta\delta\delta$ *trimethylhexan-γ-ol*, $CMe_2 \cdot CH(OH) \cdot CMe_2Et$, b. p. 170—171°, the *phenylurethane* of which has m. p. 64°. γγεε-*Tetramethylheptan-δ-one*,

$$CMe_2Et \cdot CO \cdot CMe_2Et,$$

prepared by the ethylation of *iso*propyl *tert.*-amyl ketone in benzene solution, has b. p. 196—198°, and does not give an oxime or a semicarbazone. Sodium and absolute alcohol convert it into γγεε-*tetramethylheptan-δ-ol*, b. p. 210—212° (*phenylurethane*, m. p. 62—63°).

By repeated methylation of *iso*valerone in benzene solution and subsequent fractional distillation, the following products have been obtained : (i) $\beta\gamma\epsilon\zeta$-*tetramethylheptan-δ-one*,

$$CHMe_2 \cdot CHMe \cdot CO \cdot CHMe \cdot CHMe_2,$$

b. p. 76—78°/13 mm., which, when energetically treated, appears to yield small quantities of the corresponding *oxime*; (ii) $\beta\gamma\gamma\epsilon\zeta$-*pentamethylheptan-δ-one*, $CHMe_2 \cdot CHMe \cdot CO \cdot CMe_2 \cdot CHMe_2$, b. p. 88—89°/13 mm., which does not yield an oxime when heated with Crismer's reagent in alcoholic solution. $\beta\gamma\gamma\epsilon\epsilon\zeta$-*Hexamethylheptan-δ-one*,

$$CHMe_2 \cdot CMe_2 \cdot CO \cdot CMe_2 \cdot CHMe_2,$$
b. p. 107—109°/14 mm., is prepared by the methylation of trimethyl-*iso*valerone in toluene solution. When reduced with sodium and alcohol, it yields a small quantity of a *substance* which behaves like an unsaturated hydrocarbon, and $\beta\gamma\gamma\epsilon\epsilon\zeta$-*hexamethylheptan-δ-ol*,

$$CHMe_2 \cdot CMe_2 \cdot CH(OH) \cdot CMe_2 \cdot CHMe_2,$$

b. p. 115—117°/13 mm. (*phenylurethane*, m. p. 91—92°).

H. W.

Optically Active Complex Glucinum Sugar Compounds. BENNO BLEYER and L. PACZUSKI (*Zeitsch. physikal. Chem.*, 1913, **84**, 1—14).—The authors have determined the influence of an alkaline solution of glucinum hydroxide on the rotatory power of mannitol. It is shown that when an alkaline solution of glucinum hydroxide is added to a solution of inactive mannitol, the solution becomes markedly lævorotatory. The influence of the alkaline glucinum solution is shown to depend on the presence of GlO_2'' ions in the solution, that is, it is due to sodium glucinate. The presence of glucinum hydroxide as a colloid could not produce so large a change in the rotation. A method is worked out, depending on the change of rotation, for determining the relative strength of the acid in amphoteric metal hydroxides. On adding solutions of sodium glucinate to mannitol, a condition is reached at which a constant rotation is reached ; further additions cannot change this in either sense. This condition is reached when the concentration 13·84 grams mannitol, 72 grams sodium hydroxide, and 56·64 grams of glucinum sulphate per litre of solution is reached. A complex compound is formed by the action of sodium glucinate on mannitol, which is not hydrolysed at the concentrations examined, $(1/640—10/640)n$. This compound is similar to the complex glucinum hydroxydicarboxylic acid of Rosenheim and Itzig (A., 1899, i, 739).

J. F. S.

Unfermentable Residue in Hydrolytic Products of Starch.
ARTHUR P. BRYANT and C. S. MINER (*Eighth Intern. Cong. App. Chem.*, 1912, 13, 57—61).—Results are recorded which tend to show that some of the hydrolytic products of starch, such as "grape-sugar" and "liquid glucose," contain *iso*maltose.   W. H. G.

Presence of Maltose in Acid Hydrolysed Starch Products.
GEORGE DEFREN (*Eighth Intern. Cong. App. Chem.*, 1912, 13, 111—112). —It has been found possible to isolate maltose from a crude glucose obtained by the hydrolysis of starch with acids. The dextrose present in the crude product was removed by fermentation, making use of *Saccharomyces apiculatus*, and the dextrin separated from the maltose subsequently by fractional precipitation with alcohol.   W. H. G.

Hydrolysis of Starch by Acids with Some Additional Results. on the Speed of Hydrolysis. GEORGE DEFREN (*Eighth Intern. Cong. App. Chem.*, 1912, 13, 113—123).—An investigation on the hydrolysis of starch by acids. The relative speeds of hydrolysis using hydrochloric, sulphuric, oxalic, sulphurous and acetic acids are given, likewise results which show the effect of the concentration of the acid and the temperature on the rate of hydrolysis. The increase in the rate of hydrolysis with rise of temperature above 100° is very great, indicating that the starch molecule becomes very "labile" at these temperatures.   W. H. G.

Osmotic Pressure of Colloids. V. Colloid Chemistry of the Dextrins. WILHELM BILTZ (and WILHELM TRUTHE) (*Zeitsch. physikal. Chem.*, 1913, 83, 683—707. Compare A., 1910, ii, 22, 673 ; 1911, ii, 702 ; this vol., i, 593).—The molecular weight of a number of dextrins is determined by extrapolation to concentration zero from the calculated molecular weights obtained from the measurement of the osmotic pressure of dilute solutions. It is shown that even in dilute solutions the dextrins associate very markedly. The following values are found for the molecular weights: amylodextrin (*a*) 22200, amylodextrin (*b*) 20500, achroodextrin 10200. diastase dextrin (from grain) 11700, diastase dextrin (from beer) 8200, erythrodextrin 6800, erythrodextrin IIa 3000, acid dextrin 4000, achroodextrin I 1800, achroodextrin II 1200, dextrin β 950, sucrose 340, commercial dextrin (2 specimens) 5000, 6000, specially purified commercial dextrin 2800 and 2700. dextrin purified by dialysis 6200. The gold numbers of the various dextrins are determined, and it is shown that a relationship exists between the molecular weight and the gold number ; generally a small gold number accompanies a large molecular weight. The authors have shown that in many cases the dextrins possess more than one gold number, and that there is an oscillating protecting action of the colloid between given concentrations. The viscosity of the dextrins in dilute solutions, that is, up to 5%, is determined, and it is shown that a parallelism exists between the viscosity and the molecular weight. It is also shown that the higher the molecular weight, the more the dextrins are adsorbed by ferric hydroxide gels.   J. F. S.

Hydrolysis and Acetolysis of Cellulose. HERMANN OST (*Annalen*, 1913, **398**, 313—343. Compare this vol., i, 446).—The composition of the hydrocelluloses obtained as the initial product of the hydrolysis of cellulose by dilute mineral acids has long been a matter of dispute. The author finds that cellulose can be dried completely, without discoloration, by heating slowly to 100° and finally at 120—125°; the same is true of hydrocelluloses, some specimens of which, however, become discoloured at 125—150°. Since the ultimate analysis of completely dried cellulose and hydrocelluloses fails to disclose any differences in the percentages of carbon and of hydrogen, the author abandons his previous views that hydrocelluloses are hydrated celluloses, and inclines to Stern's opinion (T., 1904, **85**, 336) that there is no difference in the composition of celluloses and hydrocelluloses. The molecular magnitude of the latter is the smaller, as is indicated, not only by the smaller viscosity of their solutions, but also by their greater reducing action on copper salts, hydroxyl or aldehydo-groups being produced during the hydrolysis of the cellulose.

The acetolysis of cellulose is described in detail, the conditions under which cellobiose octa-acetate or dextrose a-penta-acetate (Ost, *loc. cit.*) are produced being definitely determined. The uncrystallisable syrup obtained in the acetolysis of cellulose resembles that obtained in the acetolysis of dextrose in acetic acid content, in rotatory power, and in yielding crystallised dextrose a-penta-acetate by further acetylation. Both syrups consist essentially of dextrose acetates mixed with acetates of *iso*maltose and dextrins and of other foreign substances.

The total yield of dextrose and cellobiose acetates obtained by the acetolysis of cellulose is 90% of that theoretically possible. Acetolysis, therefore, furnishes another proof that the cellulose molecule is composed only of dextrose residues.   C. S.

Absorption Spectra of the Copper Derivatives of Primary Aliphatic Nitroamines. ANTOINE P. N. FRANCHIMONT and HILMAR J. BACKER (*Rec. trav. chim.*, 1913, **32**, 158—163. Compare T., 1912, **101**, 2256).—The authors have examined the absorption spectra of aqueous solutions of the copper salts of methylnitroamine, ethylnitroamine, ethylnitrosohydroxylamine, of copper nitrate and ammoniacal copper nitrate at equivalent concentrations. The copper salts of the nitroamines are much more strongly absorbent than a solution of copper nitrate with the same copper content, whilst the light which is not absorbed is less violet than in the case of the copper salt of ethylnitrosohydroxylamine. The spectra of the copper salts of methyl- and ethyl-nitroamines are practically identical, and do not show an absorption band.

The electrical conductivity of solutions of the copper salts of nitroamines is noticeably less than that of their sodium salts or of ordinary copper salts. The copper salt of ethylnitrosohydroxylamine conducts still more feebly.

Solutions of the copper salts of nitroamines give the ordinary reactions for copper, whilst that of ethylnitrosohydroxylamine, although yielding precipitates with sodium hydroxide and with

hydrogen sulphide, gives only a brown coloration with potassium ferrocyanide.

The authors are led to the conclusion that the copper derivative of ethylnitrosohydroxylamine is probably a complex internal salt, but in view of the differences existing between this substance and the copper salts of the nitroamines, hesitate to assign a similar structure to the latter substances, although their intense colour and feeble electrical conductivity point to a relationship between the metal and nitrogen.

H. W.

Oxalyl Derivatives of Amino-acids.   D. J. MEYERINGH (*Rec. trav. chim.*, 1913, **32**, 140—157).—The author has prepared a series of oxalyl derivatives of amino-acids which contain the residues of two different amino-acids, by the action of ethyl chloroglyoxylate on the hydrochloride of the ester of an amino-acid, followed by treatment of the product so obtained with the potassium salt of a second amino-acid.

Ethyl chloroglyoxylate is best obtained by heating a mixture of equimolecular quantities of ethyl oxalate and phosphorus pentachloride until evolution of ethyl chloride ceases. It has b. p. 135°.

Methyl oxamidodiacetate, $C_2O_2(NH·CH_2·CO_2Me)_2$, has m. p. 158·5°, instead of 139—140° recorded by Kerp and Unger (A., 1897, i, 269).

Oxamidoacetic acid, $NH_2·CO·CO·NH·CH_2·CO_2H$, is obtained from oxamethane and potassium aminoacetate according to the method of Kerp and Unger (*loc. cit.*). The corresponding *methyl* ester, m. p. 157°, is obtained by treatment of the *silver* salt with an excess of methyl iodide and is converted by ammonia into the *amide*, needles, m. p. 251—252° (decomp.).

Ethyl ethoxalylaminoacetate, $CO_2Et·CO·NH·CH_2·CO_2Et$, b. p. 188°/18 mm., m. p. 16°, is prepared in 84% yield by heating an equimolecular mixture of ethoxalyl chloride and ethyl aminoacetate hydrochloride in dry benzene until evolution of hydrogen chloride ceases. It is converted by ammonia into the corresponding di-amide.

Methyl ethoxalyl-a-aminopropionate, $CO_2Et·CO·NH·CHMe·CO_2Me$, b. p. 173·5°/19 mm., is similarly prepared from ethyl chloroglyoxylate and methyl a-aminopropionate hydrochloride. The *diamide*, prepared by means of liquid ammonia, forms slender needles, m. p. 216·5°. No evidence of the formation of an isomeric diamide could be obtained.

Methyl glycineoxalyl-a-aminopropionate,

$$CO_2H·CH_2·NH·CO·CO·NH·CHMe·CO_2Me,$$

m. p. 136—137°, is prepared by the addition of methyl ethoxalyl-a-aminopropionate to a solution of potassium aminoacetate, care being taken that the temperature does not exceed 5°. At higher temperatures, and in the presence of excess of alkali, the ester is readily saponified, the corresponding *acid* decomposing at 210° when rapidly heated.

When a solution of a-alanine in potassium hydroxide is added to ethyl ethoxalylglycine, *ethyl a-alanineoxalylglycine*,

$$CO_2H·CHMe·NH·CO·CO·NH·CH_2·CO_2Et,$$

m. p. 142·5°, is obtained if the temperature does not rise above 5°. At higher temperatures, and in the presence of more concentrated potassium hydroxide, alanine separates and the potassium salt of ethyl

oxalylaminoacetate is produced. In alcoholic solution, alanine always separates to some extent, and the *potassium* salt of *ethyl a alanineoxalylglycine* is obtained.

Dimethyl a-alanineoxalylglycine,
$$CO_2Me \cdot CHMe \cdot NH \cdot CO \cdot CO \cdot NH \cdot CH_2 \cdot CO_2Me,$$
m. p. 98·5°, is prepared by saturating a methyl alcoholic solution of methyl glycine oxalyl-a-aminopropionate with hydrogen chloride. *Methyl ethyl a-alanineoxalylglycine,*
$$CO_2Me \cdot CHMe \cdot NH \cdot CO \cdot CO \cdot NH \cdot CH_2 \cdot CO_2Et,$$
m. p. 106°, is formed by similar treatment of a methyl alcoholic solution of ethyl a-alanineoxalylglycine or of an ethyl alcoholic solution of methyl glycineoxalyl-a-aminopropionate, whilst *diethyl a-alanineoxalylglycine,* $CO_2Et \cdot CHMe \cdot NH \cdot CO \cdot CO \cdot NH \cdot CH_2 \cdot CO_2Et$, m. p. 120°, is similarly produced from ethyl a-alanineoxalylglycine or from the corresponding free acid.

a-Alanineoxalylglycinediamide,
$$NH_2 \cdot CO \cdot CHMe \cdot NH \cdot CO \cdot CO \cdot NH \cdot CH_2 \cdot CO \cdot NH_2,$$
m. p. 272—274° (decomp.), is obtained by the action of liquid ammonia on dimethyl a-alanineoxalylglycine.

a-Aminoisobutyric acid does not react with ethyl ethoxalylglycine in the presence of the calculated quantity of potassium hydroxide at 0°.

Methyl ethoxalyl-a-phenylaminoacetate, $CO_2Et \cdot CO \cdot NH \cdot CHPh \cdot CO_2Me,$ m. p. 56°, is prepared by heating ethyl chloroglyoxylate and methyl a-phenylaminoacetate hydrochloride in benzene solution. The corresponding *diamide* has m. p. 229°. By the action of oxalyl chloride (1 mol.) on methyl a-phenylaminoacetate hydrochloride in dry benzene, two isomeric *forms* of dimethyl oxalyldi (a-phenylaminoacetate), $C_2O_2(NH \cdot CHPh \cdot CO_2Me)_2,$ are obtained which may be separated by taking advantage of their different solubilities in benzene. They have m. p. 169—170° and 195° respectively.

Unsuccessful attempts have been made to prepare acetyl and nitro-derivatives of several of the above substances.

The presence of the oxalyl group has been actually ascertained in each of the above derivatives. They have further been examined with regard to their ability to give the biuret reaction. It appears that only those substances show this reaction in which at least one of the amino-groups is intact. H. W.

Nitriles of Diaminodimethyl- and Diaminomethylethyl-succinic Acids and their Behaviour on Hydrolysis. OTTO DIELS and HAJIME OTSUKI (*Ber.,* 1913. **46,** 1877—1983).—The cyanohydrins of dimethyl diketone and methyl ethyl diketone react with ammonia, yielding the nitriles of diaminodimethyl- and diaminomethylethyl-succinic acids which, on hydrolysis with hydrochloric acid, are converted into compounds $C_6H_8N_2Cl$ and $C_7H_{10}N_2Cl$ respectively. The constitution of the latter compounds has not been definitely established, but from their pronounced basic properties and their behaviour toward nitrous acid, the conclusion is drawn that they contain only one amino-group. The halogen atom is very firmly attached, and cannot be removed by any of the usual reagents.

When treated with nitric acid, the compounds are completely decomposed, yielding a chloro-nitromethane. The formation of the latter compound indicates that the halogen is attached to one of the carbon atoms.

Methyl ethyl diketone cyanohydrin, OH·CMe(CN)·CEt(CN)·OH, is prepared by the action of hydrogen cyanide in ethereal solution on methyl ethyl diketone in the presence of potassium carbonate. It forms small, hygroscopic, crystalline plates, m. p. 76°, and when heated for five minutes with strong nitric acid is transformed into an *isomeride*, which sinters at 100°, m. p 103°.

Diaminomethylethylsuccinonitrile, NH₂·CMe(CN)·CEt(CN)·NH₂, prepared by the action of concentrated aqueous ammonia on the preceding cyanohydrin at 0°, crystallises in hexagonal platelets or needles, m. p. 68°, and when maintained at 37° for two days with concentrated hydrochloric acid yields the *compound*, $C_7H_{10}N_3Cl$, which crystallises in lustrous, slender needles, m. p. 77·5°, forms a crystalline *hydrochloride* and *sulphate*, and on treatment with nitrous acid is converted into a *hydroxy*-compound, $C_7H_9ON_2Cl$, m. p. 147°.

s-*Diaminodimethylsuccinonitrile*, NH₂·CMe(CN)·CMe(CN)·NH₂, prepared from diacetylcyanohydrin (A., 1912, i, 942) and strong aqueous ammonia at 0°, crystallises in plates or leaflets, m. p. 166·5°. It is accompanied by a *substance*, $C_{12}H_{20}O_3N_6$, which forms small, tabular crystals, m. p. 234° (decomp.). On hydrolysis with concentrated hydrochloric acid at 37°, it yields the *compound*, $C_6H_8N_3Cl$. This forms long, lustrous needles, m. p. 140·5°, and is converted by the action of nitrous acid into a *hydroxy*-compound, $C_6H_7ON_2Cl$, which crystallises in lustrous needles, m. p. 227°, and when methylated by means of aqueous potassium hydroxide and methyl sulphate yields a *methyl ether*, $C_7H_9ON_2Cl$, crystallising in needles, m. p. 96°; if the methylation is carried out with diazomethane, an isomeric *methyl ether* of m. p. 54—55° is obtained.   F. B.

The Origin of Optically Active Compounds in the Living Cell; the Artificial Preparation of Optically Active Compounds Without the Intervention of Asymmetrical Molecules or Asymmetrical Forces. EMIL ERLENMEYER (*Biochem. Zeitsch.*, 1913, **52**, 439—470).—In compounds of the type $C(R_1R_2R_3)$—$C(R_4R_5R_6)$ there are, according to van't Hoff, twelve isomerides possible, of which eight can be derived from the four others, simply by rotation about the C—C axis. Isomerides which can be derived from one another simply by a rotation of this description are designated by the author as "relative isomerides" in contradistinction to the isomerides ("bond-isomerides") which can only be derived from one another by changes in the bonds uniting the R groups. If the assumption is made that mirror images have the same solubilities as one another, they are not separable from one another by fractional crystallisation. If, however, a racemic mixture containing the two mirror images can be subjected to such treatment that the antipodes can be converted into their "relative isomerides," then it is possible that the two constituents can change at different rates, or that the rotation about the C—C axis can take place in opposite directions. If, therefore, it is possible, by any

method, to produce "relative isomerides" in a racemic mixture, then it is also conceivable that a mixture can be produced which contains isomerides which are no longer mirror images of one another, and which are postulated to be separable from one another by a process of fractional crystallisation. The author in conjunction with G. Hilgendorff has applied the above conceptions to the investigation of the asparagines. He confirms the observations of Piutti, that a mixture of the *d*- and *l*-substances can be separated by crystallisation from hot water. He shows, furthermore, that a mixture, in equimolar proportions, of these two isomerides has double the solubility of either constituent separately, and that by recrystallisation at 20° the two constituents are not separable from one another. If, however, the mixture is first heated with water for some hours, subsequent fractional crystallisation can yield crops of crystals, which rotate light in the opposite direction. It is assumed here that, in accordance with the theory given above, the isomerides which form mirror images are converted into "relative isomerides" by the action of heat which are no longer mirror images. Copper salts were also obtained by fractional crystallisation from the mixture of the heated acids, of which the various fractions differed markedly from one another both in colour and solubilities. An attempt to obtain optically active isomerides in a similar way from racemic acid failed. It is pointed out, however, that when the *d*- and *l*-tartaric acids are combined there is development of heat, and a product of higher melting point, and less soluble in water than either the *d*- or *l*-acids, is obtained ; in the case of combination of the *d*- and *l*-asparagines no heat is developed, and the product is more soluble than the antipodes and has a lower m. p. Apparently a true racemic combination is not produced in this case. The action of heat on the sodium–ammonium salt of racemic acid led, however, to a very partial separation into optically active isomerides. It is claimed that the experiments described above afford the first examples of the production of optically active substances without intervention of asymmetrical substances and forces, and the biological significance of the results is discussed in some detail.

S. B. S.

Preparation of Carbonyl Cyanide. DANIEL BERTHELOT and HENRY GAUDÉCHON (*Compt. rend.*, 1913, 156, 1990—1992. Compare this vol., i, 715).—It has already been shown that, in a manner analogous to the combination with chlorine, hydrogen and ammonia producing carbonyl chloride, formaldehyde and formamide respectively, carbon monoxide undergoes combination with cyanogen if a mixture is exposed to ultra-violet light, yielding carbonyl cyanide, CN·CO·CN.

Endeavours to prepare this substance by other methods reveal the fact that the silent electric discharge, which, although it frequently causes similar effects to ultra-violet light, exerts a quite distinct effect in other cases, also gives rise to a combination of the two gases. The mixture may contain varying proportions of the gases as long as neither becomes exhausted, but the action is most rapid when equal volumes are applied. With a tension of 6000 volts combination occurs much more rapidly than in ultra-violet light, and in one experiment

a mixture of 5 c.c. of carbon monoxide with an approximately equal volume of cyanogen gave a contraction of 3 c.c. in ten minutes. The yellow solid product is partly soluble in water and wholly soluble in alkalis. From the slow rate of its hydrolysis by dilute sulphuric acid, the substance evidently represents an even higher stage in the polymerisation of the simple molecule $CN \cdot CO \cdot CN$ than the product of ultra-violet illumination.

Attempts were made to prepare the unpolymerised substance by chemical processes, such as the action of carbonyl chloride on cyanide of silver or mercury, or from carbon monoxide and cyanogen by mere heating, but the results were consistently negative.

<div align="right">D. F. T.</div>

Some Complex Copper Alkali Ferrocyanides. KSHITIBHUSAN BHADURI and SARASHILAL SARKAR (*Zeitsch. anorg. Chem.*, 1913, **82**, 164—172).—Dextrose is added to a solution of potassium ferro-cyanide, which is then mixed with Fehling's solution. A cream-coloured precipitate is obtained, which is crystalline if the solutions are dilute. It is washed with boiling water and dried in a vacuum over sulphuric acid. It becomes violet and blue with sulphuric acid, and yields a nitroprusside with nitric acid. The crystalline characters are described. The formula of the original salt is
$$K_2Cu_2Fe(CN)_9, 2H_2O,$$

the blue salt being $K_3Cu_3Fe(CN)_9, K_2Cu[Fe(CN)_6]_2$, and the nitro-prusside, $K_2Fe(CN)_5 \cdot NO, 2Cu_2Fe(CN)_5 \cdot NO, 13H_2O$. Alkali yields a compound $K_2CuFe(CN)_6, CuO, 3\frac{1}{2}H_2O$. *Lithium copper ferrocyanide*, $Li_2Cu_2Fe(CN)_8, 4H_2O$, is lemon-yellow, and the sodium compound has also been obtained. The *ammonium* salt is obtained by dissolving cupric oxide in ammonia, and adding dextrose and ammonium ferro-cyanide, giving a red precipitate, $(NH_4)_2Cu_2Fe(CN)_6, 3NH_3$, and, from the filtrate, pale blue crystals of $(NH_4)_8Cu_5[Fe(CN)_6]_3, 8NH_3$. The compounds $2CuK_2Fe(CN)_6, 8CuO, 16H_2O$ and

$$(NH_4)_8Cu_4KFe_2(CN)_{12}, 5NH_3$$
have also been obtained. When copper sulphate is added to potassium ferricyanide and the precipitate is dissolved in ammonia, brown crystals of ammoniacal cupric ferrocyanide are obtained,

$$Cu_3Fe(CN)_6, 3NH_3.$$
The nature of the reduction process is unknown.

<div align="right">C. H. D.</div>

The Action of Different Metals on Potassium Ferricyanide Solutions. GEORGE McPHAIL SMITH [and RALPH ATKINSON LYNCH] (*Zeitsch. anorg. Chem.*, 1913, **82**, 63—70. Compare Beutel, A., 1912, i, 543).—Powdered iron prepared by reduction reduces potassium ferricyanide in an atmosphere of hydrogen:

$$4K_3Fe(CN)_6 + 2Fe = Fe_2Fe(CN)_6 + 3K_4Fe(CN)_6.$$
Nickel and zinc also reduce to ferrocyanide without passing into solution, and form precipitates. Silver reacts in the cold:

$$4K_3Fe(CN)_6 + 4Ag = Ag_4Fe(CN)_6 + 3K_4Fe(CN)_6,$$
but at $100°$ silver goes into solution as a complex salt. With mercury, metallic iron is first formed: $2K_3Fe(CN)_6 + 3Hg = 3K_2Hg(CN)_4 + 2Fe.$ This iron then reacts as above, and, in presence of alkali hydroxide,

ferric hydroxide is ultimately formed. Gold dissolves slowly in ferricyanide solutions.

[With MICHELE CROCE.]—Silver ferrocyanide dissolves in potassium ferrocyanide solution, forming potassium silver cyanide, $KAg(CN)_2$.

C. H. D.

Univalent Nickel Compounds. II. ITALO BELLUCCI and R. CORELLI (*Atti R. Accad. Lincei*, 1913, [v]. 22, i, 703—708. Compare this vol., ii, 604).—Continuing their work on the nature of the compound contained in the red liquid obtained by the reduction of potassium nickelocyanide, the authors criticise adversely the second also of the analytical methods employed by Moore (*loc cit.*), so that they reject the formula Ni_3X_2 proposed by that author. By three analytical methods they obtain concordant results indicating that the red solution contains a cyano-salt in which nickel is univalent. The analytical methods employed were : (1) the measurement of the amount of hydrogen evolved by the solution in the warm ; (2) titration with $N/10$-iodine solution ; (3) titration with a standard hydrogen peroxide solution.

New Compounds and Scissions of Azodicarboxylic Acid. OTTO DIELS and MAX PAQUIN (*Ber.*, 1913, 46, 2000—2013).—The decomposition of derivatives of azodicarboxylic acid on dehydration, hydrolysis or heating is described. When azodicarboxylamide is heated with phosphoric oxide, nitrogen, water, cyanic acid and hydrogen cyanide are formed, according to the equation :

$$N_2(CONH_2)_2 = H_2O + N_2 + HCNO + HCN.$$
Substituted azoamides, such as azodicarboxyldiethylamide, yield *iso*-cyanates and *iso*nitriles : $N_2(CO\cdot NHEt)_2 = H_2O + N_2 + C_2H_5NCO + C_2H_5NC$. The same compound also readily forms a brick-red *silver* salt which decomposes at 141°, or when treated with iodine, into ethylcarbimide : $N_2(CO\cdot NAgEt)_2 = 2Ag + N_2 + 2CO\colon NEt$;

$$N_2(CO\cdot NAgEt)_2 + I_2 = 2AgI + N_2 + 2CO\colon NEt.$$
When azodicarboxylamide is heated with concentrated sulphuric acid, it decomposes into carbon dioxide, carbon monoxide, sulphur dioxide and nitrogen, but, in the cold, hydrazine sulphate and hydrazoic acid are formed. When boiled with dilute sulphuric acid, the compound gives a larger yield of hydrazoic acid, the other products including carbon monoxide, carbon dioxide, nitrogen and hydrazine and ammonium sulphates. Angeli (A., 1910, ii, 844) observed the production of hydrazoic acid under these conditions from azodicarboxylic acid itself, and explained it by assuming that di-imine, $NH\colon NH$, is first formed, and that it polymerises to the hypothetical tetrazen, which may decompose in two ways :

$$2NH\colon NH \longrightarrow NH_2\cdot N\colon N\cdot NH_2 \longrightarrow NH_3 + N_3H \text{ or } N_2 + N_2H_4.$$
The primary decomposition of azodicarboxylamide might also follow two courses :

$$N_2(CO\cdot NH_2)_2 + 2H_2O = 2CO_2 + 2NH_3 + NH\colon NH \text{ or}$$
$$N_2(CO\cdot NH_2)_2 = 2CO + NH_2\cdot N\colon N\cdot NH_2.$$
Methyl hydrazodicarboxylate, $N_2H_2(CO_2Me)_2$, was obtained in radiating bundles of broad needles by the action of methyl chloroformate on

hydrazine hydrate, and oxidised by concentrated nitric acid to *methyl azodicarboxylate*. The latter has b. p. 85°/7 mm., is hydrolysed by water to the hydrazo-ester, carbon dioxide and hydrazoic acid, and is oxidised by fuming nitric acid to oxalic acid.

Whereas primary amines convert the esters of azodicarboxylic acid into amides, secondary and tertiary amines usually form additive compounds which, on hydrolysis with dilute acids, yield the corresponding hydrazo-esters together with aldehydes and amines which contain one radicle less attached to the nitrogen atom than the original amine does. Thus the *compound* of ethyl azodicarboxylate with dimethylamine yields ethyl hydrazodicarboxylate, formaldehyde and methylamine, its constitution being therefore represented by the formula $CO_2Et\cdot N(CH_2\cdot NHMe)\cdot NH\cdot CO_2Et$. The compound forms well-defined prisms or rhombic plates, m. p. 95°, decomposes, when the aqueous solution is boiled, into ethyl hydrazodicarboxylate, dimethylamine, nitrogen and carbon dioxide, and is oxidised by nitric acid to ethyl azodicarboxylate. When submitted to dry distillation, it decomposes vigorously, giving a good yield of hydrazomethane, together with ethyl hydrazodicarboxylate, ethylcarbimide and formaldehyde :

$$2CO_2Et\cdot N(CH_2\cdot NHMe)\cdot NH\cdot CO_2Et =$$
$$2CH_2O + 2CO:NEt + N_2H_2(CO_2Et)_2 + N_2H_2Me_2.$$
When the decomposition and distillation are carried out under reduced pressure, however, the chief product is ethyl dimethylcarbamate :

$$2CO_2Et\cdot N(CH_2\cdot NHMe)\cdot NH\cdot CO_2Et = N_2 + EtOH + CO + NMe\cdot CO_2Et.$$

The latter was characterised by conversion into methylnitroamine (Franchimont and Klobbie, A., 1889, 492).
The *compound*, $CO_2Et\cdot N(CHMe\cdot NHEt)\cdot NH\cdot CO_2Et$, prepared by mixing ethyl azodicarboxylate with diethylamine, forms clusters of needles, m. p. 68°, is sparingly soluble in cold water or water at 80—90°, but is readily soluble at 50°, and yields acetaldehyde on hydrolysis. The *compound*, $CO_2Me\cdot N(CH_2\cdot NMePh)\cdot NH\cdot CO_2Me$, obtained from methyl azodicarboxylate and dimethylaniline, crystallises from ether in prismatic columns and rhombic plates, m. p. 95—96°, and yields formaldehyde, methylaniline, and methyl hydrazodicarboxylate on hydrolysis. The *compound*,

$$NHEt\cdot CO\cdot N(CH_2\cdot NHMe)\cdot NH\cdot CO\cdot NHEt,$$

prepared by mixing azodicarboxylethylamide with ether and dimethylamine in the cold in a sealed tube, forms rhombic plates, m. p. 109—111° (decomp.), and yields formaldehyde on hydrolysis.

J. C. W.

1 : 1-Dimethyl*cyclo*hexane. NICOLAI D. ZELINSKI and NICOLAI N. LEPESCHKIN (*J. Russ. Phys. Chem. Soc.*, 1913, 45, 613—616).— β-Methyl-Δ²-hepten-ζ-one was converted into the η-acetyl derivative, the latter transformed by the action of sulphuric acid into 6-acetyl-1 : 1-dimethyl*cyclo*hexan-5-one, and this hydrolysed to 1 : 1-dimethyl-*cyclo*hexan-5-one, which, on reduction in ethereal solution by means of sodium and water, gave 1 : 1-*dimethylcyclohexan-5-ol*,

$$CH_2\begin{array}{c}CH(OH)\cdot CH_2\\CH_2 ----- CH_2\end{array}CMe_2,$$
b. p. 185°/754 mm., D_4^{15} 0·9071, n_D^{15} 1·4558. Reduction of the

alcohol with hydriodic acid yields 1:1-dimethyl*cyclo*hexane, b. p. 119·2—119·7°, D_4^{16} 0·7843, D_1^{20} 0·7792, n_D^{16} 1·4320 (compare Crossley and Renouf, T., 1905, **87**, 1487). When treated with bromine in presence of aluminium bromide, this hydrocarbon is readily converted into tetrabromo-*p*-xylene, one of the methyl groups migrating to the para-position under the conditions of bromination (compare A., 1902, i, 143). T. H. P.

The Benzene Problem. KURT GEBHARD (*J. pr. Chem.*, 1913, ii], **88**, 94—96).—A reply to Liebig (this vol., i, 607). F. B.

A New Method for the Introduction of Iodine into Aromatic Substances. KARL ELBS and A. JAROSLAVZEV (*J. pr. Chem.*, 1913, [ii], **88**, 92—94).—Iodo-derivatives of aromatic hydrocarbons may be readily prepared by boiling the latter with iodine and sodium persulphate in glacial acetic acid solution. Thus benzene yields iodo- and *p*-di-iodobenzene, whilst toluene gives rise to *o*- and *p*-iodotoluenes.

The following iodo-compounds have also been prepared by this method : 4-iodo-*m*-xylene, 4-iodo-*o*-xylene, 2-iodo-*p*-xylene, and iodo-ψ-cumene.

s-*Di*-p-*iododiphenylethane*, prepared from dibenzyl, has m. p. 152° ; the position of the iodine atoms has been established by its oxidation to *p*-iodobenzoic acid by chromic acid in glacial acetic acid solution. F. B.

Some Aromatic Fluorine Compounds. FRÉDÉRIC SWARTS (*Bull. Acad. roy. Belg.*, 1913, 241—278).—The compounds described are mostly prepared by decomposing aromatic diazonium salts with hydrofluoric acid in vessels of silver or platinum. They were obtained for thermochemical investigations (compare A., 1907, ii, 9 ; 1908, ii, 354 ; 1909, ii, 297).

o-Fluoronitrobenzene could not be prepared : the para-isomeride forms colourless crystals, m. p. 27°, b. p. 205°/735 mm., and the *meta* derivative has m. p. 3·6°, b. p. 200°/756 mm., D_{17} 1·3272, n_D 1·5207.

1-Fluoro-2 : 4-dinitrobenzene forms large, colourless, hard crystals m. p. 25·8°, b. p. 178°/25 mm.

m-*Fluoroacetanilide* crystallises in large, colourless prisms, m. p. 84·5° ; the para-isomeride forms tiny needles, m. p. 152°. 4-*Fluoro*-3-*nitroacetanilide* separates in very pale yellow needles, m. p 138·5°.

p-*Fluorophenol*, prepared by heating fluorophenetole with aluminium chloride, has b. p. 185·5°. It forms transparent, tabular crystals, m. p. 26·5—27°, but this modification changes on keeping into a stable form, m. p. 45°, consisting of acicular crystals resembling phenol.

m-*Fluorophenol*, prepared by decomposing *m*-fluorobenzenediazonium sulphate, forms large, prismatic crystals, m. p. 13·7°. o-*Fluorophenol*, b. p. 151—152°, m. p. 16·1°, has a penetrating odour.

ω-*Trifluoro*-m-*cresol*, $CF_3 \cdot C_6H_4 \cdot OH$, prepared by diazotising trifluorotoluidinesulphate and decomposing the diazonium compound with

dilute sulphuric acid, forms a viscid liquid, b. p. 178·3°, which yields crystals, m. p. − 1·8°.

On diazotising o-phenetidine in hydrofluoric acid a mixture of o-fluorophenetole and ordinary phenetole is obtained.   o-*Fluorophenetole* has b. p. 171·4°, m. p. − 16 7°.   m-*Fluorophenetole*, prepared in a similar manner, is a colourless liquid, b. p. 171·4°/755 mm., $D_{16·4}$ 1·0716, n_D 1·4847.

p-*Fluorophenetole* cannot be separated from phenetole by distillation ; after fractional crystallisation the pure product had m. p. − 8·5°, b. p 172·8° 766 mm., $D_{18·9}$1·07148, n_D1·48257.   The product described by Valentiner and Schwarz (*Zeitsch. angew. Chem.*, 1898, 11, 441), b. p. 197°, as p-fluorophenetole is shown to be mainly p-chlorophenetole.

On nitration of p-fluorophenol, 4-*fluoro-2-nitrophenol* is obtained, crystallising in hexagonal prisms, m. p. 73·7° ; the *sodium* and *potassium* salts form long, red needles which explode when heated.

The   corresponding   4-*fluoro-2 nitrophenetole*   yields   colourless crystals, m. p. 33·7°.   4-*Fluoro-2 : 6 dinitrophenol* crystallises in very beautiful yellow prisms, m. p. 50·2°.

On nitration of m-fluorophenol, a *dinitro*-derivative is obtained in large, colourless, straw-like crystals becoming yellow on exposure to light, m. p. 72—74° ; the constitution has not been established.

p-*Difluorobenzene* prepared from p fluoroaniline is an oil, b. p. 88—89°, $D_{18·5}$ 1·1725, n_D 1·4422, m. p. − 23·7°.

On nitration 1 : 4-*difluoro-2-nitrobenzene* is obtained as a pale yellow oil, b. p. 103°/25 mm., m. p. − 11·7° ; it is very viscous at low temperatures.   The oil has $D_{17·2}$ 1·4671, n_D 1·5115.   E. F. A.

Chloronitrotoluenes with Reactive Chlorine.   WALTHER BORSCHE and ANNA FIEDLER (*Ber.*, 1913, 46, 2117—2131.   Compare A., i, 175).—In continuation of the earlier investigation which led to the isolation of pure 2-chloro-3 : 5-dinitrotoluene, the authors have turned their attention to the corresponding derivatives of p- and m-chlorotoluenes.   Their results indicate, among other facts, that pure 4-chloro-3 : 5-dinitrotoluene has not been previously obtained (compare Hönig, A., 1887, 1034).

The further nitration of 4-chloro-3-nitrotoluene by gradual addition to a cooled mixture of equal volumes of sulphuric acid and nitric acid (D 1·52) gives an impure reaction product from which by repeated crystallisation from alcohol pure 4-chloro-3 : 5-dinitrotoluene, needles, m. p. 115—116°, can be separated.   It reacts with ethyl sodiomalonate in warm ethereal solution, producing, after acidification, *ethyl 2 : 6 dinitro-p-tolylmalonate*, $C_6H_2Me(NO_2)_2 \cdot CH(CO_2Et)_2$, colourless crystals, m. p. 90°, which on heating with a mixture of acetic acid and a little diluted sulphuric acid passes into 2 : 6-*dinitro-p-tolylacetic acid*,

$$C_6H_2Me(NO_2)_2 \cdot CH_2 \cdot CO_2H,$$
colourless needles, m. p. 241—242° (decomp.).   4-Chloro-3 : 5-dinitrotoluene also reacts with aniline, yielding 3 : 5-dinitro-4-anilinotoluene. The chlorodinitrotoluene can also be obtained in small quantity by the action of toluene-p-sulphonyl chloride on dinitro-p-cresol in the presence of diethylaniline.   In preparing the compound by the first method a

substance, m. p. 108°, possibly 4-chloro-2 : 5-dinitrotoluene, which does not react with aniline, is simultaneously produced.

The main product in the nitration of *m*-chlorotoluene by Reverdin and Crepieux's method (A., 1900, i, 638) is 3-chloro-4 : 6-dinitro toluene, m. p. 91°. It reacts in warm ethereal solution with ethyl sodioacetoacetate, producing *ethyl* 4 : 6-*dinitro*-m-*tolylacetoacetate*,

$$C_6H_2Me(NO_2)_2 \cdot CHAc \cdot CO_2Et,$$
yellow tablets, m. p. 98°, which on warming with sulphuric acid undergoes scis-ion, yielding 4 : 6-*dinitro*-m-*tolylacetone*,

$$C_6H_2Me(NO_2)_2 \cdot CH \cdot CO \cdot CH_3,$$
leaflets, m. p. 92°; also with ethyl sodiomalonate, it gives *ethyl* 4 : 6-*dinitro*-m-*tolylmalonate*, pale yellow crystals, m. p. 62°, which on heating with diluted sulphuric acid in acetic acid solution passes into 4 : 6-*dinitro*-m-*tolylacetic acid*, colourless needles, m. p. 176°; this substance when maintained at its m. p. loses carbon dioxide with production of 4 : 6-dinitro-1 : 3-xylene, m. p. 93—94°. *Ethyl* 4 : 6-*dinitro*-m-*tolylacetate*, colourless needles, m. p. 70°, is slowly converted by the action of sodium and more *m*-chlorodinitrotoluene in alcoholic solution at the ordinary temperature into *ethyl* 4 : 6 : 4' : 6'-*tetranitro-di*-m-*tolylacetate*, $CO_2Et \cdot CH_2[C_6H_2Me(NO_2)_2]_2$, needles, m. p. 159—160°, and also condenses at 180° with salicylaldehyde in the presence of a little piperidine, producing 3-o'p *dinitro*-m-*tolylcoumarin*,

$$\begin{matrix} C_6H_4\!-\!CH \\ O \quad -\!CO \end{matrix}\!\!\!>\!\!C\!-\!C_6H_2Me(NO_2)_2,$$ yellow needles, m. p. 240°, with a
little 4 : 6-*dinitro-3-coumarino-2'-hydroxystilbene*,

$$\begin{matrix} C_6H_4\!-\!CH \\ O \quad\quad -\!CO \end{matrix}\!\!\!>\!\!C\!-\!C_6H_2(NO_2)_2 \cdot CH\!:\!CH \cdot C_6H_4 \cdot OH.$$
4 : 6-Dinitro-*m*-toluidine is obtainable by heating the corresponding chlorodinitrotoluene with alcoholic ammonia at 100°, and if the ammonia be replaced by aniline, *phenyl-*4 : 6-*dinitro*-m-*tolylamine*,

$$C_6H_2Me(NO_2)_2 \cdot NHPh,$$
orange-coloured leaflets, m. p. 145°, is obtained. The former of these products readily condenses at 180—190° with benzaldehyde in the presence of piperidine with formation of 4 : 6-*dinitro-3-anilinostilbene*, $NHPh \cdot C_6H_2(NO_2)_2 \cdot CH\!:\!CHPh$, deep red leaflets, m. p. 182°. The chlorodinitrotoluene likewise condenses with piperidine when heated with the hydrochloride of the base and sodium acetate in alcoholic solution, giving 4 : 6-dinitro-3-piperidinotoluene, yellow rhombs, m. p. 116°; this can be further condensed with benzaldehyde, 4 : 6-*dinitro-3-piperidinostilbene*, yellowish-red crystals, m. p. 172°, being produced.

If the mother liquors from the crystallisation of 3-chloro-4 : 6-dinitrotoluene are treated with ethyl sodiomalonate or sodioacetoacetate, an unreactive isomeride, 3-*chloro*-2 : 4-*dinitrotoluene*, yellowish-white needles, m. p. 73°, remains unaffected ; its structure is indicated by its conversion through the corresponding *dinitrotolylhydrazine* (*hydrochloride*, yellow needles) by the action of ammonium hydroxide into 4-*nitro-5-methyl-1-hydroxy* 1 : 2 : 3-*benzotriazole*,

$$C_6H_2Me(NO_2)\!\!<\!\!\begin{matrix} \overbrace{\quad\quad}\!\!-N \\ N(OH) \end{matrix}\!\!\!>\!\!N,$$
decomp. at 176° (compare Borsche and Rantscheff, A., 1911, i, 329).

2-Chloro-3 : 5-dinitrotoluene reacts with ethyl sodioacetoacetate in ethereal suspension with formation of *ethyl a-4 : 6-dinitro-o-tolylacetoacetate*, yellow needles, m. p. 79—80°, from which 4 : 6-*dinitro-o-tolylacetone*, pale yellow leaflets, m. p. 103—104°, can be obtained by hydrolysis with dilute sulphuric acid. In a similar manner, condensation with ethyl sodiomalonate yields *ethyl 4 : 6-dinitro-o-tolylmalonate*, yellow prisms, m. p. 87—88°, which on heating with diluted sulphuric acid in acetic acid solution is converted into 4 : 6-*dinitro-o-tolylacetic acid*, colourless needles, m. p. 202° (decomp.) ; this when heated readily loses a molecule of carbon dioxide with formation of 3 : 5-*dinitro-*1 : 2-*xylene*, m. p. 74—75°.   D. F. T.

Solubilities of the Rare Earth Salts of Bromonitrobenzenesulphonic Acid. S. H. KATZ and CHARLES JAMES (*J. Amer. Chem. Soc.*, 1913, **35**, 872—874).—1 : 4 : 2-Bromonitrobenzenesulphonic acid, prepared by sulphonation of bromonitrobenzene, forms nicely crystalline salts with lanthanum ($8H_2O$), cerium ($8H_2O$), yttrium ($10H_2O$), praseodymium ($8H_2O$), neodymium ($8H_2O$), samarium ($10H_2O$), europium ($10H_2O$), gadolinium ($10H_2O$), erbium ($12H_2O$), thulium ($12H_2O$), and ytterbium ($12H_2O$). The solubility of each salt was determined at 25°, and it is interesting that on plotting the solubilities against the atomic weight, salts containing the same amount of water of crystallisation fall on distinct portions of the curve.   D. F. T.

Nitration of Iodobenzene. ARNOLD F. HOLLEMAN (*Rec. Trav. chim.*, 1913, **32**, 134—139).—In a previous investigation of the nitration of iodobenzene (A., 1912, i, 87), the author has found that the quantity of ortho-isomeride formed is less than that obtained in the nitration of bromobenzene, whilst in the nitration of other aryl haloids, the quantity of this isomeride increases with the atomic weight of the halogen, and also that a greater amount of o-iodonitrobenzene is obtained at −30° than at 0°, although the amount of accessory product generally increases with increasing temperature of nitration.

[With A. F. H. LOBRY DE BRUYN and W. J. DE MOOY.]—The previous work has been repeated and a new source of error discovered due to the ready solubility of o-iodonitrobenzene in iodobenzene, in which p-iodonitrobenzene is practically insoluble. The iodobenzene is now added slowly to the nitric acid (D 1·482 for nitration at 0° and D 1·488 for nitration at −30°) with brisk stirring, smaller quantities of concentrated nitric acid being added from time to time if the mass becomes too viscous. Agitation is continued for two to three hours after completion of the addition of iodobenzene. The mass is then poured into water, filtered, dried, and distilled under diminished pressure. In this manner the determination of the point of solidification is greatly facilitated.

The authors are led to the conclusion that the iodobenzene does not differ from that of the other phenyl haloids. At −30°, 39·1% of the ortho- and 60·9% of the para-isomeride are obtained, whilst at 0° the figures are 41·1% ortho- and 58·7% para-isomeride.   H. W.

Some Diphenylpentanes and the Corresponding Dicyclo-hexylpentanes. PAUL SABATIER and MARCEL MURAT (*Compt. rend.*, 1913, **156**, 1951—1954. Compare this vol., i, 716; A., 1912, i, 617, 757).—The authors have already reduced various diphenylethanes, diphenylpropanes, and diphenylbutanes to the corresponding dicyclohexyl derivatives, and in order to test the general character of the hydrogenation still further, have now submitted three of the eighteen theoretically possible diphenylpentanes to similar treatment.

By catalytic treatment of β-phenylpropionic acid with thoria or iron oxide, $\alpha\epsilon$-*diphenylpentan-γ-one*, $CH_2Ph\cdot CH_2\cdot CO\cdot CH_2\cdot CH_2Ph$, was first prepared, which, by contact with a not too active nickel at 180° in the presence of hydrogen, is converted smoothly into $\alpha\epsilon$-*diphenylpentane*, a fluorescent colourless liquid, b. p. 324° (corr.), D_0^9 0·9924, n_D^{19} 1·559. By hydrogenation under the influence of a very active nickel at 165°, this hydrocarbon is entirely reduced to $\alpha\epsilon$-*dicyclohexylpentane*, $C_6H_{11}\cdot[CH_2]_5\cdot C_6H_{11}$, a colourless liquid, b. p. 311° (corr.), D_0^9 0·8832, n_D^{21} 1·479, which resists the action of a cold mixture of nitric and sulphuric acids.

Methyl *iso*valerate reacts with magnesium phenyl bromide, yielding $\alpha\alpha$-*diphenyl-γ-methylbutanol*, $CHMe_2\cdot CH_2\cdot CPh_2\cdot OH$, which undergoes dehydration when distilled under the ordinary pressure, with production of $\alpha\alpha$-*diphenyl-γ-methyl-Δ^α-butene*, $CHMe_2\cdot CH:CPh_2$, a pale yellow liquid, b. p. 298—299° (corr.), D_0^{21} 0·9792, n_D^{21} 1·581. When submitted to the action of hydrogen under the influence of a sluggish nickel catalyst at 180°, the last-named hydrocarbon undergoes reduction to $\alpha\alpha$-*diphenyl-γ-methylbutane*, $CHMe_2\cdot CH_2\cdot CHPh_2$, a colourless, slightly fluorescent liquid, b. p. 297° (corr.), D_0^9 0·9756, n_D^{21} 1·551, which is still further reduced under the catalytic influence of a very active specimen of nickel at 160—165°, giving $\alpha\alpha$-*dicyclohexyl-γ-methylbutane*, $CHMe_2\cdot CH_2\cdot CH(C_6H_{11})_2$, a colourless liquid, b. p. 290—291° (corr.), D_0^9 0·9058, n_D^{21} 1·489.

Magnesium ethyl iodide reacts with *diphenylpropanone*,
$$CH_2Ph\cdot CO\cdot CH_2Ph,$$
which is obtainable by catalytic treatment of phenylacetic acid with iron oxide, producing *dibenzylethylcarbinol*, $CH_2Ph\cdot CEt(OH)\cdot CH_2Ph$; this passes on mere distillation under ordinary pressure into $\alpha\gamma$-*diphenyl-β-ethyl-Δ^α-propylene*, $CHPh:CEt\cdot CH_2Ph$, b. p. 306—307°, D_0^{21} 1·0159, n_D^{21} 1·589. By means of a sluggish nickel catalyst at 230° this can be hydrogenated to $\alpha\gamma$-*diphenyl β-ethylpropane*, $CH_2Ph\cdot CHEt\cdot CH_2Ph$, a colourless, fluorescent liquid, b. p. 304—305° (corr.), D_0^9 0·9855, n_D^{21} 1·553. When submitted to an active nickel catalyst below 180° it is reduced by hydrogen to $\alpha\gamma$-*dicyclohexyl-β-ethylpropane*,
$$C_6H_{11}\cdot CH_2\cdot CHEt\cdot CH_2\cdot C_6H_{11},$$
a colourless liquid, b. p. 296° (corr.), D_0^9 0·8966, n_D^{21} 1·843, which is not attacked by a cold mixture of sulphuric and nitric acids.
A comparison of the m. p.'s and b. p.'s of the diphenyl derivatives in which the two phenyl groups are connected by a normal chain of carbon atoms reveals the fact that whilst the latter increases steadily with an increasing number of linking atoms, the m. p.'s exhibit an undulating increase similar to that observed with the dicarboxylic acids. It is also noteworthy that whilst all the diphenyl hydro-

carbons are fluorescent, this property is most marked in those having the two phenyl radicles coupled by a normal chain of methylene linkings ; the dicyclohexyl derivatives possess no fluorescence.

<div align="right">D. F. T.</div>

The Constitution of Naphthalene. EUGEN BAMBERGER (*Ber.*, 1913, **46**, 1899—1903).—Since his earlier publications (a list of which is appended to the paper), the author's views on this subject have undergone modifications. Although he still regards the symmetry of naphthalene as highly probable, he realises that there has been no final proof. The formula suggested by Willstätter and Waser (A., 1912, i, 17) fails to express the reduction of naphthalene and its derivatives, which possess no true aromatic character, to aromatic compounds. This peculiar behaviour of naphthalene derivatives can be explained by other symmetrical formulæ in addition to the author's, provided that they do not include a true benzene ring, but the author repeats his earlier statement (*J. pr. Chem.*, 1890, **42**, [2], 205) that it is not possible to represent completely the various chemical phenomena presented by naphthalene derivatives in any one formula of the usual type.

<div align="right">D. F. T.</div>

10-Bromophenanthrene-3- or -6-sulphonic Acid. HÅKAN SANDQVIST (*Annalen*, 1913, **398**, 125—137).—By heating with 96—97% sulphuric acid on the water-bath and finally at 150—155°, 10-bromophenanthrene is converted into an acid which is proved to be 10-bromophenanthrene-3- or -6-sulphonic acid, and is isolated as the potassium salt. The free acid, prepared from the chloride and water at 130—135°, is an almost colourless, crystalline powder. It contains $3H_2O$, and has m. p. 162—164·5° (anhydrous, 200—201·5°). A 10% aqueous solution of the acid, which is as clear and viscous as water, becomes syrupy by the addition of a little dilute hydrochloric, nitric, or sulphuric acid, and finally deposits crystals of the acid by further addition of the mineral acid. The following salts are described, the figures in brackets denoting the weight of anhydrous salt dissolved by 100 grams of water at 19·5°: *ammonium* salt containing H_2O (0·327), *sodium* salt containing $1\frac{1}{2}H_2O$ (0·142), *potassium* salt with H_2O (0·163), *calcium* salt with $4H_2O$, *barium* salt with $2\frac{1}{2}H_2O$, *cupric* salt with $4H_2O$; the last three salts are quantitatively insoluble. The *methyl* ester, m. p. 172·5—173°, *ethyl* ester, m. p. 173—173·3°, *chloride*, $C_{14}H_8O_2ClBrS$, m. p. 184·5—185°, *sulphonamide*, m. p. 280—281°, and dimorphous *anilide*, m. p. 185·5—186° or 193°, are described.

By oxidation with chromic acid in boiling glacial acetic acid, 10-bromophenanthrene-3-(or 6-)-sulphonyl chloride and methyl 10-bromophenanthrene-3-(or 6-)-sulphonate respectively yield substances, m. p. 230—238° and 230—233°, which are apparently phenanthraquinone-3-sulphonyl chloride, m. p. 232—234°, and methyl phenanthraquinone-3-sulphonate, m. p. 234°, respectively.

Potassium or methyl 10-bromophenanthrene-3-(or 6-)-sulphonate are not attacked by reducing agents in acid or neutral media ; concentrated aqueous ammonia and zinc dust on the water-bath reduce the potassium salt, yielding phenanthrene-3-sulphonic acid.

<div align="right">C. S.</div>

Photochemical Transformations of Acenaphthylene. II. KARL DZIEWOŃSKI and C. PASCHALSKI (*Ber.*, 1913, **46**, 1986 -1992. Compare A., 1912, i, 844).—The two hydrocarbons, m. p. 306—367° and m. p. 232—234°, which are obtained by the action of sunlight on acenaphthylene are *cis-trans*-isomerides and may be represented by the formulæ :
The compounds are formed in different quantities according to the nature and concentration of the solution and to the intensity of the light. They both yield naphthalic anhydride on oxidation and are partly converted into the parent substance in the molten state, but they form entirely different picrates and bromo compounds. Although it cannot be said which of the isomerides is the labile modification, it is proposed to call the higher and the lower melting forms α- and β-*heptacyclene* respectively.

The former is the chief product when a benzene solution of acenaphthylene is illuminated, but the β-form predominates when petroleum is used as the solvent. β-*Heptacyclene*, $C_{24}H_{16}$, forms large, monoclinic prisms or tablets, $a : b : c = 0.7223 : 1 : 0.9527$, $\beta = 119°6'$, and is readily soluble in benzene. Both substances yield new, complex hydrocarbons when kept in the molten state for some time, but, when the mass is quickly cooled, some acenaphthylene is obtained and this is probably the parent of the new compounds, for it is unstable above 110°.

α-Heptacyclene combines with two molecules of picric acid in ethylene dibromide solution, yielding the *picrate*,

$$C_{24}H_{16}, 2C_6H_2(NO_2)_3 \cdot OH,$$
in orange needles, m. p. 225—227°, which are decomposed even by solvents, whereas β-heptacyclene forms a stable *picrate*,

$$C_{24}H_{16}, C_6H_2(NO_2)_3 \cdot OH,$$
in carmine-red needles, m. p. 215—216°. The α-hydrocarbon reacts very sluggishly with bromine in the cold, but the β-form absorbs bromine at once. J. C. W.

Perylene and Its Derivatives. II. RICHARD WEITZENBÖCK and CHRISTIAN SEER [with A. VON BARTSCH] (*Ber.*, 1913, **46**, 1994—2000. Compare A., 1910, i, 616).—Attempts have been made to improve the yield of perylene or its derivatives. The best result was obtained by the condensation of 4 : 4'-dicyano-1 : 1'-dinaphthyl to 3 : 10-dicyanoperylene.

From bromonaphthalene and aluminium chloride, a 4% yield of perylene was obtained at 140°, but at 30—35° the product was 2 : 2'-dinaphthyl, which was probably formed by the rearrangement of 1 : 1'-dinaphthyl. β-Dinaphthylene oxide (Eckstein, A., 1905, i, 885)

was also heated with aluminium chloride, when alkali extracted from the product, 1-*hydroxyperylene* (I). This forms long, slender, yellow needles, m. p. 197°, which give yellow solutions with green fluorescence, and yield a *benzoate*, $C_{27}H_{16}O_2$, in slender, lemon-yellow needles, m. p. 170—170·5°, and a *methyl ether* in yellow nodules, m. p. 111°. The residue from the extraction with alkali contained 1 : 12-*furoperylene* (II), which forms a reddish-brown powder, and gives dark red solutions with yellowish-brown fluorescence.
3 : 10-*Dicyanoperylene*, $C_{22}H_{10}N_2$, was obtained in good yield by the condensation of 4 : 4′-dicyano-1 : 1′-dinaphthyl (Seer and Scholl, this vol., i, 734) in brown, microscopic needles, m. p. 368—369°. It is sparingly soluble in acetic acid or xylene with intense green fluorescence, and yields 3 : 10-*perylenedicarboxylic acid*, $C_{22}H_{12}O_4$, when heated with alcoholic sodium hydroxide in a sealed tube. The acid forms reddish-brown, microscopic needles, and the solutions in alkalis are yellow with intense green fluorescence. The *ethyl* ester, $C_{26}H_{20}O_4$, forms brick-red leaflets, m. p. 247—248°.

4 : 4′-Di-iodo-1 : 1′-dinaphthyl (Willgerodt and Schlösser, A., 1900, i, 282) was prepared from naphthidine by treating the diazonium salt with potassium iodide. When heated with aluminium chloride, extensive decomposition took place.   J. C. W.

Degradation of Decacyclene [Trinaphthylenebenzene]. KARL DZIEWONSKI [with J. PODGÓRSKA and A. MIKLASZEWSKI] (*Ber.*, 1913, 46, 2156—2162).—When finely powdered decacyclene (A., 1903, i, 431) is heated for some hours with sodium dichromate and 30% sulphuric acid, it is broken down into *tribenzoylenebenzenetricarboxylic acid*, $C_6\left(<^{CO}_{C_6H_3 \cdot CO_2H}\right)_3$, which is formed in good quantity, as a brownish-red, voluminous, microcrystalline mass, m. p. above 360°. The acid gives blood-red solutions in alkalis, and forms, by precipitation, a brown *silver* salt, $C_{30}H_9O_9Ag_3$, and a reddish-brown *barium* salt, $(C_{30}H_9O_9)_2Ba_3$. When the calcium salt is distilled with lime, a sublimate of large, orange-yellow needles of tribenzoylenebenzene (truxenequinone),
$$C_6\left(<^{CO}_{C_6H_4}\right)_3$$
(Michael, A., 1906, i, 518) is formed. On heating the acid for three or four hours with the theoretical amount of potassium permanganate in a large excess of 2% sodium hydroxide, it is oxidised to dicarboxyphenylglyoxylic acid, $C_6H_3(CO_2H)_2 \cdot CO \cdot CO_2H$ (Graebe and Bossel, A., 1896, i, 436), and an acidic by-product, but complete oxidation with an excess of permanganate results in the formation of hemimellitic acid (Graebe and Leonhardt, A., 1896, i, 437). The constitution of decacyclene is therefore represented by the annexed formula.   J. C. W.

Strain Laws of Ring Systems. Oscar Hinsberg (*J. pr. Chem.*, 1913, **88**, [ii], 58—60).—It has been shown previously (A., 1902, i, 238; 1904, i, 200) from a comparison of the stability of various azines and acridine derivatives, that the strain in tertiary ring systems, composed of 6-membered rings arranged in linear order, increases rapidly with the complexity of the molecule, so that a system containing five conjugated rings is either very unstable or incapable of existence.

The author refers to the unsuccessful attempts of W. A. and M. Mills (T., 1912, **101**, 2194) to prepare dinaphanthracene by the oxidation of its di- and tetra-hydro-derivatives in support of this view, and points out that their work renders it probable that the strain laws, developed by him for ring-systems containing carbon and nitrogen, are also applicable to systems composed wholly of carbon rings.

F. B.

Metaquinonoids. II. Otto Stark and O. Garben (*Ber.*, 1913, **46**, 2252—2259).—The possibility that the yellow hydrocarbon, obtained previously (this vol., i, 362) by the removal of halogen from tetraphenyl-*m*-xylylene dichloride, is a triarylmethyl derivative and not a true metaquinonoid compound, is excluded on account of the comparatively great stability of the hydrocarbon towards air and oxygen, and its inability to form additive compounds with ether, ethyl acetate, benzene, alcohol, acetic acid, and acetic anhydride.

A benzene solution of the hydrocarbon, after being exposed to air for eight weeks, and occasionally treated with oxygen during this time, deposited a white, amorphous *oxide*,
which is insoluble in all the usual solvents with the exception of hot nitrobenzene, and when heated becomes discoloured and slowly decomposes at 200°, the decomposition being complete at 250°.

On treatment with hydrogen chloride in benzene, it yields an additive *compound* formed by the union of four molecules of the hydrocarbon with one of hydrogen chloride. This compound crystallises in white needles, m. p. 286—287° (decomp.), with previous darkening at 275°, and is considered to have the following constitution :

$$CPh_2 \cdot C_6H_4 \cdot CPh_2 \cdot CPh_2 \cdot C_6H_4 \cdot CHPh_2$$
$$CPh_2 \cdot C_6H_4 \cdot CPh_2 \cdot CPh_2 \cdot C_6H_4 \cdot CPh_2Cl$$
It dissolves in boiling benzene, yielding deep yellow solutions, but the molecular weight in these solutions is only half that corresponding with the above formula. The authors interpret these results as indicating that the substance undergoes dissociation, at the position shown by the dotted line, into two triarylmethyl residues.

During the preparation of the hydrocarbon, an isomeride was obtained (*loc. cit.*) which had a higher m. p., and was supposed to be identical with Thiele's tetraphenyl-*p*-xylylene. The identity of the two compounds has now been fully established. The simultaneous

formation of the para-quinonoid hydrocarbon is due, however, not to a wandering of the groups in the meta-compound as was imagined previously, but to the original methyl *iso*phthalate, from which the hydrocarbon was prepared, being contaminated by considerable quantities of methyl terephthalate.

The *diethyl ether* of tetraphenyl-*m*-xylylene glycol, prepared by boiling the corresponding chloride with alcohol, has m. p. 116—117°; the *methyl ether*, m. p. 103—104°. The *diacetyl* derivative, prepared from the glycol and acetic anhydride, has m. p. 90—91 5°.

Tetraphenyl-*p*-xylylene glycol crystallises from glacial acetic acid in well developed prisms, m. p. 168—169°, containing the solvent (1 mol.), which is removed by heating the crystals under diminished pressure at 130—140°; the glycol then has m. p. 171—171·5°. The *diacetyl* derivative sinters at 198°, m. p. 203—204°.

Tetraphenyl-p-*xylylene dichloride*, prepared by passing hydrogen chloride into an acetic acid solution of the glycol, crystallises in slender, flat prisms, m. p. 239—240°, with previous sintering and darkening.   F. B.

Nitro-derivatives of *p*-Phenetidine.   FRÉDÉRIC REVERDIN and LUDWICK FURSTENBERG (*Arch. Sci. phys. nat.*, 1913, 35, 594—605; *Bull. Soc. chim.*, 1913, [iv], 13, 671—681).—The present work has been undertaken in continuation of the experiments of Reverdin and de Luc (A., 1909. i, 377, 913) on the nitration of *p*-anisidine.   The initial materials in the various experiments are aceto-*p*-phenetidide, toluenesulpho-*p*-phenetidide, o-*nitrotoluenesulpho*-p-*phenetidide*,

OEt·C₆H₄·NH·SO₂·C₆H₃Me·NO₂,
needles, m. p. 128°, and m-*nitrophenylsulpho-p-phenetidide*.

OEt·C₆H₄·NH·SO₂·C₆H₄·NO₂,
prismatic needles, m. p. 129—130°, the two latter substances being obtained by the action of the corresponding chlorides on an alcoholic solution of *p*-phenetidine in the presence of sodium acetate.

2 : 3-Dinitro-*p*-phenetidine (compare Wender, A., 1890, 751) is formed by the action of concentrated sulphuric acid on 2 : 3-*dinitro-p-toluene-sulphophenetidide*, white needles, m. p. 163°, obtained by the addition of nitric acid (D 1·52) to a solution of toluenesulpho *p*-phenetidide in glacial acetic acid.

3 : 5-*Dinitro-o-nitrotoluenesulpho-p-phenetidide*,

OEt·C₆H₂(NO₂)₂·NH·SO₂·C₆H₃Me·NO₂,
slender needles, m. p. 163°, is prepared by the action of nitric acid (D 1·4) on a solution of *o*-nitrotoluenesulpho-*p*-phenetidide in glacial acetic acid.   Energetic treatment with concentrated sulphuric acid converts it into 3 : 5-dinitro-*p*-aminophenol, m. p. 230°, from which the position of the nitro-groups is ascertained, whilst a milder treatment leads to the formation of 3 : 5-*dinitro*-p-*phenetidine*, red leaflets, m. p. 138—139°.   The same base can be obtained by the saponification of the product formed when 3-nitrotoluenesulpho-*p*-phenetidide is nitrated in acetic acid solution.

When phenacetine is nitrated in sulphuric acid solution under definite conditions, 2 : 6-dinitro-*p*-phenacetine, OEt·C₆H₂(NO₂)₂·NHAc, white needles, m. p. 148°, is formed, which, when hydrolysed by dilute

sulphuric acid, is converted into 2:6-*dinitro*-p-*phenetidine*, yellow leaflets, m. p. 172°. The constitution of the base follows from the identity with the product obtained by the ethylation of *isopicramic* acid.

Unsuccessful attempts have been made to prepare 2:5-dinitro-*p*-phenetidine by the nitration of phenacetine or of *m*-nitrobenzene-sulpho-*p*-phenetidide. In the latter case, the main product of the change was a 2:3-dinitro-derivative, m. p. 178°, which, on hydrolysis, yielded 2:3-dinitro-*p*-phenetidine, smaller quantities of a 3:5-dinitro-derivative being also formed

2:3:5-*Trinitrotoluenesulpho*-p-*phenetidide*, white needles, m. p. 217°, is prepared by nitrating 2:3-dinitrotoluenesulpho-*p*-phenetidide, and, when acted on by sulphuric acid, yields 2:3:5-*trinitro*-p-*phenetidine*, fine red needles with green reflex, m. p. 126—127°. The constitution of this substance is deduced from its analogy with the trinitro-*p*-anisidine obtained by Reverdin (A., 1910, i, 470) in which the nitro-groups are in the 2:3:5-positions, that in position 2 being mobile (compare Meldola and Kuntzen, T., 1910, 97, 444). This is established by converting it into dinitroguaiacol, dinitrocatechol, and dinitroveratrole of known constitution.

2:3:5-*Trinitroaceto*-p-*phenetidide*, OEt·$C_6H(NO_2)_3$·NHAc, white needles, m. p. about 245°, is obtained by the action of acetic anhydride and a trace of concentrated sulphuric acid on the free amine.

The following derivatives have been prepared by the replacement of the mobile nitro-group of 2:3:5-trinitro-*p*-phenetidine; 3:5-*dinitro-2-anilino*-p-*phenetidine*, OEt·$C_6H(NO_2)_2(NH_2)$·NHPh, brown leaflets, m. p. 151—152°; 3:5-*dinitro-2-methylamino*-p-*phenetidine*,

$$OEt·C_6H(NO_2)_2(NH_2)·NHMe,$$
red needles, m. p. 166—167°; 3:5-*dinitro-2-dimethylamino*-p-*henetidine*, OEt·$C_6H(NO_2)_2(NH_2)$·NMe₂, m. p. 119—120°; 3:5-*dinitro-2 phenoxy*-p-*phenetidine*, OEt·$C_6H(OPh)(NO_2)_2$·NH₂, red needles, m. p. 185—186°; 3:5-*dinitro-2-amino*-p *phenetidine*, OEt·$C_6H(NO_2)_2(NH_2)_2$, m. p. 250°; 3:5-*dinitro-2-piperidino*-p-*phenetidine*,

$$OEt·C_6H(NO_2)_2(NH_2)·C_5NH_{10},$$
red leaflets, m. p. 143—144°.

2:5-*Dinitro-1-ethoxy-3:4-quinonediazide* (annexed formula: compare

Meldola and Reverdin, T., 1910, 97, 1204) is formed by the addition of sodium nitrite to a solution of 2:3:5-dinitro-*p*-phenetidine in sulphuric acid. It separates from acetic acid in orange prisms, m. p. 186°.
3:5-*Dinitro-2-hydroxy-p-phenetidine*, brown needles or blackish crystals with green metallic reflex, m. p. 166—167°, is prepared by boiling a solution of 2:3:5-trinitro-*p*-phenetidine in acetone with an alcoholic solution of sodium acetate. When the amino-group is removed in the usual manner, 3:5-*dinitro-2-hydroxyphenetole*, yellow leaflets, m. p. 155°, is obtained, the *barium* and *silver* salts of which were also examined. The latter, when treated with an alcoholic solution of ethyl iodide, yields slightly impure 3:5-dinitro-1:2-diethoxybenzene, m. p. 90—91°, probably identical with the product described by Blanksma (A., 1905, i, 431) to which the m. p. 94—95° is now assigned. **H. W.**

The Molecular Rearrangement of Triphenylmethylhydroxylamine. JULIUS STIEGLITZ and PAUL N. LEECH (*Ber.*, 1913, **46**, 2147—2151).—In accordance with Stieglitz's views as to the molecular rearrangement of bromoamides, hydroxamic acids, etc. (A., 1897, i, 43), which regard the Beckmann rearrangement with an oxime to occur by the steps

$$CR_2 \cdot N \cdot OH \xrightarrow{HCl} CR_2Cl \cdot NH \cdot OH \xrightarrow{H_2O} CR_2Cl \cdot N: \longrightarrow CRCl:NR,$$

it is found that triphenylmethylhydroxylamine, $CPh_3 \cdot NH \cdot OH$, which in constitution closely resembles the first class of product in the above series of changes, when treated in ethereal solution with phosphorus pentachloride is converted into benzophenoneanil, $CPh_2:NPh$, m. p. 111—112°. The above course of the rearrangement is thus confirmed.

<div align="right">D. F. T.</div>

The Molecular Rearrangement of Triphenylmethylbromoamine. JULIUS STIEGLITZ and ISABELLE VOSBURGH (*Ber.*, 1913, **46**, 2151—2156).—In an endeavour to decide which of the tautomeric forms $R \cdot CO \cdot NMX$ and $R \cdot C(OM):NX$ (M = metal, X = halogen) of the metallic salts of the halogenamides is to be regarded as the intermediate stage in the production of amines from halogen-amides by Hofmann's rearrangement, the authors have prepared and examined triphenylmethylbromoamine, $CPh_3 \cdot NHBr$, with which the possibility of tautomerism is excluded. By the action of alkali, the elements of hydrogen bromide are eliminated from this substance with formation of benzophenoneanil. The series of changes must therefore be $CPh_3 \cdot NHBr \longrightarrow CPh_3 \cdot NMBr \longrightarrow CPh_3 \cdot N: \longrightarrow CPh_2:NPh$. The former of the alternative structures thus receives support without excluding the possibility of the second formula being the correct one for the structure involved.

Triphenylmethylbromoamine, colourless crystals, m. p. 63°, was obtained by the action of bromine on triphenylmethylamine in chloroform solution in the presence of sodium hydroxide solution. By heating with soda-lime at 100—120°, or with a hot methyl alcoholic solution of sodium methoxide, it is converted into benzophenoneanil, m. p. 111—112°.

When heated to its m. p., triphenylmethyldichloroamine rapidly loses chlorine with the formation of benzophenoneanil with a little chlorobenzophenoneanil.

<div align="right">D. F. T.</div>

Oxidation of Organic Developers with Silver Salts. *p*-Aminophenol and Metol. FRITZ KROPF (*J. pr. Chem.*, 1913, [ii], **88**, 73—77).—On the addition of silver nitrate to an aqueous solution of *p*-aminophenol or *p*-methylaminophenol, the liquid acquires a bluish-violet colour and benzoquinone is produced.

In ammoniacal solution a blue coloration is produced, but no definite compound could be isolated from the reaction product.

When dissolved in aqueous sodium hydroxide and treated with silver bromide, *p*-aminophenol yields a *substance* which crystallises in brown leaflets having a metallic glance, m. p. 194° (not sharp), and gives a dark blue coloration on treatment with phenol and ammonia.

The addition of silver bromide to a solution of *p*-aminophenol in aqueous sodium hydroxide and in the presence of potassium meta-bisulphite results in the formation of a small amount of a white substance, which is probably a sulphonic acid ; under similar conditions metol yields a strongly green fluorescent solution, but no definite compound could be isolated.

The amount of silver reduced in the above reactions, and also the amount of sulphite which disappears, depends on the conditions under which the reduction is carried out. F. B.

Nitration of Anisole to Trinitroanisole. ALFRED L. BROAD-BENT and FIN SPARRE (*Eighth Inter. Cong. App. Chem.*, 1912, **4**, 15—17).—No experimental details of the preparation of 2 : 4 : 6-tri-nitroanisole from anisole appear to have been published ; the literature contains merely statements that the nitration is possible.

After considerable difficulties, the authors have evolved the follow-ing details which permit a yield of 85% of that theoretically expected from the anisole taken.

A mixture of 130 grams of nitric acid (D 1·52) with 220 grams of sulphuric acid (D 1·84), which is mechanically agitated by a stirrer, is cooled to −5° by immersion in a freezing mixture of ice and salt whilst 30 grams of anisole are added in small drops. The addition should occupy two to three hours, and the temperature of the mixture should never reach 0°. After all the anisole has been introduced, the temperature is raised to 65—70° for twenty minutes with continued stirring, and the mixture is then poured into water. After washing with warm water and dilute sodium carbonate solution successively, with subsequent drying, the product has m. p. 64—65°, D^{20} 1·408, and is slowly hydrolysed by water to methyl alcohol and picric acid.

D. F. T.

Hydrolysis of Trinitroanisole by Alkalis and Water. WALTER E. MASLAND and FIN SPARRE (*Eighth Inter. Cong App. Chem.*, 1912, **4**, 77) —Pure trinitroanisole is hydrolysed fairly rapidly by hot solutions of the alkali carbonates and slowly by hot water ; the action of each of these in the cold is much more feeble. Picric acid is produced in each case. D. F. T.

Action of Nitric Acid on Halogen Derivatives of *o* Alkyl-phenols. II Nitric Acid Derivatives of 3 : 4 : 5- and 3 : 5 : 6-Tribromo-*o*-cresols. THEODOR ZINCKE and NELSON W. JANNEY (*Annalen*, 1913, **398**, 343—353).—3 : 4 : 5- and 3 : 5 : 6-Tribromo-*o*-cresols react with nitric acid in the sense of the equation : $C_7H_5OBr_3 + 2HNO_3 = C_7H_5O_6N_2Br_3 + H_2O$, but the two products exhibit quite different behaviour. 3 : 4 : 5-Tribromo-*o*-cresol and nitric acid, D 1·48, yield by keeping 3 : 4 : 5 *tribromo*-o *cresol nitroquinitrol*,

$$NO_2 \cdot O \cdot C(OH) \underset{OBr(NO_2) \cdot CBr}{\overset{OMe \underline{\qquad} CH}{<}} > CBr,$$
m. p. 126° (decomp.), colourless needles, which is not reconverted into the tribromo-*o*-cresol by reduction, yields tribromo-*p*-toluquinone by warming with concentrated sulphuric acid, and by boiling with

toluene, glacial acetic acid, or tetrachloroethane is converted by loss of nitrosyl bromide into 4 : 5-*dibromo-o-toluquinone* 2-*nitrate*,

$$NO_2 \cdot O \cdot C(OH) < ^{CMe:CH}_{CO-CBr} > CBr,$$
m. p. 173° (decomp.), pale yellow prisms. The latter is stable, dissolves in alkalis, and is reduced by stannous chloride, hydrochloric acid, and a little alcohol, to 4 : 5-*dibromo*-2 : 3-*dihydroxytoluene*, m. p. 104°, colourless needles, which forms a *diacetyl* derivative, m. p. 137—138°, and is oxidised by nitric acid, D 1·15, to 4 : 5-*dibromo-o-toluquinone*, $C_7H_4O_2Br_2$, m. p. 96—98°, dark red, crystalline powder.

3 : 5 : 6-Tribromo-*o*-cresol and nitric acid, D 1·48, at 0° yield 3 : 5 : 6-*tribromo-o-cresolnitroquinitrol*, $NO_2 \cdot O \cdot C(OH) < ^{CBr=CH}_{CMe(NO_2) \cdot CBr} > CBr,$
m. p. 96° (decomp.), faintly yellow leaflets or needles, which regenerates the tribromo-*o*-cresol by reduction with stannous chloride solution after being initially heated with glacial acetic acid for a short time.   C. S.

Bromo-derivatives of *o*-Cresol. NELSON W. JANNEY (*Annalen*, 1913, **398**, 354—372).—The author describes the preparation of some of the unknown brominated *o* cresols; usually the constitutions are determined by converting the substance ultimately into a quinone of the ortho- or of the para series.

4-*Bromo-o-cresol*, m. p. 80°, broad needles, prepared from diazotised 4-bromo-*o*-toluidine in the usual manner, forms a *benzoate*, m. p. 41°, and is converted by nitric acid, D 1·4, in glacial acetic acid into a *nitro-* and a *dinitro*-derivative, the latter, m. p. 169°, crystallising in yellow prisms.

3 : 4-*Dibromo-o-cresol*, m. p. 94—95°, colourless needles, is obtained by brominating 4-bromo-*o*-cresol in chloroform in the presence of a little iron. It forms an *acetate*, m. p. 49°, is converted by nitric acid, D 1·52, in glacial acetic acid into the preceding bromo-dinitro-*o*-cresol, and yields 3 : 4-dibromo-5-nitro *o*-cresol (see below) by treating its solution in glacial acetic acid with powdered sodium nitrite. 3 : 6-*Dibromo-o-cresol*, m. p. 38° (*benzoate*, m. p. 104°, white needles), is prepared in a similar manner from 6-bromo-*o*-cresol. Its constitution follows from the fact that it yields only oily products by treatment with sodium nitrite and acetic acid; were it 5 : 6-dibromo-*o*-cresol, it must have yielded 5 : 6-dibromo-3-nitro-*o*-cresol identical with that obtained from 3 : 5 : 6-tribromo-*o*-cresol (see below).

3 : 5-Dibromo-*o*-cresol is already known. By treatment with sodium nitrite and acetic acid at 12—15°, it is converted into 5-bromo-3-nitro-*o*-cresol, by the reduction of which 5-bromo-3-amino-*o*-cresol (*diacetyl* derivative, m. p. 203°) is obtained. The hydrochloride of the last substance, dissolved in glacial acetic and concentrated hydrochloric acids, is converted by moist chlorine into the *diketo-chloride*, $CClBr < ^{CCl:CMe}_{CCl_2-CO} > CO$, m. p. 80°, stout, yellow prisms, by the reduction of which by stannous chloride 4 : 6-*dichloro-5-bromo*-2 : 3-*dihydroxytoluene*, m. p. 186°, colourless needles (*diacetate*, m. p. 176—177°), is obtained. By oxidation with nitric acid, D 1·4, the last compound is

converted into 4 : 6-*dichloro*-5-*bromo*-o-*toluquinone*, m. p. 121—122°, red, crystalline powder.

By treatment with nitric acid, D 1·4, and glacial acetic acid, 3 : 5-dibromo-o cresol yields Auwers' 3-bromo-5-nitro-o-cresol, and finally 3 : 5-dinitro-o-cresol. By reduction with alcohol and stannous chloride, the former is converted into 3-*bromo*-5-*amino*-o-*cresol*, m. p. 146°, stout prisms (*acetyl* derivative, m. p. 152°; *diacetyl* derivative, m. p. 167°), from the *hydrochloride* of which 3-bromo-p-toluquinone is obtained by oxidation with potassium dichromate and dilute sulphuric acid.

3 : 4 : 5-Tribromo-o-cresol, m. p. 89° (not 79°, as stated in the literature), which is only occasionally obtained pure by the bromination of o-cresol, is prepared in 90—95% yield by the action of bromine and iron on 4-bromo-o-cresol in cold chloroform. It is most conveniently obtained by treating a solution of 3 : 5-dibromo-o-cresol in glacial acetic acid with 10% calcium hypobromite, and warming the resulting *keto-bromide*. $C_7H_6OBr_2$, m. p. 110° (decomp.), yellow prisms, with concentrated sulphuric acid. The action of sodium nitrite and glacial acetic acid on 3 : 4 : 5-tribromo-o-cresol yields Zincke and Hedenström's 3 : 4-dibromo-5-nitro-o-cresol, which by successive reduction, conversion into the diketo-chloride, and reduction is converted into 3 : 6-*dichloro*-4-*bromo*-p-*toluquinol*,

$$\text{OH·C} \underset{\text{CCl·CBr}}{\overset{\text{CMe:CCl}}{<}} \!\!\!\!> \text{C·OH,}$$
m. p. 200—201°, white prisms or needles (*diacetate*, m. p. 226—227°). By oxidation with nitric acid, the quinol is converted into 3 : 6-*dichloro*-4-*bromo*-p-*toluquinone*, m. p. 233°, yellow, hexagonal leaflets. The production of a para-quinone proves the constitution of 3 : 4 : 5-tribromo-o-cresol and also of 3 : 4-dibromo-o-cresol.

3 : 5 : 6-*Tribromo*-o-*cresol*, m. p. 91°, prismatic needles (*acetate*, m. p. 76—77°), is prepared from 6-bromo-o-cresol in a similar manner as 3 : 4 - 5-tribromo-o-cresol from 4-bromo-o-cresol. By treatment with sodium nitrite and glacial acetic acid at 12—15°, it yields 5 : 6-*dibromo*-3-*nitro*-o-*cresol*, m. p. 100°, pale yellow needles (*acetate*, m. p. 74°), from which 4 : 6-dichloro-5-bromo-2 : 3-dihydroxytoluene and 4 : 6-dichloro-5-bromo-o-toluquinone, identical with the corresponding substances obtained from 3 : 5-dibromo-o-cresol, are obtained by reduction and treatment of the keto-chloride in the usual manner.　C. S.

[1-Methyl*cyclo*pentane-1-carboxylic Acid.] I. PETROV (*J. Russ. Phys. Chem. Soc.*, 1913, 45, 644).—For this acid the author finds the constants, b. p. 216—217°, D_0^0 1·0386 (compare Tschitschibabin, this vol., i, 467).　T. H. P.

Four Different Anhydrides of Dibenzylacetic Acid. The Catalytic Action of Metaphosphoric Acid on Acid Chlorides. HERMANN LEUCHS, JOHANNES WUTKE, and ERICH GIESELER (*Ber.*, 1913, 46, 2200—2215).—According to Staudinger and Ott (A., 1908, i, 602) the action of thionyl chloride on malonic acids results primarily in the formation of the semi-chlorides which may subsequently part with carbon dioxide to give the acetyl chlorides, or lose hydrogen chloride

to form malonic anhydrides and finally ketens, as in the following case :

$$CHMe_2 \cdot COCl \longleftarrow CMe_2 \!\!<^{COCl}_{CO_2H} \longrightarrow CMe_2 \!\!<^{CO}_{CO}\!\!>O \longrightarrow CMe_2 \!\!:\!\! CO.$$
In the case of dibenzylmalonic acid, the chief product is dibenzylacetyl chloride, but a by-product is also formed which is a simple polymeride of dibenzylketen and is shown to be tetrabenzyl*cyclo*butan-1 : 3-dione,

$$C(CH_2Pn)_2 \!\!<^{CO}_{CO}\!\!> C(CH_2Ph)_2$$ That its formation is due to the inter-

vention of dibenzylketen is assumed from the fact that the substance could not be obtained from dibenzylacetic acid or dibenzylacetyl chloride.

In order to moderate the action of thionyl chloride, with the hope of obtaining the semi-chloride of dibenzylmalonic acid, the reagent was diluted with ether, but it was found that the action was too moderate, the product being the ordinary anhydride of dibenzylacetic acid, $[CH(CH_2Ph)_2 \cdot CO]_2O$.

Attempts were made to prepare the *cyclo*butane derivative from dibenzylacetyl chloride. When this substance was heated at 250°, it gradually parted with hydrogen chloride, but the product was a third anhydride, m. p. 145°. In some experiments on the preparation of the chloride, it was found that, unless an excess of phosphorus penta-chloride was employed, the metaphosphoric acid, or some similar product from the phosphoryl chloride, exerted a catalytic influence on the elimination of hydrogen chloride, so that, on distillation in a vacuum, very little acid chloride was obtained, the chief product being a fourth, oily anhydride. This recalls the formation of bis-α-hydrin-done (2 : 2)-spiran by the action of phosphorus pentachloride on dibenzylmalonic acid (A., 1912, i, 179), in which case it is now found that the yield can be improved by the above process. Since the oil forms a hydrazone and is similar in deportment to methyl-, ethyl- and phenyl-α-hydrindones, it is 2-benzyl-1-hydrindone,

$$C_6H_4 \!\!<^{CH_2}_{CO}\!\!> CH \cdot CH_2Ph.$$
The solid anhydride, m. p. 145°, is bimolecular, does not yield a hydrazone, forms dibenzylacetic acid and 2-benzylhydrindone on hydrolysis with alcoholic potassium hydroxide, and dibenzylacetyl chloride and 2-chloro-2-benzyl-1-hydrindone under the influence of phosphorus pentachloride. It is therefore the *O*-dibenzylacetyl derivative of 1-hydroxy-2-benzylidene, the enolic form of 2-benzylhydrindone,

$$C_6H_4 \!\!<^{CH_2 \cdot C \cdot CH_2Pu}_{C \cdot O \cdot CO \cdot CH(CH_2Ph)_2} \!\!.$$
Dibenzylmalonic acid was boiled with thionyl chloride, and, after distilling off the dibenzylacetyl chloride at 203—204°/15 mm., the residue was extracted with light petroleum, leaving a 10% yield of *tetrabenzyl*cyclo*butan-1 : 3-dione*, $C_{32}H_{28}O_2$, which crystallised from benzene in colourless, light needles, m. p. 249—251°, and sublimed at 220—230°/18 mm. When hydrolysed by alcoholic sodium hydroxide, it gave s-*tetrabenzylacetone*, $CO[CH(CH_2Ph)_2]_2$, in the form of well-defined prisms, m. p. 124·5—125·5° (compare tetraphenylacetone,

Staudinger, A., 1911, i, 306). The ordinary *dibenzylacetic anhydride*, $C_{32}H_{30}O_3$, crystallised from alcohol in prisms, m. p. 75—76°, and formed dibenzylacetamide and ammonium dibenzylacetate when treated with ammonia in ether.

Dibenzylacetyl chloride, $C_{16}H_{15}OCl$, was prepared by the action of thionyl chloride on dibenzylacetic acid. The residue after distillation contained a little of the true anhydride, m p. 75—76°, but no *cyclo*butane derivative. The chloride is a viscous, almost colourless oil, b. p. 150°/0·25 mm., and the pale yellow, crystalline mass described by Schneidewind (A., 1888, 704), was probably not dibenzylacetyl chloride. After heating the oil for an hour at 245—255° in a low vacuum, and subsequently distilling off the unchanged chloride in a high vacuum, the residue was extracted with chloroform, precipitated by petroleum, and the 1-*dibenzylacetoxy-2-benzylindene*, $C_{32}H_{28}O_2$, was recrystallised from benzene in the form of shining, four or six-sided leaflets, m. p. 144—145°. On oxidation it yielded benzoic and phthalic acids and benzaldehyde, and on treatment with phosphorus pentachloride in chloroform suspension, it gave dibenzylacetyl chloride and

2-*chloro-2-benzylhydrindone*, $C_6H_4<^{CH_2\cdot CCl\cdot CH_2Ph}_{CO}$. The latter is insoluble in cold petroleum, forms long, colourless, glistening leaflets, m. p. 74—75°, and may be prepared by passing chlorine into a chloroform solution of 2-benzylhydrindone.

When dibenzylacetic acid is treated with a slight excess of phosphorus pentachloride, the chief product is the acid chloride, but when an insufficient amount of the reagent is employed and the product is evacuated at 200—250°, hydrogen chloride is eliminated and 2-*benzylhydrindone* distils over, mixed with a little unchanged acid. The distillate is added to an ethereal solution of ammonia, filtered, and re-distilled, giving a yellow, viscous, almost odourless oil, b. p. 223·5—224·5° (corr.)/20 mm. Phosphorus pentachloride converts it into 1-*chloro-2-benzylindene*, $C_6H_4<^{CH_2}_{CCl}>C\cdot CH_2Ph$, which crystallises in massive prisms, m. p. 64—65°, b. p. 206°(corr.)/13 mm., and yields benzaldehyde and benzoic and phthalic acids on oxidation. Its *dibromide*, $C_{16}H_{13}ClBr_2$, forms massive, sparkling, six-sided plates, m. p. 97—98°, which are hydrolysed in aqueous alcohol to 2-*bromo-2-benzylhydrindone*, $C_{16}H_{13}OBr$. The latter is best obtained by the action of bromine on β-benzylhydrindone, and forms colourless, sparkling, six-sided leaflets or prisms, m. p. 80—81°.

The *phenylhydrazone* of 2-benzylhydrindone, $C_{22}H_{20}N_2$, crystallises in light yellow, four-sided tablets, and, like the hydrazone of hydrindone itself (Kipping, T., 1894, **65**, 493), it has not a constant m. p. When the ketone is heated to 130° with an excess of phenylhydrazine, however, a *product*, $C_{28}H_{25}N_3$, is obtained in short, colourless prisms or tablets, m. p. 190—192°. J. C. W.

[Polymerisation.] CARL LIEBERMANN (*Ber.*, 1913, **46**, 2084—2086). —Polemical. A reply to Kronstein (this vol., i, 725).

D. F. T.

Some Derivatives of Diphenyleneacetic [Fluorene-9-carboxylic] Acid and Bisdiphenylenesuccinic [9 : 9'-Difluoryl-9 : 9'-dicarboxylic] Acid. ROBERT STOLLÉ and F. WOLF (*Ber.*, 1913, **46**, 2248—2252).—The action of thionyl chloride on fluorene-9-carboxylic acid leads to the formation of fluorene-9-carboxyl chloride, 9-chlorofluorene-9-carboxyl chloride, and 9 : 9'-difluoryl-9 : 9'-dicarboxyl chloride, according to the condition under which the action is carried out.

When heated for one to two hours with thionyl chloride in carbon tetrachloride solution, fluorene-9-carboxylic acid yields the corresponding chloride, which has m. p. 77° and reacts with ammonia and aniline yielding the amide, m. p. 251°, and anilide (compare Vorländer and Pritzsche, this vol., i, 724, and Staudinger, A., 1906, i, 861).
9 : 9'-*Difluoryl*-9 : 9'-*dicarboxyl chloride*,
$$C_{12}H_8{:}C(COCl){\cdot}C(COCl){:}C_{12}H_8,$$
obtained together with fluorene-9-carboxyl chloride by heating fluorene-9-carboxylic acid for several hours with thionyl chloride, forms colourless crystals, m. p. 213° (decomp.), and decomposes into bisdiphenylene-ethane (9 : 9'-difluoryl ; Graebe and Mantz, A., 1896, i, 442) when heated with concentrated hydrochloric acid. It is also produced by passing chlorine into a boiling solution of fluorene-9-carboxyl chloride in carbon tetrachloride. It reacts with sodium methoxide and sodium ethoxide, yielding the methyl ester, m. p. 237° (Kolvenbach, *Diss.*, Königsberg, 1897), and ethyl ester respectively (compare Staudinger, A., 1906, i, 825) ; the *anilide* forms a colourless powder, m. p. 250°.

If the action of thionyl chloride on fluorene-9-carboxylic acid or its chloride is continued for 200 hours, 9-chlorofluorene-9-carboxyl chloride (Klinger, A., 1912, i, 558) is produced.

Prolonged heating leads to the decomposition of thionyl chloride into chlorine and sulphur monochloride : $4SOCl_2 = 2SO_2 + 3Cl_2 + S_2Cl_2$. It is possible that the chlorinating action of thionyl chloride mentioned above is to be referred to this decomposition, but whether the formation of 9 : 9'-difluoryl-9 : 9'-dicarboxyl chloride is due to the direct oxidation of fluorene-9-carboxyl chloride, or to the interaction of the latter compound with 9-chlorofluorene-9-carboxyl chloride, has not yet been determined.   F. B.

New Method for the Ketonic Decomposition of β-Ketonic Esters. HANS MEERWEIN (*Annalen*, 1913, **398**, 242—250).—When heated at 200° with 0·5—1 volume of water, esters of β-ketonic acids undergo the ketonic decomposition quantitatively or nearly so. That the change is not due to an ordinary hydrolysis of the ester and subsequent elimination of carbon dioxide is proved by the fact that only those β-ketonic esters which are capable of enolising undergo the change. It is very probable that the enolic modification is the form which is concerned in the decomposition, since the facility with which the ketone is produced runs pari passu with the tendency of the β-ketonic ester to enolise ; thus, strongly acidic, cyclic β-ketonic esters such as ethyl succinosuccinate are decomposed most readily, then follow acyclic, non-alkylated esters such as ethyl acetoacetate and benzoyl-

acetate, and finally alkylated esters such as ethyl benzyl-, methyl-, or ethyl-acetoacetate, in the last case a temperatuie ot 250° being roquisite.

The author is of opinion that the course of the decomposition is represented by the scheme

$$R\cdot CO\cdot CH_2\cdot CO_2R' \rightarrow R\cdot CO\cdot CH\!:\!C(OH)\cdot OR' \xrightarrow{H_2O} R\cdot CO\cdot CH_3 + CO_2 + R'\cdot OH.$$
In support of this opinion are the facts that ethyl benzylmalonate is converted into ethyl β-phenylpropionate, and ethyl αγ-dicarb-ethoxyglutaconate into ethyl glutaconate, by water at 250° and 200° respectively.

The following changes are described : methyl 1-phenyl*cyclo*hexan-3-one-4 carboxylateacetate into methyl 1-phenyl*cyclo*hexan-3-one-5-acetate (A., 1908, i, 545), methyl *cyclo*pentanone-2-carboxylate into *cyclo*pentanone, ethyl succinosuccinate into *cyclo*hexan-1 : 4-dione, methyl benzoylacetate into acetophenone, ethyl acetoacetate into acetone, ethyl benzylacetoacetate into methyl β-phenylethyl ketone, ethyl methylacetoacetate into methyl ethyl ketone, and ethyl ethylacetoacetate into methyl propyl ketone. C. S.

Action of Hydroxylamine on Ketones of the Type R·CH:CH·CH:CH·CO·R. V.

RICCARDO CIUSA and G. B. BERNARDIS (*Atti R. Accad. Lincei,* 1913, [v], **22**, i, 708—711. Compare A., 1910, i, 684).—The substance $C_{26}H_{34}O_9N_4$, m. p. 213°, mentioned in the paper cited, contains one molecule of alcohol of crystallisation ; it does not react with bromine or with benzaldehyde, and it dissolves in alkalis. It is therefore composed of two molecules of the hydroxyl-amineoxime of cinnamylidenepyruvic acid united so as to saturate reciprocally their double linkings. The substance gives an insoluble, green copper salt, and a cherry-red coloration with iron salts ; in other respects it does not behave like an hydroxamic acid, and is to be regarded as an α-oximino-acid. The compound immediately yields a *sodium* salt, $C_{24}H_{26}O_8N_4Na_2$, when treated with sodium carbonate, and this salt yields with acids a *substance*, $C_{24}H_{28}O_8N_4$, m. p. 205° ; this compound has similar properties to the original one, but does not unite with alcohol. When the substance $C_{24}H_{28}O_8N_4$,EtOH, is boiled with dilute sulphuric acid, the *ethyl* ester, m. p. 207°, is obtained in small quantity.

When the action between hydroxylamine hydrochloride and ethyl cinnamylidenepyruvate is effected in the presence of sodium acetate, there is produced, in addition to the substance $C_{24}H_{28}O_8N_4$,EtOH, a sparingly soluble *sodium* salt, $C_{26}H_{31}O_8N_4Na$, which, on treatment with dilute sulphuric acid, furnishes an *isomeride* of the above-mentioned ethyl ester, m. p. 207°. This isomeride has m. p. 198°, and its properties resemble those of the compound of m. p. 207°.

From the mother liquors of the above reaction, the *oxime* of ethyl cinnamylidenepyruvate, $C_{14}H_{15}O_3N$, m. p. 181°, can be obtained. This substance is the sole product of the reaction when no sodium acetate is added.

When the sodium salt of the oxime of cinnamylidenepyruvic acid

(*loc. cit.*) is treated with dilute sulphuric acid, the corresponding *cinnamylidene-α-oximinopropionic acid* is produced; it crystallises with $\frac{1}{2}H_2O$, gives a green copper salt, and a cherry-red coloration with ferric salts. The above-mentioned sodium salt also yields the ethyl ester, m. p. 181°, already described.   R. V. S.

o-Thiolcinnamic Acid. Ch. CHMELEWSKI and PAUL FRIEDLÄNDER (*Ber.*, 1913, **46**, 1903—1908).—The above substance was prepared in order to examine its tendency to the formation of an anhydride analogous to coumarin; earlier experimental results appear to indicate that unsaturated ring systems of five carbon atoms and one sulphur atom are less easily produced, and are less stable than those corresponding with thiophen, but thiolcinnamic acid closely resembles coumaric acid in its behaviour towards dehydration.

o-Thiolcinnamic acid, $SH \cdot C_6H_4 \cdot CH:CH \cdot CO_2H$, was obtained from *o*-aminocinnamic acid by converting it into the corresponding *thiocyano*-compound, $CNS \cdot C_6H_4 \cdot CH:CH \cdot CO_2H$, needles, m. p. 175°, and then evaporating to dryness its solution in sodium hydroxide, together with sodium sulphide solution. The substance can be obtained more conveniently by introducing the solution of the diazocinnamic acid into a warm concentrated solution of sodium disulphide, and reducing the resultant *dithiocinnamic acid*, $(CO_2H \cdot CH:CH \cdot C_6H_4)_2S_2$, yellow needles, m. p. 221°, to the thiol acid by the action of zinc dust and sodium hydroxide solution. It was also prepared, through the diazo-compound, from the *xanthate*, $CO_2H \cdot CH:CH \cdot C_6H_4 \cdot S \cdot CS \cdot OEt$. *o*-Thiol-cinnamic acid, colourless needles, undergoes partial dehydration and oxidation on heating, consequently its m. p., 165°, is not sharp; its *methyl* ester forms tablets, m. p. 114°. o-*Methylthiolcinnamic acid*, $SMe \cdot C_6H_4 \cdot CH:CH \cdot CO_2H$, leaflets, m. p. 176°, obtained by the action of methyl sulphate on an alkaline solution, is more stable than the thiol acid. When heated above its m. p., or, much better, by boiling with acetic anhydride and subsequently distilling in a vacuum, *o*-thiol-cinnamic acid is dehydrated to *thiocoumarin* [1 : 2-*benzthiopyrone*],

$$C_6H_4 {\scriptstyle\diagup}^{\displaystyle CH:CH}_{\displaystyle S \!=\! CO},$$
colourless needles, m. p. 80—80·5°, which is volatile with steam, and has an odour surprisingly like that of coumarin itself. It is insoluble in cold solutions of alkali, but dissolves in warm sodium hydroxide, and can be precipitated unaltered by mineral acids. As the acid undergoes isomeric change more readily than the corresponding coumaric acid, the warming with alkali must not be prolonged, otherwise *thiocoumarinic acid* is produced, of which the derived *methylthiol-coumarinic acid* has m. p. about 136°.

In behaviour towards oxidation, *o*-thiolcinnamic acid differs markedly from *o*-coumaric acid. Although frequently oxidation yields the corresponding dithio-acid, oxidation by ferric salts in neutral solution or, better, by potassium ferricyanide in alkaline solution causes elimination of hydrogen and of carbon dioxide with separation of thionaphthen, $C_6H_4 {\scriptstyle\diagup}^{\displaystyle CH}_{\displaystyle S}{\scriptstyle\diagdown} CH$.

Reduction of *o*-thiolcinnamic acid in alkaline solution by sod·um amalgam produces *o-thiolphenylpropionic acid*,

$$SH \cdot C_6H_4 \cdot CH_2 \cdot CH_2 \cdot CO_2H,$$
colourless needles, m. p. 118°, which above their m. p., or when heated with diluted sulphuric acid, undergo dehydration to *thiohydro-coumarin* [*dihydro*-1 : 2-*benzthiopyrone*], $C_6H_4 \underset{S}{\overset{CH_2 \cdot CH_2}{<}}_{CO}$, an oil of pleasant odour.   D. F. T.

Preparation of Tyrosine. ELI K. MARSHALL, jun. (*J. Biol. Chem.*, 1913, **15**, 85—86).—The usual method of preparing tyrosine from silk is laborious and expensive. The method recommended is to obtain it from a pancreatic digest of caseinogen. The fluid on cooling deposits an abundant crystalline yield of tyrosine.   W. D. H.

Action of Nitric Acid on Heptachloro-*o*-quinocatechol Hemiether. C. LORING JACKSON and GEORGE L. KELLEY (*Amer. Chem. J.*, 1913, **49**, 435—473).—When heptachloro-*o*-quinocatechol hemiether, $OH \cdot C_6H_4 \cdot O \cdot C_6Cl_3O_2$ (Jackson and Carleton, A., 1908, i, 428), is warmed with glacial acetic acid and a little fuming nitric acid, the product sometimes yields a compound, m. p. 159—165° (decomp.), and sometimes a compound, m. p. 176—198° (decomp.); in each case the m. p. depends on the rate of heating.

The former compound, m. p. 159—165°, is probably the *tetrachloro-catechol hemiether* of *dichloronitrohydroxycyclopentadienecarboxylic acid*, $OH \cdot C_6Cl_4 \cdot O \cdot C_5Cl_2(OH)(NO_2) \cdot CO_2H$; it forms white or cream-coloured crystals.

The compound, m. p. 176—198°, is regarded as the *tetrachloro-catechol hemiether* of 2 : 4 : 5-*trichloro*-2-*nitro*-1 : 3-*dihydroxycyclopentene*-1-*carboxylic acid*, $OH \cdot C_6Cl_4 \cdot O \cdot C(OH) \underset{CCl}{\overset{CCl(NO_2) \cdot C(OH) \cdot CO_2H}{<}}_{CCl}$; it crystallises in nearly white needles, and is decomposed by boiling water with formation of tetrachlorocatechol, carbon dioxide, an oxide of nitrogen, and a tarry residue. The *methyl* ester, m. p. 221° (decomp.), forms clusters of creamy-white needles. On treating the compound (m. p. 176—198°) with methyl alcohol and sulphuric acid, it is converted into the *tetrachlorocatechol hemiether* of *methyl* 2 : 4 : 5-*trichloro*-2-*nitrocyclopentene*-1 : 3-*oxide*-1-*carboxylate*,

$$OH \cdot C_6Cl_4 \cdot O \cdot C \overset{CCl(NO_2)}{\underset{CCl=CCl}{<}}\!\!-O-\!\!>C \cdot CO_2Me,$$
m. p. 221—228° (decomp.), which crystallises in rhombic plates or needles; its *acetyl* derivative, m. p. 189° (decomp.), forms white, rhombic prisms.

When the compound (m. p. 176—198°) is heated with acetic anhydride or acetyl chloride, it yields the *acetyl* derivative of the *tetra-chlorocatechol hemiether* of 2 : 4 : 5-*trichlorocyclopentadien*-1-*one*,

$$OAc \cdot C_6Cl_4O \cdot C \overset{CCl \cdot CO}{\underset{CCl:CCl}{<}},$$
m. p. 165—168°, which crystallises in white, lustrous, rhombic plates;

on evaporating the mother liquor from this reaction, a viscous residue is obtained which when dissolved in benzene and treated with pyridine furnishes the *tetrachlorocatechol ether* of 2 : 5-*dichloro* 1 : 1-*diacetoxy-cyclopentadiene*, $C_6Cl_4O_2 \cdot C_5Cl_2(OAc)_2$, m. p. 188°, which forms white prisms or needles. The *tetrachlorocatechol hemiether* of 2 : 4 : 5-*tri-chlorocyclopentadien-1-one*, $OH \cdot C_6Cl_4O \cdot C {\displaystyle <^{CCl \cdot CO}_{CCl \colon CCl'}}$ m. p. 182—188° (decomp.), obtained by hydrolysing the acetyl derivative, crystallises in clusters of white needles. When a benzene solution of this compound or its acetyl derivative is treated with pyridine, the *tetrachlorocatechol ether* of *dichlorocyclopentadienone*,

$$C_6Cl_4 {\displaystyle <^{O \cdot C \colon CCl}_{O \cdot C \colon CCl}} > CO,$$
m. p. 264—272° (decomp.), is obtained, which forms thin, bright red, hexagonal plates and is converted by sodium methoxide into the *tetrachlorocatechol hemiether* of *dichloro-1-hydroxy-*1 : 4-*dimethoxycyclo-pentadiene*, $OH \cdot C_6Cl_4 \cdot O \cdot C_5Cl_2(OMe)_2 \cdot OH$, m. p. 175—180° (decomp.), which crystallises in white cubes ; the corresponding *diethoxy*-compound has m. p. 93°.

By the action of benzoyl chloride on the compound, melting at 176—198°, the *benzoyl* derivative of the tetrachlorocatechol hemi-ether of 2 : 4 : 5-trichloro*cyclo*pentadien-1-one,

$$OBz \cdot C_6Cl_4O \cdot C {\displaystyle <^{CCl \cdot CO}_{CCl \colon CCl'}}$$
m. p. 172°, is obtained, which forms white, lustrous scales.

When a solution of hexachloromethoxy-*o*-quinocatechol hemiether, $OH \cdot C_6Cl_4 \cdot O \cdot C_6Cl_2O_2 \cdot OMe$ (Jackson and Kelley, A., 1912, i, 275), in glacial acetic acid is warmed with fuming nitric acid, it is converted into a substance, m. p. 202—208° (decomp.), which is probably the *tetrachlorocatechol hemiether* of *dichloronitrodihydroxymethoxycyclo-pentenecarboxylic acid*, $OH \cdot C_6Cl_4 \cdot O \cdot C_5Cl_2(NO_2)(OH)_2(OMe) \cdot CO_2H$; it forms white crystals, and yields an *acetyl* derivative, m. p. 146° (decomp.).

By the action of glacial acetic acid and fuming nitric acid on hexachloroethoxy-*o*-quinocatechol hemiether (Jackson and Kelley, *loc. cit.*), a compound, m. p. 210—215° (decomp.), is produced, which crystallises in rhombic plates or prisms, and is provisionally regarded as the *nitric acid* compound of the *tetrachlorocatechol hemiether* of *dichloro-ethoxy-o-quinone*, $OH \cdot C_6Cl_4 \cdot O \cdot C_6Cl_2O_2 \cdot OEt, HNO_3$. Another substance, m. p. 130—158° (decomp.), was also obtained in this reaction, which seems to be the corresponding compound containing $2HNO_3$.

E. G.

Quinonecarboxylic Esters. KARL BRUNNER (*Monatsh.*, 1913, 34, 913—930).—Although esters of substituted *p*-benzoquinone-carboxylic acids are known, previous attempts (von Rakowski and Leppert, A., 1875, 1197 ; Brunner, *Monatsh.*, 1881, 2, 464 ; Nef, A., 1887, 255 ; Juch, A., 1905, i, 701) to prepare *p*-benzoquinone-carboxylic acid have been unsuccessful. Since this failure was possibly attributable to the employment of aqueous solutions, the

author has been led to study the oxidation of methyl gentisate in the absence of water and has thus prepared *methyl* p-*benzoquinonecarboxylate* and a number of its derivatives.

When a solution of methyl gentisate in benzene is shaken with a mixture of silver oxide and potassium carbonate for five minutes at 40—50°, methyl p-benzoquinonecarboxylate, yellowish-red crystals, m. p. 53·5—54°, is obtained. The dry substance may be preserved unchanged for months in the dark. It is rapidly decomposed when warmed with water. When mixed in warm ethereal solution with an equimolecular quantity of methyl gentisate, it is converted into *methyl quinhydronecarboxylate*, dark red crystals with metallic glance, m. p. 85—86° which, when warmed with sulphurous acid and water, is transformed into methyl gentisate, m. p. 87°. When mixed with aniline in ethereal solution, methyl p-benzoquinonecarboxylate yields *methyl dianilino-p-benzoquinonecarboxylate*, $C_8H_4O_4(NHPh)_2$, deep red, silky needles, m. p. 202—203°.

Methyl cyanoquinolcarboxylate, $C_9H_7O_4N$, is formed when an aqueous solution of sodium cyanide is added to a cold acidified alcoholic solution of methyl p-benzoquinonecarboxylate. It has m. p. 225—226°, and dissolves sparingly in ether and benzene to yield solutions which have an intense blue fluorescence. Small quantities of a substance, m. p. above 220°, are obtained as a by-product. When treated with potassium hydroxide and acetic anhydride, methyl cyanoquinolcarboxylate yields a *diacetyl* derivative, colourless crystals, m. p. 107·5—108°.

Methyl cyanoquinolcarboxylate is converted by concentrated sulphuric acid at 100° into p-dihydroxyphthalimide, sulphur-yellow needles, m. p. 273—274°. This substance appears to be in all respects identical with that prepared by Thiele and Meisenheimer (A., 1900, i, 299), from dicyanoquinol, except that it gives up its water of crystallisation with greater readiness. This phenomenon apparently depends to some extent, however, on the size of the crystals. The *lead* salt, $C_8H_3O_4NPb,H_2O$, carmine needles, is also described.

When methyl cyanoquinolcarboxylate is successively treated with concentrated aqueous potassium hydroxide and sulphuric acid, p-dihydroxyphthalic acid is obtained in practically white crystals, m. p. 219—220° (decomp.). The air-dried acid appears to be anhydrous. According to Thiele and Günther (A., 1906, i, 744) it has m. p. 213° and contains $\frac{1}{2}H_2O$. The *lead* salt, $C_8H_4O_6Pb,\frac{1}{2}H_2O$, crystallises in leaflets. When sublimed in a vacuum at 230—240°, the acid is converted into p-dihydroxyphthalic anhydride, yellow, hygroscopic needles, m. p. 232—233° (compare Thiele and Günther, *loc. cit*), which yields the corresponding diacetyl derivative, m. p. 156—156·5°. The identity of these products obtained from methyl cyanoquinolcarboxylate with those obtained from dicyanoquinol by Thiele and Günther, leads the author to propose the annexed formula for the product examined by him.
Ethyl p-*benzoquinonecarboxylate* is prepared by a method similar to that adopted for the methyl ester. Its isolation is more difficult, however, since it melts slightly above the ordinary

temperature and readily decomposes when in the liquid state. It forms yellowish-red leaflets, m. p. 22°, which decompose when preserved even at a low temperature. With aniline in ethereal solution, it yields *ethyl dianilino-p-benzoquinonecarboxylate*, dark red, almost black needles, m. p. 178—179°.   H. W.

Action of Bromine on Aliphatic-Aromatic Compounds.
HUGO BAUER and GUSTAV ENDRES (*J. pr. Chem.*, 1913, [ii], **87**, 545—552).—An account of the action of bromine on o- and p-benzylbenzoic acids, phenylphthalide, homophthalic acid, phthalidecarboxylic acid and di-p-nitrodiphenylmethane.

p-Benzylbenzoic acid reacts with bromine in the cold yielding a *tribromo*-derivative, which crystallises in slender scales, m. p. 218—220°. When heated with bromine for three or four hours in a sealed tube at 110—120°, it gives rise to *dibromotetraphenylethylenedi-p-carboxylic acid*, $CO_2H \cdot C_6H_8Br \cdot CPh \cdot CPh \cdot C_6H_8Br \cdot CO_2H$, m. p. 260—262°.

a-Phenylphthalide and bromine at 120° yields the dilactone of dihydroxytetraphenylethanecarboxylic acid (Ullmann, A., 1896, i, 563), which is also obtained from o-benzylbenzoic acid at 110—120°. If the action of bromine on o-benzylbenzoic acid is carried out at the ordinary temperature, the lactone is accompanied by a *bromo-o-benzylbenzoic acid*, m. p. 137°.

Phthalidecarboxylic acid, $CO{<}^{C_6H_4}_{O}{>}CH \cdot CO_2H$, and bromine at 120° yield hydrogen bromide, carbon dioxide, and phthalic anhydride; the same products are also obtained from homophthalic acid, $CO_2H \cdot C_6H_4 \cdot CH_2 \cdot CO_2H$.

From the product of the action of bromine on di-p-nitrodiphenylmethane, only di-p-nitrobenzophenone could be isolated.   F. B.

Hydrogenation of Santonic Acid. A Dihydrosantonin. II.
GUIDO CUSMANO (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 711—714. Compare this vol., i, 730).—The author discusses the question of the constitution of santonin in the light of the results obtained by himself and other recent workers, and points out that the production of a dihydrosantonin cannot be reconciled with the views of Wienhaus and von Oettingen (this vol., i, 474).

Dihydrosantonin, $C_{15}H_{20}O_8$, crystallises in long prisms, m. p. 99° (*loc. cit.*), and has $[a]_D^{18} +75.19°$ in 1·463% alcoholic solution. Its oxime, $C_{15}H_{21}O_8N$, forms tufts of colourless prisms, m. p. about 235°. The semicarbazone crystallises in colourless prisms, m. p. 243°.

R. V. S.

Constitution of Santonin.
ANGELO ANGELI (*Ber.*, 1913, **46**, 2233—2235).—The author points out that Asahina (this vol., i, 731), has overlooked the work of Angeli and Marino (A., 1907, i, 321) on the oxidation of santonin to heptanetetracarboxylic acid, the formation of which led them to the conclusion that santonin contains a bridged ring.   F. B.

The Ethers and Esters of Fluorescein. HANS VON LIEBIG (*J. pr. Chem.*, 1913, [ii], 88, 26—48) —In previous papers (A., 1912, i, 376; this vol., i, 79) the author has described four monomethyl ethers and esters of fluorescein, a strongly yellow form of m. p. 266°, two pale yellow ethers of m. p. 265° (corresponding with Fischer and Hepp's [A., 1895, i, 291] ether of m. p. 262°) and 272°, and also a colourless ether of m. p. 256—257°, obtained by hydrolysing the dimethyl ether of m p. 208° with ethyl alcoholic potassium hydroxide. It is now found that, during the hydrolysis, part of the methyl is replaced by ethyl, so that the colourless ether of m. p. 256—257° really consists of the lactone form of the monoethyl ether,

$$O{<}{}^{C_6H_3(OEt)}_{C_6H_3(OH)}{>}C{<}{}^{O-}_{C_6H_4}{>}CO,$$
which, in a pure condition, crystallises in white prisms, m. p. 253—254°.

If the hydrolysis is carried out with methyl alcoholic potassium hydroxide, the colourless monomethyl ether of m. p. 272° is obtained. This ether represents the lactone form of the monomethyl ether, whilst the yellow ether of m. p. 266° has the quinonoid constitution

$$O{<}{}^{C_6H_3(OMe)}_{C_6H_3O}{>}C{\cdot}C_6H_4{\cdot}CO_2H;$$
the ether of m. p. 265° (or 262°) is either a mixture or, more probably, a polymeric form similar to the quadrimolecular monomethyl ether described previously.

The monomethyl ester, obtained by warming fluorescein with methyl alcohol and sulphuric acid, has m. p. 282—283°, and not 252° as given by Feuerstein and Wallach (A., 1901, i, 723); the corresponding monoethyl ester has m p. 251—252°, and not 242°.

By methylating the monomethyl ester of fluorescein with methyl sulphate, Kehrmann and Dengler (A., 1909, i, 249) obtained a red compound of m. p. 176—177°, which they considered to be the methyl ester of the monomethyl ether of fluorescein The author finds, however, that the product of the action consists of a mixture of the dimethyl ether of m. p. 198° (Kehrmann's 3 : 6-dimethoxyfluorane) and Fischer and Hepp's (*loc. cit.*) coloured dimethyl ether of m. p. 208°.

When the dimethyl ether of m. p. 198° is heated with methyl alcohol and concentrated hydrochloric acid, and the resulting solution diluted with water and saturated with sodium chloride, a *hydrochloride* of the trimethyl ether of fluorescein is obtained which, after precipitation from alcoholic solution by means of ether, has the composition $4C_{23}H_{20}O_6,5HCl,10H_2O$ (compare Kehrmann and Scheunert, A., 1912, i, 1034); the addition of concentrated hydrochloric acid to a warm aqueous solution of this chloride causes the precipitation of a *chloride* of the composition $2C_{22}H_{18}O_5,3HCl,8H_2O$, crystallising in stout, orange prisms having a bluish glance. The *sulphate* of the trimethyl ether of fluorescein is prepared by heating the dimethyl ether of m. p. 198° with methyl alcohol and sulphuric acid; it has m. p. 226°.

That the above salts are derivatives of the trimethyl ether to fluorescein has been established by reducing the sulphate with zinc dust and glacial acetic acid, when the trimethyl ether of fluorescin

was obtained, identical with that previously prepared by the direct methylation of fluorescein with methyl sulphate.

Oxidation of the trimethyl ether of fluorescin by means of lead dioxide in hot glacial acetic acid solution gives rise to the dimethyl ether of fluorescein, having m. p. 198°, and the above-mentioned trimethyl ether of fluorescein, which was isolated in the form of its *nitrate*, $C_{22}H_{16}O_5,HNO_3$, crystallising in light yellow leaflets.

Hydrolysis of the trimethyl ether of fluorescin with alcoholic potassium hydroxide leads to the formation of the *dimethyl ether* of fluorescin, $C_{22}H_{18}O_5$, which crystallises from alcohol in white needles, m. p. 204—205°, and is also obtained, together with the trimethyl ether, by methylating fluorescin with aqueous potassium hydroxide and methyl sulphate.

When oxidised by means of lead dioxide in hot glacial acetic acid solution the dimethyl ether of fluorescin yields the dimethyl ether of fluorescein of m. p. 198°.

The monomethyl ether of fluorescein of m. p. 265° forms a potassium salt, $C_{21}H_{13}O_5K,C_{21}H_{12}O_5K_2,4H_2O$.

When heated with ethyl iodide and alcoholic potassium hydroxide, fluorescein yields a quadrimolecular *monoethyl ether* of the composition $3C_{20}H_{12}O_5,C_{22}H_{16}O_5,H_2O$, m. p. 330—331°, in addition to the diethyl ethers of m. p. 159° and 181°.

When esterified with methyl alcohol and sulphuric acid the mono-methyl ethers of fluorescein of m. p. 265°, 266°, and 272° are converted into the dimethyl ether-ester of m. p. 208°, $OMe·C_{19}H_{10}O_2·CO_2Me$, which crystallises in orange-yellow needles or dark red prisms, and is precipitated in the form of its *sulphate*, $2C_{22}H_{16}O_5,H_2SO_4,H_2O$, dark red, prismatic crystals (decomp. 140°) by the addition of water to the product of the esterification.

If, after esterification, the mixture is treated with aqueous sodium hydroxide and the precipitated ester purified by conversion into the *hydrochloride*, $C_{22}H_{16}O_5,HCl,2H_2O$, a second modification of the dimethyl ether-ester is obtained; this crystallises in yellowish-red prisms, m. p. 198°, and on repeated crystallisation from ethyl acetate is transformed into the dimethyl ether of m. p. 208°.

The *ethyl* ester of the monomethyl ether of fluorescein,

$$OMe·C_{19}H_{10}O_2·CO_2Et,$$

prepared by esterifying the monomethyl ether with ethyl alcohol and sulphuric acid, has m. p. 194—195°, and yields a *hydrochloride*,

$$C_{23}H_{18}O_5,HCl,$$

crystallising in yellowish-red needles; the *methyl* ester of the mono-ethyl ether of fluorescein, $OEt·C_{19}H_{10}O_2·CO_2Me$, obtained in a similar manner, crystallises in yellowish-red prisms or needles, m. p. 216°; the *ethyl* ester of the monoethyl ether forms a *hydrochloride*,

$$OEt·C_{19}H_{10}O_2·CO_2Et,HCl,$$

crystallising in yellowish-red needles.

A solution of the sulphate of the monomethyl ester of fluorescein (m. p. 282—283°) in sodium hydrogen carbonate deposits a *sodium* salt of the composition $C_{21}H_{14}O_5,NaHSO_4$ as a fine red powder.

According to the author (A., 1912, i, 381), the salts of fluorescein and its ethers with acids owe their solubility in water to the rupture

of the oxygen bridge of the pyrone ring and formation of compounds having the structure represented in (I).

(I.)

(II.)

(III.)
If this view is correct the salts of the trimethyl ether of fluorescein should give rise on hydrolysis to the compound (II), which with potassium hydroxide would form a quinonoid having the annexed formula (III), and, from analogy with the quinonoid salts of quinolphthalein and 4:5-dinitrofluorescein (this vol., i, 80; compare also Baeyer, A., 1910, i, 249), this salt should have a blue colour.
Such an o-quinonoid *potassium* salt has been prepared by triturating the trimethyl ether of fluorescein with 33% aqueous potassium hydroxide. It has the composition $C_{22}H_{19}O_6K,H_2O$, and rapidly decomposes when kept, yielding a brown *substance*, which has m. p. about 120°, with previous sintering, and dissolves in methyl and ethyl alcohols, yielding solutions coloured respectively pure green and brownish olive-geeen; from these solutions the addition of alkalis causes the separation of the dimethyl ether of fluorescein.

When freshly prepared and treated with water, the blue potassium salt partly dissolves with the formation of a deep blue solution, from which acetic acid precipitates a *hydrate* of the trimethyl ether-ester of fluorescein, $C_{22}H_{20}O_6,H_2O$, in yellow flocks. This melts and loses water at 173°. It dissolves in alkali hydroxides with a blue colour, and is, therefore, considered to be the parent substance of the blue potassium salt. On treatment with water, the greater part of the blue potassium salt is converted into an insoluble brown *substance*, which crystallises in needles, is insoluble in alkalis, and probably represents the trimethyl ether-ester of fluorescein of the following constitution : $O<^{C_6H_3(OMe)}_{C_6H_3(OMe)}>C(OH)·C_6H_4·CO_2Me$.   F. B.

[Fluorescein.] HANS VON LIEBIG (*J. pr. Chem.*, 1913, [ii], **88**, 96).—A correction. Owing to an error in the thermometer the m. p.'s of a number of ethers and esters of fluorescein recorded in previous papers (A., 1912, i, 376; this vol., i, 79) are too high.

The lactone form of the monomethyl ether has m. p. 266° (not 272°), the quinonoid form 259° (not 266°), and the monomethyl ester m. p. 274—275° (not 282°). The lactone form of the monomethyl ether, previously described as melting at 253—254°, has m. p. 247—248°. The monoethyl ester has m. p. 247°.   F. B.

Fluorescein Methyl Ethers. OTTO FISCHER and EDUARD HEPP (*Ber.*, 1913, **46**, 1951—1959. Compare A., 1895, i, 291).—A reply to

von Liebig (this vol., i, 79) and to Kehrmann and Dengler (A., 1909, i, 249). The divergence of the results of these workers from those previously obtained by the authors is probably to be attributed to impure fluorescein. The fluorescein used by the authors was always previously purified through the diacetyl derivative.

Methylation of purified fluorescein by methyl iodide and alcoholic potassium hydroxide gives as main product the orange-red dimethyl ether, m. p. 208°, together with a little of the colourless lactonic dimethyl derivative, m. p 197—198°, which previously escaped detection. A similar result is obtained by the application of diazomethane in nitrobenzene solution. Fluorescein monomethyl ester, m p. 282°, obtained by the interaction of fluorescein and methyl alcohol in the presence of sulphuric acid or hydrogen chloride, also gives a similar product to the above whether further methylated in methyl alcohol by methyl iodide and potassium hydroxide or in nitrobenzene solution by methyl sulphate. In the latter case no indication whatever of a substance, m. p. 176—177° (Kehrmann and Dengler, *loc. cit*), was observed.

By hydrolysis of fluorescein dimethyl ether, m. p. 208°, with methyl-alcoholic potassium hydroxide, the colourless lactonic fluorescein monomethyl ether, m. p. 265—266°, can be obtained; on methylation of this by methyl sulphate in nitrobenzene solution the chief product is the dimethyl ether, m. p. 197—198°.   D. F. T.

Substituted Crotonolactoneacetic [αγ-Monolactones of γ-Hydroxydihydromuconic] Acids. ERICH BESCHKE [with GEORG KOHRES and F. MARSCHALL] (*Annalen*, 1913, 398, 265—298).—The interaction of phenanthraquinone, ethyl bromoacetate, and zinc in boiling benzene leads to the formation of *γ-hydroxy-βγ-diphenylene-Δ²-dihydromuconic acid αγ-lactone*,
$$\begin{array}{c} C_6H_4\cdot C(CH_2\cdot CO_2H)\cdot O \\ C_6H_4\cdot C\!\!=\!\!=\!\!=\!\!=\!\!CH \end{array}\!\!\!>\!CO, \text{ m. p.}$$
216°, colourless crystals, which exhibits considerable stability towards dilute alkaline potassium permanganate, zinc dust and acetic acid, and bromine. Its *sodium* salt, $C_{18}H_{11}O_4Na$, reacts with aqueous bromine to form, after acidification, *α-bromo-γ-hydroxy-βγ-diphenylene-Δ²-dihydromuconic acid αγ-lactone*, $C_{18}H_{11}O_4Br$, m. p 195°, by the reduction of which by zinc dust and alcohol the original acid is regenerated.

The addition of saturated aqueous sodium hydroxide to a boiling alcohol solution of γ-hydroxy-βγ-diphenylene-Δ²-dihydromuconic acid γ-lactone yields *sodium γ-hydroxy-βγ-diphenylene-Δ²-dihydromuconate*,
$$\begin{array}{c} C_6H_4\cdot C(OH)\cdot CH_2\cdot CO_2Na \\ C_6H_4\cdot C\!\!:\!\!CH\cdot CO_2Na \end{array}$$, an aqueous solution of which is reduced by
3% sodium amalgam to *phenanthrene-9 : 10-diacetic acid*,
$$\begin{array}{c} C_6H_4\cdot C\cdot CH_2\cdot CO_2H \\ C_6H_4\cdot C\cdot CH_2\cdot CO_2H' \end{array}$$
m. p. 305°, colourless crystals. This acid forms an *ethyl* ester, $C_{22}H_{22}O_4$, m. p 94°, and is converted by heating into *2-ketophenanth-hydrindene*,
$$\begin{array}{c} C_6H_4\cdot C\cdot CH_2 \\ C_6H_4\cdot C\cdot CH_2 \end{array}\!\!\!>\!CO, \text{ m. p. 219°,}$$ colourless leaflets (*oxime*, m.p. 258° [decomp.])
γ-Hydroxy-βγ-diphenylene-Δ^α-dihydromuconic acid αγ-lactone forms an *ethyl* ester, $C_{20}H_{16}O_4$, m. p. 104°, from which the acid is regenerated by hydrolysis with acids. However, when a cold alcoholic suspension of the ester is treated with sodium ethoxide and the resulting yellow solution is acidified, *ethyl hydrogen βγ- diphenylenemuconate*,

$$\begin{array}{l} C_6H_4 \cdot C{:}CH \cdot CO_2Et \\ C_6H_4 \cdot C{:}CH \cdot CO_2H \end{array},$$ is obtained as a viscous, yellow mass which by

keeping or warming changes to the *ethyl* ester, m. p. 234°, colourless crystals, of the αδ-*lactone* of δ-hydroxy-βγ-diphenylene-Δ^α-dihydro-

muconic acid, $$\begin{array}{l} C_6H_4 \cdot CH \cdot CH(CO_2Et) \\ C_6H_4 \cdot C{:}CH \longrightarrow CO \end{array}>O,$$ m.p. 280° (decomp.), colourless

crystals. By treating a boiling alcoholic solution of ethyl γ-hydroxy-βγ-diphenylene-Δ^α-dihydromuconic acid αγ-lactone with concentrated aqueous sodium hydroxide, *sodium-βγ diphenylenemuconate*,

$$\begin{array}{l} C_6H_4 \cdot C{:}CH \cdot CO_2Na \\ C_6H_4 \cdot C{:}CH \cdot CO_2Na \end{array},$$
is obtained, from which a yellow acid is obtained by acidification; by recrystallisation the yellow acid, *βγ diphenylenemuconic acid*, is changed into the lactone, m. p. 280° (decomp.), of δ hydroxy-βγ-diphenylene-Δ^α-dihydromuconic acid. An aqueous alkaline solution of βγ-diphenylenemuconic acid is reduced by sodium amalgam to phenanthrene-9 . 10 diacetic acid, from which phenanthraquinone is obtained by oxidation with chromic and acetic acids.

By oxidation with chromic and acetic acids at 75° and finally at 90°, the lactone of δ hydroxy-βγ-diphenylene-Δ^α-dihydromuconic acid is

converted into the *lactone*, $$\begin{array}{l} C_6H_4 \cdot CH \cdot CH_2 \cdot O \\ C_6H_4 \cdot CH \cdot CO - CO \end{array},$$ m. p. 211°, colourless

crystals, which forms a *phenylhydrazone*, $C_{23}H_{18}O_2N_0$, m. p. 234°, faintly yellow leaflets, and o-*aminoanilino* derivative, $C_{23}H_{18}O_2N_2$, m. p. 236°, with o-phenylenediamine, and is oxidised by chromic acid in

boiling glacial acetic acid to the *lactone*, $$\begin{array}{l} C_6H_4 \cdot C \cdot CH_2 \cdot O \\ C_6H_4 \cdot C \cdot CO - CO \end{array},$$ m. p. 302°,

yellow crystals. The latter lactone, which is more conveniently obtained directly by the oxidation of the lactone of δ hydroxy-βγ-diphenylene-Δ^α-dihydromuconic acid, forms a *phenylhydrazone*, m. p. 292°, yellow needles, *anilino*-derivative, $C_{23}H_{15}O_2N$, m. p 263°, yellow needles, o-*aminoanilino*-derivative, m. p. 269° (decomp.), and *phenazine*, $C_{23}H_{14}ON_2$, m. p. 271°, yellowish-red needles.   C. S.

Synthesis of Derivatives of *dicyclo*-[1,3,3]-Nonane. I. Hans Meerwein and Wilhelm Schurmann (*Annalen*, 1913, **398**, 196—242). —Derivatives of *dicyclo*-[1 : 3 : 3]-nonane (annexed formula) have

$$\begin{array}{l} CH_2 \cdot CH - CH_2 \\ CH_2 \quad CH_2 \quad CH_2 \\ CH_2 \cdot CH - CH_2 \end{array}$$

been prepared from formaldehyde and ethyl malonate by a very simple and smooth reaction.

Perkin, in conjunction with Haworth (T., 1898, **73**, 330) and Bottomley (T., 1900, **74**, 294), has shown that formaldehyde and malonic esters condense to form, under different conditions, methylenemalonic esters, methylenebismalonic esters, or pentane-ααγγεε-hexacarboxylic esters. By this

method the authors have prepared *methyl methylenemalonate*,

$$CH_2 : C(CO_2Me)_2,$$

as a mixture, b. p. 150—180°/15 mm., of the uni- and bi-molecular forms (the latter is an amorphous, white powder which is depolymerised by distillation at 200—203°), and also *methyl pentane-aαγγεε-hexa-carboxylate*, $CH(CO_2Me)_2 \cdot CH_2 \cdot C(CO_2Me)_2 \cdot CH_2 \cdot CH(CO_2Me)_2$, m. p. 62—63°, hard, colourless prisms. The latter, which can also be obtained by the interaction of methyl methylenebismalonate and methyl methylenemalonate in alcoholic sodium methoxide at the ordinary temperature, is converted by boiling methyl alcoholic sodium methoxide into methyl carbonate and *methyl* cyclohexan-1-one-2 : 4 : 4 : 6-*tetra-carboxylate*, $CO \overset{CH(CO_2Me) \cdot CH_2}{\underset{CH(CO_2Me) \cdot CH_2}{<}} > C(CO_2Me)_2$, m. p. 121—122°, colour-less, rhombic prisms, methyl *bicyclo* [1,3,3] - nonane-2 : 6-dione-1 : 3 : 5 : 7-tetracarboxylate (see below) being also formed. Methyl *cyclo*hexan-1-one - 2 : 4 : 4 : 6-tetracarboxylate exists as the ketonic modification in the solid state, but is rapidly enolised by alcohol, the solution in this solvent producing a reddish-violet coloration with ferric chloride. By acidifying a solution of the ester in alcoholic sodium methoxide, the enol is precipitated as a viscous oil, the ethereal solution of which deposits almost quantitatively the ketonic modification after a short time. This property of rapidly ketonising is utilised to separate the ester from the accompanying *dicyclo*nonanedionetetra-carboxylate.

By heating with half volume of water at 200° for thirty minutes (compare following extract), methyl *cyclo*hexan-1-one-2 : 4 : 4 : 6-tetra-carboxylate undergoes the ketonic decomposition and yields *methyl* cyclo*hexan-1-one-4 : 4-dicarboxylate*, b. p. 160—161°/14 mm., which has no acid properties, does not give a coloration with ferric chloride, forms a *semicarbazone*, m. p. 190° (decomp.), and *dicinnamylidene* derivative, $C_{28}H_{26}O_5$, m. p. 186°, yellow needles dissolving to a blue solution in concentrated sulphuric acid, and yields Perkin's *cyclo*hexan-1-one-4-carboxylic acid (T., 1904, **85**, 421; 1906, **89**, 1648) by hydrolysis.

All the substances, namely, methyl methylenemalonate and methyl methylenebismalonate, and methyl pentane-aαγγεε-hexacarboxylate, produced by the interaction of formaldehyde and methyl malonate,

$$\begin{array}{c}
CH_2 \cdot C(CO_2Me) \cdot CO \\
CO_2Me \cdot CH \quad CH_2 \\
CO - C(CO_2Me) \cdot CH_2
\end{array}$$

yield more or less *methyl* bicyclo-[1,3,3]-*nonan*-2 :6-*dione*-1 : 3 : 5 : 7-*tetracarboxylate* (annexed formula), m. p. 163—164°, colourless prisms, by boiling with concentrated methyl-alcoholic sodium methoxide, the best yield being obtained by using methyl methylenebismalonate (1 mol.) and methyl methylene-malonate (2 mols.).

The constitution of the *dicyclo*nonane derivative, which can also be prepared by heating methyl malonate (4 mols.) and methylene iodide (3 mols.), or methyl *cyclo*hexan-1-one-2 : 4 : 4 : 6-tetracarboxylate and methyl methylenemalonate, with methyl alcoholic sodium methoxide, is proved, not only by the preceding method of preparation, but also by the following reactions.

Methyl *dicyclo*-[1,3,3]-nonan-2 : 6-dione-1 : 3 : 5 : 7-tetracarboxylate develops a reddish-violet coloration with alcoholic ferric chloride, forms a pale green *copper* derivative and a crystalline *disodium* derivative, $C_{17}H_{18}O_{10}Na_2$, and possesses pronounced acid properties, indicating that the substance is a cyclic

$$CH_2 \cdot C(CO_2Me) \cdot CO$$
$$CH_2 \quad CH_2 \qquad CH_2$$
$$CO-C(CO_2Me) \cdot CH_2$$
β-ketonic ester. By heating with water at 170—180°, it is converted quantitatively into *methyl* dicyclo-[1,3,3]-*nonan*-2 : 6-*dione*-1 : 5-*dicarboxylate* (annexed formula), m. p. 187—188°, colourless prisms or quadratic plates. This ester is insoluble in alkalis and does not develop a coloration with ferric chloride. However, it still contains two β-ketonic groups because it reacts
$$NH \begin{matrix} N=C-CH_2 \cdot CH_2 \\ CO \cdot C-CH_2 \cdot C \cdot CO \\ CH_2 \cdot CH_2 \cdot C=N \end{matrix} NH$$

with hydrazine hydrate and with phenylhydrazine in glacial acetic acid to form respectively the *dipyrazolone* (annexed formula), m. p. 300° (decomp.), colourless prisms, and corresponding *diphenyldipyrazolone*, m. p. 270°, pale yellow leaflets.

The decomposition of methyl *dicyclo*-[1,3,3]-nonan-2 : 6-dione-1 : 3 : 5 : 7-tetracarboxylate by dilute alkali hydroxide is too profound to be of any service, but by hydrolysis by aqueous barium hydroxide at 105° and acidification of the resulting barium salt, the ester yields 3 : 7-*dimethyl* 1 : 5-*dihydrogen* dicyclo-[1,3,3]-*nonan*-2:6-*dione*-1 : 3 : 5 : 7-*tetracarboxylate*, m. p. 205—207° (decomp.), small prisms or needles, which gives a violet coloration with ferric chloride, regenerates the original ester, m. p. 163—164°, by treatment of its silver salt with methyl iodide, and is converted by heating into *methyl* dicyclo-[1,3,3]-*nonan*-2 : 6-*dione*-3 : 7-*dicarboxylate*, $C_{13}H_{16}O_6$, m. p. 136—137°, colourless prisms. The latter is soluble in alkalis, develops a reddish-violet coloration with ferric chloride, and forms a *dipyrazolone*, $C_{11}H_{12}O_2N_4$, decomp. above 300°, and *diphenyldipyrazolone*, $C_{23}H_{30}O_2N_4$, decomp. above 300°, thus indicating that the original *dicyclo*nonane derivative, methyl *dicyclo*-[1,3,3]-nonan-2 : 6-dione-1 : 3 : 5 : 7-tetracarboxylate, must contain four β-keto-groups.
$$CH_2 \cdot CH-CO$$
$$CH_2 \quad CH_2 \quad CH_2$$
$$CO-CH-CH_2$$

dicyclo-[1,3,3]-*Nonan*-2 : 6-*dione* (annexed formula), m. p. 141°, b. p. 180°/20 mm., rhombic prisms, is obtained in about 34% yield by boiling methyl *dicyclo*-nonanedionetetracarboxylate or methyl *dicyclo*nonanedione-1 : 5-dicarboxylate with dilute hydrochloric acid, or quantitatively by heating 3 : 7-dimethyl 1 : 5-dihydrogen *dicyclo*nonanedionetetracarboxylate, or methyl *dicyclo*nonanedione-3 : 7-dicarboxylate with water at 200°. *dicyclo*Nonanedione is volatile with steam, forms a *diphenylhydrazone*, $C_{21}H_{24}N_4$, and a *di-oxime*, $C_9H_{14}O_2N_2$, m. p. 205—206° (decomp.), regular octahedra, and is stable to potassium permanganate, these reactions indicating that the substance is a dicyclic diketone. It condenses very readily with alcoholic benzaldehyde, or cinnamaldehyde in the presence of a little concentrated sodium hydroxide, yielding 3 : 7-*dibenzylidene*dicyclo-[1,3,3]-*nonan*-2 : 6-*dione*, $C_{23}H_{20}O_2$, m. p. 201°, faintly yellow needles, and the *dicinnamylidene* derivative, $C_{27}H_{24}O_2$, m. p. 246°, pale yellow powder, which dissolve in concentrated

sulphuric acid with a pale yellow and orange-red colour respectively. The significance of these slight colorations is important, because Wallach, Stobbe, and others have shown that the dibenzylidene and dicinnamylidene derivatives of cyclic ketones of the type

$$[CH_2]_x \!\!<\!\! \begin{array}{c} C(:CHAr)\!\!-\!\! \\ C(:CHAr)\!\!- \end{array} \!\!\!>\!\! CO$$
develop intensely yellow and violet colorations respectively with concentrated sulphuric acid. Hence the inference is drawn that only one methylene group is attached directly to a carboxyl group in the *dicyclo*-nonanedione.

The oxidation of *dicyclo*nonanedione by warm nitric acid, D 1·2, yields Guthzeit and Engelmann's pentane-$a\beta\delta\epsilon$ tetracarboxylic acid (*anhydride*, $C_9H_8O_8$, m. p. 161°; *methyl* ester, $C_{13}H_{20}O_8$, m. p. 60°, b. p. 210°/20 mm.). The formation of this acid proves that the diketone must have either the formula assigned to it by the authors (which is proved by the formation of methyl *dicyclo*nonanedionetetra-carboxylate, and therefore indirectly of the diketone, from a substance already containing a *cyclo*hexane ring [see above]) or the formula

$$CH_2 \!\!<\!\! \begin{array}{c} CO\!\!-\!\! \\ CH_2 \end{array} \!\!\!>\!\! CH \cdot CH_2 \cdot CH \!\!<\!\! \begin{array}{c} CO\!\!- \\ CH_2 \end{array} \!\!\!>\!\! CH_2 \;;$$ against the latter tells the

fact that the formation of a *cyclo*butane derivative has never been observed when there is a possibility for the reaction to produce a *cyclo*hexane derivative.   C. S.

Quantitative Investigation of the Photochemical Transformation of o-Nitrobenzaldehyde into o Nitrosobenzoic Acid. FRITZ WEIGERT and LUDWIG KUMMERER (*Ber.*, 1913, **46**, 1884—1885. Compare this vol., ii, 370; Kailan, *ibid.*, i, 51, 733).—A further criticism of Kailan's work on this subject.   F. B.

Quantitative Investigation of the Photochemical Transformation of o-Nitrobenzaldehyde into o-Nitrosobenzoic Acid. II. ANTON KAILAN (*Ber.*, 1913, **46**, 2175—2179. Compare this vol., i, 51).—In reply to Weigert and Kummerer's criticism (this vol., ii, 370) that the titration of o-nitrosobenzoic acid using phenolphthalein is not trustworthy in presence of much o-nitrobenzaldehyde, the author shows that the method gives satisfactory results.   J. C. W.

Bromination of Certain Ketones and of Some Secondary Hydroaromatic Alcohols. FERNAND BODROUX and FELIX TABOURY (*Compt. rend.*, 1913, **156**, 1840—1841. Compare A., 1912, i, 567).—Bromination was effected by the addition of a solution of the ketone or alcohol in carbon tetrachloride to an excess of bromine dissolved in the same solvent. After six hours, excess of bromine and carbon tetrachloride were removed by means of a current of air.

1-Methyl-2-*cyclo*hexanone yielded *tetrabromomethylcyclohexanone*, small, white needles, m. p. 105—107°, together with a small quantity of a mixture of tribromomethyl*cyclo*hexanones which could not be separated from one another. 1-Methyl-2-*cyclo*hexanol gave a poor yield of a mixture of tribromomethyl*cyclo*hexanones.

1-Methyl-3-*cyclo*hexanone was practically quantitatively converted

into a tribromomethyl*cyclo*hexanone. The latter was very difficult to purify, but had m. p. 55—58°.

1-Methyl-4-*cyclo*hexanone yielded a *tetrabromo*-derivative, white needles, m. p. 79°. The same substance was obtained from 1-methyl-4-*cyclo*hexanol.

1 : 3-Dimethyl-4-*cyclo*hexanone gave a *tetrabromo*-derivative, white prisms, m. p. 62—63°.

The bromo-derivatives of the homologues of *cyclo*hexanone a.e somewhat unstable. At temperatures slightly above their m p.'s, they are decomposed into bromine, hydrogen bromide, and bromo-phenols. The same transformation occurs slowly at the ordinary temperature under the influence of light. H. W.

Catalytic Hydrogenation of the Two Methyl*cyclo*pentanones. MARCEL GODCHOT and FELIX TABOURY (*Bull. Soc. chim.*, 1913, [iv], 13, 591—599).—It is shown that the reduction of the methyl*cyclo*pentanones by Sabatier and Senderens' method is quite analogous to that of *cyclo*pentanone (A., 1911, i, 385 ; 1912, i, 34), the products being the corresponding methyl*cyclo*pentanols and dimethyl*cyclo*pentyl*cyclo*pentanones, the latter predominating (compare Zelinsky, A., 1911, i, 988).

1-Methyl*cyclo*pentan-3-one yields 1-methyl*cyclo*pentan-3-ol (*phenylurethane*, m. p. 82°, colourless needles from alcohol) and 3-*methyl*cyclo*pentyl-2′(or 3′)-*methylcyclopentan-5′-one* (annexed formulæ), D_{16}^{16} 0·9365,

n_D^{16} 1·4700, b. p. 245°, a colourless liquid having an odour of menthol ; it yields a *semicarbazone*, m. p. 137°, crystallising in needles, and with hydroxylamine a *product*, m. p. 75—100°, which is probably a mixture of two stereoisomeric oximes.

$$\begin{array}{l}\text{CH}_2\text{---CH}_2\\ \text{CHMe·CH}_2\end{array}\!\!>\!\text{CH·CH}\!<\!\!\begin{array}{l}\text{CO---CH}_2\\ \text{CH}_2\text{·CHMe}\end{array}\ \text{or}$$

$$\begin{array}{l}\text{CH}_2\text{---CH}_2\\ \text{CHMe·CH}_2\end{array}\!\!>\!\text{CH·CH}\!<\!\!\begin{array}{l}\text{CO---CH}_2\\ \text{CHMe·CH}_2\end{array}$$

Attempts to prepare 1-methyl*cyclo*pentan-2-one by (1) the action of magnesium methyl iodide on 1-chloro*cyclo*pentan-2-one and (2) the action of methyl iodide on *cyclo*pentanone in presence of sodamide were unsuccessful; the second reaction yielded *cyclo*pentylidene-3-methyl*cyclo*pentan-2-one, of which the *oxime*, m. p. 85°, colourless needles, and the *semicarbazone*, m. p. 193°, were prepared.

The 1-methyl*cyclo*pentan-2-one required was prepared by Bouveault's method (A., 1900, i, 171). On reduction by nickel at 150°, 1-methyl-*cyclo*pentan-2-ol, D_{16}^{16} 0·9238, n_D 1·4466, b. p. 146—147° (*phenylurethane*, m. p. 84°), was obtained with 2-*methyl*cyclopentyl-3′-methyl-cyclo*pentan-2′-one* as a principal product. The latter has D_{16}^{16} 0·9238, n_D 1·4724, b. p. 239—241°, and is a colourless liquid with an odour of menthol ; it yields a *semicarbazone*, m. p. 202—203°, crystallising from alcohol in needles. Looft (A., 1894, i, 405) has already prepared a methyl*cyclo*pentanol, which may be identical with that described above. T. A. H.

Ketimines. CHARLES MOUREU and GEORGES MIGNONAC (*Compt. rend.*, 1913, 156, 1801—1806).—The authors have succeeded in

isolating a series of ketimines of the general formula CR_2:NH, the bromomagnesium derivatives of which are formed as intermediate products in the preparation of ketones by the action of Grignard's reagents on nitriles.

For the preparation of purely aromatic ketimines, the solid product of the action of the aryl-nitrile on the magnesium aryl haloid is brought, little by little, into a mixture of crushed ice and ammonium chloride, the mixture extracted with ether, the ethereal solution dried and saturated with dry hydrogen chloride. The precipitated imine-hydrochloride is filtered, suspended in ether, and decomposed by dry ammonia gas. After removal of ammonium chloride, the imine is obtained by evaporating the ethereal solution. Mixed fatty-aromatic ketimines are generally more readily decomposed by water, and their isolation is preferably effected by passing dry hydrogen chloride directly into the ethereal suspension of the magnesium derivative. The free imine is isolated from the hydrochloride so formed in the same manner as that adopted for aromatic ketimines.

Ketimines are generally oils or solids of low m. p. which yield crystalline salts. The hydrochlorides dissolve readily in chloroform, and are decomposed by water into the corresponding ketone and ammonium chloride. The free bases are much less sensitive to the action of water than the salts. Ketimines readily combine with bromine. They yield acyl derivatives which are decomposed by cold dilute hydrochloric acid with the formation of ketones. The constants of the following ketimines are given: *Phenyl ethyl ketimine*,

$$CEtPh:NH,$$
has b. p. 101·5—102·5°/13·5 mm., D_4^{22} 0·9902, n_D^{22} 1·5476. Its *hydrochloride* and *acetyl* derivative have m. p. 145° and 126° respectively. *Phenyl propyl ketimine*, has b. p. 99°/8 mm., D_4^{18} 0·9751, n_D^{18} 1·5353. *Phenyl isobutyl ketimine*, b. p. 113—114°/12·5 mm., D_4^{20} 0·9489, n_4^{2} 1·5270. *Phenyl cyclohexyl ketimine*, b. p. 135—138°/5 mm. *Diphenyl ketimine*, b. p. 127°/3·5 mm., D_4^{19} 1·0847, n_D^{19} 1·6191. *Phenyl o-tolyl ketimine*, b. p. 136—137°/4 mm., $D_4^{19·5}$ 1·0614, $n_D^{23·5}$ 1·6065. *Phenyl p-tolyl ketimine*, m. p. 37°, b. p. 147°/5 mm., D_4^{19} 1·0617, n_D^{20} 1·6097. *Phenyl a-naphthyl ketimine*, m. p. 68—69°, b. p. 181·5°/4·5 mm..   H. W.

Catalytic Formation of Benzophenone by Calcium Carbonate. Paul Sabatier (*Anal. Fis. Quim.*, 1913, **11**, 274—275).— When the vapour of benzoic anhydride is passed over calcium carbonate at about 500°, benzene, benzophenone, and traces of anthraquinone are formed.   G. D. L.

Transformation of 2:6-, 2:4'- and 2:4-Dibromobenzo-phenones into Bromofluorenones. Pieter J. Montagne and Jacob Moll van Charante (*Rec. trav. chim.*, 1913, **32**, 164—173. Compare A., 1910, i, 42).—When 2:6-, 2:4'-, or 2:4-dibromobenzophenone is heated, hydrogen bromide is evolved, and a bromofluorenone formed. Concurrently a certain amount of bromination occurs, due apparently to the hydrogen bromide evolved, and, since different by-products are obtained from 2:4'- and 2:4-dibromobenzophenone, it appears that it is the unchanged original substance which is thus affected.

8-*Bromofluorenone*, $C_6H_3Br \underset{CO}{\diagup}\underset{}{\diagdown} C_6H_4$, m. p. 135°, b. p. ca. 395° (decomp.), is obtained when 2 : 6-dibromobenzophenone is heated at its b. p. during two to three days. On reduction by means of sodium amalgam in boiling alcoholic solution, it is converted into fluorenyl alcohol, m. p. 153°, whilst oxidation by concentrated sulphuric acid and mercuric sulphate transforms it into phthalic anhydride.

When 2 : 4'-dibromobenzophenone is heated, it yields a mixture of unchanged material and two substances which can be separated by sublimation under reduced pressure. At about 170—180°, 6-*bromofluorenone* is obtained. After recrystallisation from benzene, it forms needles and plates, m. p. 165·5°, or compact crystals, m. p. 162·5°. After re-solidification the latter melt at 165·5°. Reduction with sodium amalgam in boiling alcoholic solution transforms it into fluorenone, m. p. 82°, whilst, when oxidised with concentrated sulphuric acid and mercuric sulphate, it yields phthalic anhydride. The residue obtained from the sublimation of 6-bromofluorenone, when sublimed at about 225°, gives a dibromofluorenone, $C_{13}H_6OBr_2$, yellow crystals, m. p. 215·5—216°.

When 2 : 4-dibromobenzophenone is treated in the same manner as the 2 : 4'-isomeride, it yields 6-bromofluorenone. The residue left in the sublimation apparatus, after repeated crystallisations from benzene and alcohol, gives 6 : 8-dibromofluorenone, m. p. 225°. H. W.

αβ-Unsaturated Diketones. OTTO DIELS and PETER SHARKOFF (*Ber.*, 1913, **46**, 1862—1870. Compare A., 1911, i, 464).—Under the influence of 33% aqueous potassium hydroxide, dimethyl diketone monoxime readily condenses with benzaldehyde, cinnamaldehyde and furfuraldehyde, yielding oximes of αβ-unsaturated ketones of the formula $CHR:CH \cdot C(N \cdot OH) \cdot COMe$, from which the corresponding ketones cannot be obtained by any of the usual methods. The removal of the oximino-group may, however, be effected by distilling a mixture of the oxime with phthalic anhydride or succinic anhydride in superheated steam, but the yield of unsaturated diketone thus obtained is very small.

Styryl methyl diketone monoxime, $CHPh:CH \cdot C(N \cdot OH) \cdot COMe$, prepared from benzaldehyde and dimethyl diketone monoxime, crystallises from alcohol in long, colourless needles, m. p. 147° (corr.), and dissolves in aqueous alkali hydroxides, yielding yellow solutions; with 33% potassium hydroxide it forms a *potassium* salt. It is accompanied by an orange-yellow *substance*, probably

$$CHPh[CH_2 \cdot CO \cdot C(N \cdot OH) \cdot CH:CHPh]_2,$$
m. p. 216—220° (decomp.).

That the condensation of the aldehyde takes place at the methyl group adjacent to the oximino-group has been established by the conversion of the styryl methyl diketone monoxime by boiling with strong hydrochloric acid into 3-*acetyl*-5-*phenyl*-4 : 5-*dihydroisooxazole*,

$$\underset{O \underline{\qquad} N}{CHPh \cdot CH_2} >C \cdot COMe,$$

which crystallises in stout prisms, m. p. 97—98°, and when warmed with aqueous potassium hydroxide is transformed into a *substance*, m. p. about 254° (decomp.).

On treatment with oxalyl chloride in ethereal solution the oxime yields a *compound*, CHPh:CH·C(COMe):N·O·COCl, which crystallises in colourless needles, m. p. 59°, and is decomposed by water with the formation of cinnamic acid. The *dibromide* of styryl methyl diketone forms yellow crystals, m. p. 86°, and slowly decomposes when kept.

Cinnamylidenediacetyl monoxime (*β-styrylvinyl methyl diketone monoxime*), CHPh:CH·CH:CH·C(N·OH)·COMe, crystallises in slender, yellow needles, m. p. 148°, which become strongly electric when rubbed, give an intense purple-red coloration with sulphuric acid, and on distillation with phthalic anhydride in superheated steam yield *cinnamylidinediacetyl monoxime*, brownish-yellow needles, m. p. 49°.

Furfurylidenediacetyl monoxime (*β-furylvinyl methyl diketone monoxime*), $C_4H_3O·CH:CH·C(N·OH)·COMe$, has m. p. 132°, and with strong aqueous potassium hydroxide yields a *potassium* salt.　　F. B.

Curcumin. VICTOR LAMPE and J. MIŁOBĘDZKA (*Ber.*, 1913, **46**, 2235—2240).—The authors are endeavouring to confirm, by direct synthesis, the formula, $CH_2[CO·CH:CH·C_6H_3(OMe)·OH]_2$, proposed for curcumin by Miłobędzka, Kostanecki, and Lampe (A., 1910, i, 628), and with this object in view have first of all turned their attention to the preparation of the parent substance, dicinnamoylmethane (IV), the synthesis of which was finally accomplished from ethyl cinnamoylacetoacetate by the method indicated in the following scheme :

(I) CHPh:CH·CO·CH(COMe)·CO₂Et →

    (II) CHPh:CH·CO·CH₂·COMe + CHPh:CH·COCl →

(III) COMe·CH CO·CH:CHPh)₂ →

    (IV) CH₂(CO·CH:CHPh)₂ + CH₃·CO₂H.
Cinnamoylacetone (II), prepared by hydrolysis and simultaneous elimination of carbon dioxide from ethyl cinnamoylacetoacetate (I), crystallises in yellow prisms, m. p. 86—88°, and develops a yellowish-green coloration with sulphuric acid. Its alcoholic solution gives with copper acetate a green precipitate, and with ferric chloride a deep red coloration. When boiled with hydroxylamine hydrochloride in alcoholic solution, it is converted into 3(or 5) *styryl-*5(or 3)*-methyl-isooxazole*,

    $\overset{CMe:CH}{\underset{O\text{———}N}{}}$>C·CH:CHPh or $\overset{CMe·CH}{\underset{N\text{———}C}{}}$>C:CH:CHPh, which

crystallises in white leaflets, m. p. 92—94°. On successive treatment with sodamide and cinnamoyl chloride in ethereal solution, it yields *dicinnamoylacetone* (III). This has m. p. 112—114°, gives the same reactions as cinnamoylacetone with cupric acetate and ferric chloride, and yields strongly yellow, fluorescent solutions with sulphuric acid.

Dicinnamoylmethane (IV), prepared by boiling dicinnamoylacetone with 50% acetic acid, crystallises in bronze-yellow, prismatic needles, m. p. 144°. In its chemical properties it strongly resembles curcumin. Thus, it dyes cotton a pale yellow without a mordant, dissolves in sulphuric acid, yielding an orange-red solution having a yellow fluor-

escence, and gives with copper acetate and ferric chloride in alcoholic solution a green precipitate and a deep red coloration respectively. When boiled with alcoholic hydroxylamine hydrochloride it is converted into 3 : 5-*distyrylisooxazole*,

$$\underset{N \quad - \quad O}{\overset{CHPh\!:\!CH\cdot C\cdot CH}{\parallel}}\!\!>\!C\cdot CH\!:\!CHPh, \quad crystal-$$

lising in almost colourless, prismatic needles, m. p. 170—172°.

Attempts to prepare ethyl dicinnamoylmalonate by the successive action of sodium and cinnamoyl chloride on ethyl malonate in ethereal solution led to the formation of *ethyl* 4-*cinnamoyl*-1-*phenyl*-Δ^1-*cyclopenten*-3 : 5-*dione*-4-*carboxylate*,

$$\underset{CH - CO}{\overset{CPh\cdot CO}{\parallel}}\!\!>\!C\!\!<\!\underset{CO_2Et}{\overset{CO\cdot CH\!:\!CHPh}{}}, \quad which$$

forms prismatic needles, m. p. 188—189°, and is accompanied by *ethyl* 1-*phenyl*-Δ^1-*cyclopenten*-3 : 5-*dione*-4-*carboxylate*,

$$\underset{CH - CO}{\overset{CPh\cdot CO}{\parallel}}\!\!>\!CH\cdot CO_2Et,$$
This crystallises in prismatic needles, m. p. 107—109°, and yields deep red alcoholic solutions. F. B.

Diketones Obtained by the Action of Xylylene Dibromides on the Sodium Derivative of Phenyl *iso*Propyl Ketone, and their Decomposition by Sodamide. PH. DUMESNIL (*Compt. rend.*, 1913, **157**, 53—55. Compare A., 1911, i, 719, and Haller and Bauer, A., 1911, i, 726).—o-, m-, and p-Xylylene dibromides react with the sodium derivative of phenyl *iso*propyl ketone in benzene solution to give the corresponding *bis*-(β-*benzoyl*-β-*methylpropyl*)*benzenes*,

$$C_6H_4(CH_2\cdot CMe_2\cdot COPh)_2.$$
The *ortho*-derivative is obtained as small, colourless crystals, m. p. 68°, giving a *dioxime*, m. p. 240° ; the *meta* in large, colourless crystals, m. p. 44°, giving a *dioxime*, m. p. 210°, and the *para* in colourless needles, m. p. 113°, yielding a *dioxime*, m. p. 278°. All three of these diketones are decomposed, by warming them with sodamide in xylene solution, into the corresponding bis-dimethyl-acetamides. o-*Xylylene-bisdimethylacetamide*,

$$C_6H_4(CH_2\cdot CMe_2\cdot CO\cdot NH_2)_2,$$
is a colourless, crystalline solid, m. p. 130° ; the *meta*-isomeride, colourless needles, m. p. 162° ; and the *para*-isomeride, m. p. 238°. They are all hydrolysed by heating with 50% sulphuric acid in sealed tubes for six hours at 150° to the corresponding *acids* having respectively m. p.'s 135°, 155°, and 217°. W. G.

Di-iminonaphthol Hydrochlorides. III. OSWALD MILLER (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 580—608. Compare A., 1911, i, 308, 465).—When crystallised from water and from alcohol, di-iminonaphthol hydrochloride shows different solubilities in 50% aqueous alcohol. Further, whilst hydration in neutral aqueous solution of the salt obtained from water gives yields of amino-α-naphthaquinone varying regularly with the temperature, the hydrochloride separated from alcohol always yields smaller and inconstant proportions of the quinone owing to the simultaneous formation of a third amino naphthaquinone or β-oximinonaphthol.

From these isomeric di-iminonaphthol hydrochlorides ammonia separates identical bases, but dissociation into base and hydrogen chloride is peculiar to the normal or α-salt; the β'-salt, which does not dissociate, decomposes immediately into β-oximinonaphthol and ammonia.

The decomposition of the hydrochlorides in aqueous solution proceeds normally at temperatures up to about 60°, beyond which the primary products of the reaction yield two secondary products : (1) a dark blue colouring matter, which results from the condensation of α-oximinonaphthol and dissolves in alcohol, giving a blue solution with an intense brick-red fluorescence; it dissolves in varying degree in the products of the reaction, and of the product obtained at 94° it forms about 0·5%. (2) 2-Hydroxy-α-naphthaquinone, which is formed by hydration of the amino-group of aminoquinone, $\cdot NH_2 + H_2O = \cdot ONH_4$. The velocity of this hydration differs for these three quinones, being almost negligible for amino-α-naphthaquinone, only slightly greater for β-oximinonaphthol, and more or less considerable for α-oximinonaphthol. Hence, when the hydration is continued for only ten hours, it may be assumed that the 2-hydroxy-α-naphthaquinone formed is derived entirely from α-oximinonaphthol.

The actual amounts of the three primary products of the reaction are calculated from the equations : (I) amino-α-naphthaquinone $= \alpha + 0·046\alpha + 0·84$; (II) α-oximinonaphthol $= \beta - 0·046\alpha - 4·20 + 0·247$, and (III) β-oximinonaphthol $= \beta' - 0·47\beta'/100 + 4·20$, where α, β, and β' are the experimental quantities of the three products per 100 grams of the hydrochloride.

When crystallised from dilute hydrochloric acid, all the different modifications of the hydrochloride are converted into one and the same form, identical in its decomposition products with that obtained by repeated crystallisation of the crude salt from water. This salt, termed the A-salt, is the one mostly employed in the present investigation.

In the decomposition of the hydrochloride (A-salt) by acid, the yields of amino-α-naphthaquinone and of α-oximinonaphthol obtained are diminished by repeated crystallisation from either water or acid, and the same is the case with the amount of α-oximinonaphthol converted into hydroxynaphthaquinone and colouring matter ; on the other hand, the proportions of β-oximinonaphthol formed gradually increase. By two or three crystallisations from 95% alcohol, the A-salt is transformed into another, which has constant properties and is termed the B-salt. If the conversion of the B-salt into the A-salt by crystallisation from N/10-hydrochloric acid is determined by absorption of the acid by the salt, the inverse change consists in the gradual removal of the acid from the salt under the influence of the solvent. The A-salt must hence contain, not only chemically combined, non-esterifiable acid, but also a certain amount of acid in another form of combination, and capable of esterification by the action of alcohol.

The change produced in the A-salt by crystallisation is also effected by prolonged heating or by remaining over sodium hydroxide.

From these results it appears highly probable that the principal

part in the transformations of di-iminonaphthol hydrochlorides is played by traces of free hydrochloric acid fixed by the crystals on their formation in an acid solution, the maximum and minimum (zero) of such fixation being represented by the A- and B-salts respectively.

The composition of the B-salt having been found to vary with the acidity of the surrounding medium, a C-salt, the acidity of which remains constant, was prepared by suitable heating and crystallisation. When this salt is heated with dilute hydrochloric acid solutions of different concentrations, it is found that the transformation of the B-salt reaches its limiting value with 0·018 mol. of hydrochloric acid per mol. of C-salt, further addition of acid producing no extra increase in the yield of amino-α-naphthaquinone. The amounts of (1) amino-α-naphthaquinone, (2) α-oximinonaphthol, (3) β-oximino-naphthol, and (4) 2-hydroxy-α-naphthaquinone obtained with different concentrations of hydrochloric acid are shown in the form of curves. The second and third curves are approximately straight lines and are therefore in good agreement with the law of mass action. Curve (1), however, rises at first rapidly and then gradually to a limit, its course being closely similar to that of an adsorption curve. It seems, therefore, that when di-iminonaphthol is crystallised from water containing free hydrochloric acid, the latter is adsorbed to some extent on the faces of the crystals. Thus, adsorption in a hetero-geneous system is not limited to substances in a colloidal state, but takes place also with crystalloids.

Further experiments show that in a 1% solution of the B-salt maintained at 94·5°, two processes occur simultaneously : (1) deco m position of the normal A-salt in 0·66% solution, with formation of α- and β-aminonaphthaquinones, and (2) decomposition of the β'-salt, not yet isolated, in 0·33% solution, with formation of β-oximino-naphthol.

β-Oximinonaphthol crystallises in shining, flat, reddish-brown needles having the same composition as the α-compound,

$$C_{10}H_7O_2N,\tfrac{1}{2}H_2O.$$

The two isomeric di-iminonaphthol hydrochlor l s are regarded as having the structures :

(α) $C_6H_4{<}^{CO \cdot C(NH_2)}_{C(:NH_2Cl)-}{>}OH$ and (β) $C_6H_4{<}^{C \cdot \text{------} C:NH_2Cl}_{C(NH_2):CH}$.
The following salts of di-iminonaphthol have been prepared and analysed : the normal *sulphate*, $(C_{10}H_8ON_2)_2,H_2SO_4,4H_2O$; the *acid acetate*, $C_{10}H_8ON_2,2C_2H_4O_2$, and the normal *acetate*,

$$C_{10}H_8ON_2,C_2H_4O_2,xH_2O.$$

T. H. P.

Lakes. II. PAUL PFEIFFER [and PH. FISCHER, J. KUNTNER, P. MONTI, and Z. PROS] (*Annalen*, 1913, **398**, 137—196. Compare A., 1911, i, 899).—The main object of the paper is to show that in hydroxyketones and hydroxyquinones, particularly of the anthra-quinone series, the formation of normal salts occurs quite differently from that of internally complex salts.

The author has already shown in connexion with his theory of

halochromy (A., 1911, i, 788) that carbonyl compounds and stannic chloride form additive compounds of the type $Cl_4Sn{\cdot}{\cdot}{\cdot}\begin{smallmatrix} O{:}CRR' \\ O{:}CRR'' \end{smallmatrix}$ When the ketone or quinone contains a hydroxyl group in the ortho-position to the carbonyl group, a substituted compound is formed which is represented by the formula $\begin{smallmatrix} RC{=}O \\ | \\ Ar{-}O \end{smallmatrix}{>}SnCl_3$, and is closely related to the tin lakes (*loc. cit.*). The correctness of this view is supported by the following new facts. Acetophenone, benzophenone, xanthone, and *p*-methoxychalkone form with stannic chloride additive compounds of the first type, whilst their *o*-hydroxy-derivatives yield substituted, internally complex salts of the second type. The formation of the substituted compound is preceded by that of the additive compound because in the cases of *o* hydroxyacetophenone, resacetophenone, and benzylidenepaeonol, the additive compound,

$$Cl_4Sn{<}\begin{smallmatrix} O{:}CRAr \\ O{:}CRAr' \end{smallmatrix}$$
can be isolated; by loss of hydrogen chloride, it changes to the internally complex salt, $\begin{smallmatrix} RC{:}O \\ | \\ Ar{\cdot}O \end{smallmatrix}{>}SnCl_3$. So also, alizarin dimethyl ether and stannic chloride in dry benzene at the ordinary temperature yield $Cl_4Sn{...}OC{<}\begin{smallmatrix} C_6H_4 \\ C_6H_2(OMe)_2 \end{smallmatrix}{>}CO$, which is converted by warming into $Cl_3Sn{<}\begin{smallmatrix} O{:}C{-}C_6H_4 \\ O{\cdot}C_6H_2(OMe) \end{smallmatrix}{>}CO$, methyl chloride being evolved.

The theory that the $SnCl_3$ compounds are internally complex salts containing $Sn{...}O$ is supported by the fact that the colours of these substances are in harmony with the generalisations made with respect to the colours of $SnCl_4$ additive compounds (*loc. cit.*); for example, in the case of resacetophenone derivatives, $OMe{\cdot}C_6H_3{<}\begin{smallmatrix} O{-}SnCl_3 \\ CMe{:}O \end{smallmatrix}$ is colourless, $CHPh{:}CH{\cdot}C{<}\begin{smallmatrix} C_6H_3(OMe){\cdot}O \\ O{\cdots\cdots\cdots}SnCl_3 \end{smallmatrix}$ is orange-yellow, and

$$OMe{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}C{<}\begin{smallmatrix} C_6H_3(OMe){\cdot}O \\ O{\cdots\cdots\cdots}SnCl_3 \end{smallmatrix}$$
is orange-red. The violet-black colour of the $SnCl_3$ compound of alizarin (and also of alizarin β-methyl ether), in comparison with the red colour of the $SnCl_3$ compound of 1-hydroxyanthraquinone, is in agreement with the rule that in halochromatic substances the presence of a hydroxyl or methoxyl group in the meta-position to the carbonyl group causes a deepening of the colour (*loc. cit.*).

Only *o*-hydroxyketones and *o*-hydroxyquinones yield $SnCl_3$ substituted compounds; the *m*- and *p*-hydroxy-isomerides form $SnCl_4$ additive compounds of the normal type. *o*-, *m*-, and *p*-Hydroxyacetophenones, benzylidenepaeonol (2-hydroxy-4-methoxyphenyl styryl ketone), phenyl *o* hydroxystyryl ketone, 1-, 2- and 4-hydroxyxanthones, and 1- and 2-hydroxyanthraquinones have been examined; of these,

o-hydroxyacetophenone, benzylidenepaeonol, 1-hydroxyxanthone, and 1-hydroxyanthraquinone alone yield $SnCl_3$ substituted compounds. The fact that resacetophenone, resobenzophenone, 2 : 4'-dihydroxy-benzophenone, euxanthone, and alizarin form mono-substituted $SnCl_3$ compounds, not disubstituted $SnCl_2$ compounds, also proves that only the hydroxyl group in the ortho-position to the carbonyl group is concerned in the formation of the internally complex $SnCl_3$ salt.

The $SnCl_3$ derivatives of *o*-hydroxyketones and of *o*-hydroxyquinones, being internally complex salts, must be closely related to the tin lakes of these substances, which are typical representatives of internally complex salts (Tschugaeff, A., 1907, i, 17, 392, 830; Werner, A., 1908. i, 441). On the fibre these lakes do not contain chlorine, and therefore must be derived from the author's compounds simply by replacement of chlorine by oxygen or a hydroxyl group : $C_6H_4\begin{smallmatrix}O-SnCl_3\\ \\CR:O\end{smallmatrix}$

$\longrightarrow C_6H_4\begin{smallmatrix}O-SnO(OH)\\ \\CR:O\end{smallmatrix}$. The author shows that the $SnCl_3$ compounds are converted into tin lakes by hydrolysis. The careful addition of water to the orange solution of the $SnCl_3$ compound of alizarin in pyridine precipitates an orange-red *substance*,

$$(HO)OSn\begin{smallmatrix}O:C-C_6H_4\\ \\O\cdot C_6H_2(OH)\end{smallmatrix}CO,\tfrac{1}{2}C_5NH_5,$$
which is unstable to acids, stable to aqueous ammonia on the water-bath, and dyes silk and wool, but not cotton, orange red.

The close relationship between the tin lakes and the author's $SnCl_6$ compounds is also made evident by the following analogy—only hydroxyketones and -quinones containing a hydroxyl group in the ortho-position to the carbonyl group form $SnCl_3$ compounds—only dyes containing a hydroxyl group in the ortho- or peri-position to the chromophoric group are mordant dyes according to Möhlau and Steimming (*Zeitsch. Farb. Text-chem.*, 1904, 3, 358).

According to the preceding, internally complex $SnCl_3$ salts of hydroxy-anthraquinones are obtained by substitution at the ortho-hydroxyl group. Hence it might be anticipated that this hydroxyl group is also concerned in the formation of the normal salts. Experiment shows that this is not so; 1-hydroxyanthraquinone and quinizarin do not form pyridine salts in hot pyridine, whilst 2-hydroxyanthraquinone, 2 : 6-dihydroxyanthraquinone, alizarin. 1 : 7 dihydroxyanthraquinone, and purpurin form pyridine salts, the number of pyridine molecules added being equal to the number of hydroxyl groups in the meta-position to a carbonyl group.

Hence in the formation of normal salts with weak bases just those hydroxyl groups are concerned which do not exhibit any tendency to complex salt formation with tin tetrachloride. Strong bases, such as the hydroxides of the alkali and the alkaline earth metals, react with both *m*- and *o*-hydroxyl groups, but preferably with the former; 2-hydroxyanthraquinone dissolves easily in 1% aqueous sodium carbonate, whilst 1-hydroxyanthraquinone does not.

It follows from the preceding that hydroxyl groups in the ortho-

position to the carbonyl group are concerned in complex salt formation, whilst the production of normal salts is due primarily to hydroxyl groups in the meta-position, normal salt formation at an *o*-hydroxyl group being a secondary effect. This is readily explicable. The hydrogen atom of the *o*-hydroxyl group is attached co-ordinatively to the oxygen atom of the carbonyl group, and therefore its acidic function is weaker than that of the hydrogen atom of the hydroxyl group in the meta-position. Normal salt formation, therefore, occurs firstly at the *m*-hydroxyl group by the addition, in accordance with the modern view of the phenomenon of neutralisation, of the hydroxide, with the formation of an aquo-salt which then loses water.

The compounds obtained by the action of stannic chloride on hydroxy-acetophenones, hydroxychalkones, hydroxybenzophenones, and hydroxy-xanthones are described. The production of a $SnCl_4$ additive compound or of an $SnCl_3$ substituted compound, and also the colours of the products, are quite in accordance with the rules previously stated except in the cases of quinizarin and purpurin which yield the compounds $C_6H_4{<}^{CO}_{CO}{>}C_6H_2{<}^{O}_{O}{>}SnCl_2$ and

$$C_6H_4{<}^{CO}_{CO}{>}C_6H(OH){<}^{O}_{O}{>}SnCl_2$$
respectively.

The following *substances* have been prepared by warming the carbonyl compound with stannic chloride, alone or in the presence of dry benzene : $OMe \cdot C_6H_3(OSnCl_3) \cdot COMe$, m. p. about 235°, almost colourless leaflets containing $\frac{1}{2}C_6H_6$, from paeonol ;

$$CO_2Me \cdot C_6H_4 \cdot OSnCl_3,$$

m. p. 230°, colourless leaflets, from methyl salicylate ;

$$CO_2Et \cdot C_6H_4 \cdot OSnCl_3,$$
m. p. about 220°, colourless leaflets, from ethyl salicylate ;

$$NH_2 \cdot CO \cdot C_6H_4 \cdot OSnCl_3,$$

m. p. about 260°, white crystals containing $\frac{1}{2}C_6H_6$, from salicylamide ; $OH \cdot C_6H_3(OSnCl_3) \cdot COPh$, m. p. 295—297°, yellow crystals containing $\frac{1}{4}C_6H_6$, from resobenzophenone ; $OMe \cdot C_6H_3(OSnCl_3) \cdot COPh$, m. p. about 262°, yellow crystals, from resobenzophenone methyl ether ; $OH \cdot C_6H_4 \cdot CO \cdot C_6H_4 \cdot OSnCl_3$, m. p. 294—296°, yellow leaflets, from 2 : 4'-dihydroxybenzophenone ; $C_6H_4{<}^{O}_{CO}{>}C_6H_3 \cdot OSnCl_3$, m. p. 282—284°, yellow crystals containing $\frac{1}{2}C_6H_6$, from 1-hydroxy-xanthone ; $SnCl_4, 2C_6H_4{<}^{O}_{CO}{>}C_6H_3 \cdot OH$, m. p. 239°, yellowish-brown powder, from 2-hydroxyxanthone ; $SnCl_4, C_6H_4{<}^{O}_{CO}{>}C_6H_3 \cdot OH$, m. p. about 230°, yellow crystals, from 4-hydroxyxanthone (m. p. 242°, not 224° as stated in the literature) ;

$$OMe \cdot C_6H_3(OSnCl_3) \cdot CO \cdot CH{:}CHPh,$$
m. p. about 278°, orange-yellow, crystalline powder, from benzylidene-paeonol ; $OMe \cdot C_6H_3(OSnCl_3) \cdot CO \cdot CH{:}CH \cdot C_6H_4 \cdot OMe$, m. p. indefinite at about 250°, orange-red crystals containing $\frac{1}{4}C_6H_6$, from *p*-anisylidene-paeonol ; $OMe \cdot C_6H_3(OSnCl_3) \cdot CO \cdot CH{:}CH \cdot C_6H_3 {:} O_2 {:} CH_2$, decomp. above

200°, orange-red crystals containing $\frac{1}{2}C_6H_6$, from piperonylidenepaeonol ; $C_6H_4{<}{CO \atop CO}{>}C_6H_3{\cdot}OSnCl_3$, brownish-red powder containing $\frac{1}{2}C_6H_6$, from 1-hydroxyanthraquinone ; $C_6H_4{<}{CO \atop CO}{>}C_6H_2(OH){\cdot}OSnCl_3$, violet-black, crystalline powder containing $\frac{1}{4}C_6H_6$, from alizarin ;

$$C_6H_4{<}{CO \atop CO}{>}C_6H_2(OMe){\cdot}OSnCl_3,$$
violet-black powder containing $\frac{1}{2}C_6H_6$, from alizarin β-methyl ether ; $C_6H_4{<}{CO \atop CO}{>}C_6H_2{<}{O \atop O}{>}SnCl_2$, red, crystalline powder, from quinizarin ; $C_6H_4{<}{CO \atop CO}{>}C_6H(OH){<}{O \atop O}{>}SnCl_2$, almost black, crystalline powder containing C_6H_6, from purpurin ; $SnCl_4{,}C_6H_4{<}{CO \atop CO}{>}C_6H_2(OMe)_2$, brownish, or golden-yellow leaflets, from alizarin dimethyl ether ; $SnCl_4{,}2C_6H_4{<}{CO \atop CO}{>}C_6H_2(OMe)_2$, m. p. 242°, brownish-orange leaflets, from hystazarin dimethyl ether.

In addition to the normal pyridine salts of the hydroxyanthraquinones previously mentioned, the following have been prepared :

$$CH_3{\cdot}CO{\cdot}C_6H_3(OH)_2{,}C_5NH_5,$$
colourless crystals, from resacetophenone ;

$$C_6H_5{\cdot}CO{\cdot}C_6H_3(OH)_2{,}C_5NH_5,$$
m. p. 58°, colourless plates, from resobenzophenone ;

$$OH{\cdot}C_6H_3{<}{O \atop CO}{>}C_6H_3{\cdot}OH{,}C_5NH_5,$$
yellow needles, from euxanthone. C. S.

Some Derivatives of Aceanthrenequinone and 1 : 9-Anthracene. M. KARDOS (*Ber.*, 1913, **46**, 2086—2091).—The action of aceanthrenequinone with an equimolecular proportion of hydroxylamine hydrochloride and a half-molecular proportion of sodium carbonate in the presence of alcohol at water-bath temperature, yields *aceanthrenequinoneoxime,*

$$CH{<}{C_6H_4 \atop C_6H_3}{>}\begin{matrix}C{\cdot}CO\\---C{:}NOH\end{matrix} \quad\text{or}\quad CH{<}{C_6H_4 \atop C_6H_3}{>}\begin{matrix}C{\cdot}C{:}NOH\\---CO\end{matrix},$$
yellow prisms, m. p. 251° (decomp.), which dissolves in sulphuric acid to a brown colour changing to red on warming. When caused to undergo the Beckmann rearrangement, by heating for several hours with hydrogen chloride in acetic acid solution, this substance forms *anthracene-*1 : 9-*dicarboxylimide,* $CH{<}{C_6H_4 \atop C_6H_3}{>}\begin{matrix}C{\cdot}CO\\---CO\end{matrix}{>}NH$, needles, m. p. 293—294°, which is reducible by alkaline reducing agents to a yellow solution, and dissolves in sulphuric acid to a beautiful red solution which fluoresces slightly ; there are obtained simultaneously *anthracene-*1 : 9-*dicarboxylic acid,* which readily passes into its *anhydride,* m. p. 289—290° (*methyl ester,* m. p. 149°), and also *anthracene-*1 : 9-*dicar-*

boxylamic acid, which in the free state rapidly passes into the imide; its solutions in alkali exhibit a beautiful sky-blue fluorescence; the *sodium* and *silver* salts were analysed. Endeavours to methylate the remaining carboxylic group of the acid amide by means of methyl sulphate yielded the *anhydride* of *methyl anthracene*-1:9-*carboxyl-amate*, $CH\underset{C_6H_3}{\overset{C_6H_4}{<}}\underset{CO}{\overset{C\cdot C(OMe)}{>}}N$, or $CH\underset{C_6H_3}{\overset{C_6H_4}{<}}\underset{C(OMe)}{\overset{C\cdot CO}{>}}N$, m. p. 170—171°.
Anthracene-1:9-dicarboxylimide is obtainable in theoretical yield by warming aceanthrenequinoneoxime with sulphuric acid for about a half-hour; heating with potassium hydroxide and a little water at 200—230° converts the imide into a green *dye*, $C_{33}H_{12}O_4N_2$; this on reduction by hyposulphite yields a red vat which colours cotton reddish-violet, passing on exposure to the air to a beautiful green. Similar dyes can be produced from halogen-substituted aceanthrene-quinones.

In an examination of the action of malonyl chloride on anthracene (compare Freund and Fleischer, A., 1910, i, 490; Liebermann and Zsuffa, A., 1911, i, 202) it is found that the condensation product is *anthracene*-1:9-*indandione*, $CH\underset{C_6H_3}{\overset{C_6H_4}{<}}\underset{CO}{\overset{C-CO}{>}}CH_2$, a red powder, m. p. 280° (decomp.) with previous blackening, which in sulphuric acid gives a carmine-red solution with a strong fluorescence; *sodium* salt, red leaflets. On oxidation with alkaline potassium permanganate solution, it produces anthraquinone-1-carboxylic acid. When heated with benzaldehyde at 130°, condensation occurs with formation of the *benzylidene* derivative, $CH\underset{C_6H_3}{\overset{C_6H_4}{<}}\underset{CO}{\overset{C-CO}{>}}C:CHPh$, a brownish-red powder, decomp. at 290°, which gives a reddish-violet solution in sulphuric acid.　　　　　　　　　　　　　　　　D. F. T.
Influence of Constitution on the Rotatory Power of Optically Active Substances. V. Keto-enolic Transformations of Derivatives of Menthyl Acetoacetates. HANS RUPE and EDUARD LENZINGER (*Annalen*, 1913, **398**, 372—378).—*l*-Menthyl *d*-phenylacetoacetate exists in the solid state as the ketonic modification. In benzene it is initially dextrorotatory, but in course of time becomes lævorotatory as the change to the enolic modification proceeds and the *l*-menthyl group becomes the only source of optical activity. It has previously been shown that the rate of transformation is very variable, and been suggested that this variation is caused by the presence of catalysts such as the alkali in the glass vessel. This hypothesis has now been proved. A 9·958% solution, D_4^{20} 0·8891, of *l*-menthyl *d*-phenyl-acetoacetate in benzene containing a trace of piperidine had $[a]_D^{20} + 26\cdot09°$ initially and a final constant value, $[a]_D^{20} - 67\cdot20°$ after ten hours. A similar solution ($c = 10\cdot02$, $D = 0\cdot8895$) containing a drop of piperidine

had initially $[a]_D^{20}$ +26·23°, and a final constant value, – 67·09°, after eight minutes. Within certain limits, the velocity of the keto-enolic change is a function of the concentration of the catalyst.

l-Menthyl *d*-benzoylphenylacetate exhibits a constant rotation in benzene ; also, its alcoholic solution does not develop a coloration with ferric chloride. Hence the stability of the ketonic modification is greatly increased when the methyl group in menthyl phenylacetoacetate is replaced by a phenyl group. However, again the presence of a trace of piperidine increases the velocity of the change from the ketonic to the enolic modification because a solution ($c = 9·08$, D_4^{20} 0·8924) of *l*-menthyl *d*-benzoylphenylacetate in benzene containing a trace of piperidine has $[a]_D^{20}$ +20·76° initially and – 62·83° after eighteen hours.   C. S.

Cardol. LEOPOLD SPIEGEL and M. CORELL (*Ber. Deut. pharm. Ges.*, 1913, **23**, 356—378. Compare Spiegel and Dobrin, A., 1896, i, 653). —Cardol can be distilled in superheated steam or under reduced pressure. In the latter case the principal fraction has b. p. 190°/3 mm., but is of variable composition, as shown by the analysis of two specimens. It is named apo*cardol*, and its reactions with bromine, ozone, permanganate, nitric acid, and on distillation with zinc dust are described. In most cases these do not lead to well-defined products, but the zinc dust distillation yielded ethylene, propylene, 1 : 3-butadiene, and a *substance*, $C_{13}H_{12}O$, m. p. 10°, b. p. 98—100°/14 mm.

In addition to *apocardol* a fraction, b. p. 200—220°/2—5 mm., is obtained.   T. A. H.

Constituents of Ethereal Oils. Eudesmol and its Derivatives. Globulol. FRIEDRICH W. SEMMLER and ERNST TOBIAS (*Ber.*, 1913, **46**, 2026—2032).—The authors have carried out a series of experiments on the sesquiterpene alcohols, eudesmol, which is widely distributed in eucalyptus oils, and globulol, which occurs in the ethereal oil from *Eucalyptus Globulus*. The former has been investigated by Baker and Smith, who consider it to be an oxide having the formula $C_{10}H_{18}O$, and describe a dinitro-derivative, $C_{10}H_{14}(NO_2)_2O$, and a dibromide, $C_{10}H_{16}OBr_2$. The authors, however, are led to the conclusion that it is a bicyclic sesquiterpene alcohol, $C_{15}H_{26}O$, containing one double bond.

Eudesmol has b. p. 156°/10 mm., D^{20} 0·9884, n_D^{21} 1·516, m. p. 78° (Baker and Smith give m. p. 79—80°), $[a]_D^{20}$ +31°21' in chloroform solution. When boiled with acetic anhydride and sodium acetate, it yields *eudesmol acetate*, $CH_3 \cdot CO_2 \cdot C_{15}H_{25}$, b. p. 165—170°/11 mm., D^{20} 0·9933, n_D^{20} 1·49204, $[a]_D^{20}$ +31°.

Dihydroeudesmol, $C_{15}H_{28}O$, b. p. 155—160°/12·5 mm., m. p. 82°, is obtained when an ethereal solution of eudesmol is reduced by hydrogen in the presence of platinum. When treated with sodium acetate and acetic anhydride, it yields the corresponding *acetate*, b. p. 158—164°/10 mm., D^{20} 0·9776, n_D^{20} 1·4788, $[a]_D^{20}$ +13°, from which dihydroeudesmol is recovered unchanged after saponification with

alcoholic potassium hydroxide. When boiled with absolute formic acid, dihydroeudesmol yields *dihydroeudesmene*, $C_{15}H_{26}$, b. p. 126—130°/10 mm., D^{30} 0·9067, n_D^{20} 1·48762, $[a]_D - 7°$.

Eudesmene, $C_{15}H_{24}$, obtained when eudesmol is heated with 90% formic acid, has b. p. 129—132°/10 mm., D^{20} 0·9204, n_D^{20} 1·50738, $[a]_D^{20} + 49°$, and is thus apparently a member of the sesquiterpenes derived from hydrogenated naphthalenes. It yields a characteristic *dihydrochloride* and *dihydrobromide*. The former, m. p. 79—80°, is obtained either by treatment of eudesmol with a saturated solution of hydrogen chloride in glacial acetic acid or by passing hydrogen chloride into eudesmene dissolved in the same solvent. The hydrocarbon is regenerated when the dihydrochloride is boiled with alcoholic potassium hydroxide. The dihydrobromide, m. p. 104—105°, can be prepared by precisely similar methods, and also gives eudesmene when acted on by alcoholic potassium hydroxide.

When treated with zinc dust, eudesmol gives a small quantity of the hydrocarbon, $C_{15}H_{26}$, but is mainly converted into eudesmene. The latter substance is also obtained when phosphorus pentachloride reacts with eudesmol. Oxidation with ozone or potassium permanganate did not lead to definite results.

Globulol, $C_{15}H_{26}O$ (compare A., 1904, i, 604), has b. p. 283°/755 mm. It differs physically from eudesmol, but, possibly, similar relationships exists between the two alcohols as between borneol and *isoborneol*; otherwise they are chemically different. When treated with dehydrating agents, globulol yields a l-*sesquiterpene*, $C_{15}H_{24}$, b. p. 102—103°/6 mm., 247—248°/748 mm., $[a]_D - 55°48'$, n_D^{20} 1·49287, D^{11} 0·8956, and a d-*sesquiterpene*, $C_{15}H_{24}$, b. p. 265·5—266°/750 mm., $a_D + 58°40'$, n_D^{20} 1·50602, D^{15} 0·9236. The latter is possibly identical with eudesmene.   H. W.

Determination of Constitutions in the Camphene Group.

V. Ossian Aschan (*Annalen*, 1913, **398**, 299—313).—Since Auwers has recently upheld, on refractometric evidence, Wagner's formula for camphene, the author has examined two carefully purified specimens of the hydrocarbon. These have been obtained from American and Grecian turpentines respectively, through the pinene hydrochlorides. Each has been twice recrystallised from methyl alcohol (whereby the m. p. is constant), and finally distilled over sodium in a vacuum. The camphene from American turpentine has b. p. 158—158·5°, m. p. 43—43·5°, $D_4^{7''}$ 0 8486, n_a^0 1·46048, and $[a]_D^{1b} + 17·95°$ in benzene. The camphene from Grecian turpentine has b. p. 157·2—157·9°/742 mm., m. p. 46—47°, $D_4^{7'}$ 0·8446, n_D' 1·45641, and $[a]_D^{20} + 74·55°$ in benzene. The molecular refractions, 43·98 and 43 85 respectively, are in close agreement with the value, 43·91, calculated for the semicyclic formula.

The formula $\begin{matrix} CH_2\cdot CH_2 \\ CO\text{——}O \end{matrix}{>}C(CO_2H)\cdot CMe_2\cdot CO_2H$ previously assigned by the author (A., 1910, i, 710) to the lactone-dicarboxylic acid, m. p. 256°, obtained from dehydrocamphenic acid, is now proved to be incorrect. The lactone-dicarboxylic acid is reduced to *iso*camphoronic

acid by hydriodic acid, b. p. 127—128°, at 170—180°. Since the constitution of *isocamphoronic* acid is

$$CO_2H \cdot CH_2 \cdot CMe_2 \cdot CH(CO_2H) \cdot CH_2 \cdot CO_2H,$$
and the lactone-dicarboxylic acid yields formic, succinic, and *iso*butyric acids by fusion with potassium hydroxide, it follows that the hydroxy-acid from which the lactone-dicarboxylic acid is derived must be

$$CO_2H \cdot CH(OH) \cdot CMe_2 \cdot CH(CO_2H) \cdot CH_2 \cdot CO_2H.$$
By boiling with hydriodic acid, by heating with 40% hydrogen bromide in glacial acetic acid, or with concentrated sulphuric acid at 100°, or with hydrochloric acid at 170—180°, the lactone-dicarboxylic acid is changed into a stereoisomeric *lactone-dicarboxylic acid*, $C_9H_{12}O_6$, m. p. 185—186°, large prisms. Such stereoisomerism is possible only when at least two side-chains are present attached to different carbon atoms of the lactone ring. Hence the constitutions of the two lactone-dicarboxylic acids are represented by

$$CO_2H \cdot CH_2 \cdot CH \overset{CO\text{---}O}{\underset{CMe_2 \cdot CH \cdot CO_2H}{<}} \cdot$$
On account of its sparing solubility, the isomeride, m. p. 256°, is regarded as having the trans-configuration.

The author is of opinion that Wagner's formula correctly represents the constitution of camphene. If this is the case, it follows from the preceding work that a transformation must have occurred in the carbon skeleton during the oxidation of camphene by alkaline potassium permanganate.　　　　　　　　　　　　　　　　C. S.

Bornylene and Ethyl Diazoacetate (with a Nomenclature for Tricyclic Carbon Ring Systems). EDUARD BUCHNER and WILHELM WEIGAND (*Ber.*, 1913, **46**, 2108—2117).—The constitution of camphene has recently been demonstrated in a purely chemical manner by the action of ethyl diazoacetate, and the same method is now applied to bornylene (this vol., i, 376). The results indicate that this reagent is of especial value for distinguishing between hemicyclic and endocyclic ethylenic linkings in terpene molecules.

The bornylene applied in this investigation, obtained from borneol through the corresponding methyl xanthate compound, was possibly not quite pure, as its optical activity was somewhat lower than that recorded in the literature; the impurities, however, could not be of such a nature as to affect the trustworthiness of the reaction with ethyl diazoacetate. A solution of ethyl diazoacetate in a little borneol was gradually introduced into a mixture of borneol with a little copper powder at 150°; the reaction is more sluggish than with camphene, but fractional distillation of the product separated *methyl* 4 : 5 : 5-*tri-methyl*tricyclo-[0,1,3 ⁴·⁶, 2]-*octane-2-carb-oxylate* (annexed formula), a colour-less oil, b. p. 136—137°/22 mm., D_4^{21} 1·0283, n_D 1·48337, $[\alpha]_D^{26}$ −8·72°.

$$\begin{array}{l} ^8CH_2 \cdot \overset{6}{C}H\text{---}CH \\ \mid \quad ^5CMe_2 \quad \mid^1 \searrow CH \cdot CO_2Me \\ CH_2 \cdot CMe\text{---}CH \\ ^7 \quad ^4 \quad ^3 \end{array}$$
By hydrolysis with alcoholic potassium hydroxide, the corresponding *acid* is obtained, leaflets, m. p. 137°; *calcium, barium, lead,* and *silver* salts, colourless, insoluble substances; *amide,* needles, m. p. 174°.

When the acid is heated with an acid solution of potassium permanganate, oxidation slowly occurs with formation of an oily substance, *trans-cyclo*propane-1 : 2 : 3-tricarboxylic acid, which very gradually crystallised. The identity of this acid was confirmed by the preparation of the silver and calcium salts and of the methyl ester, the m. p., 56—57°, of which was unaffected by admixture with a specimen of synthetic origin. These results are in accord with the annexed usual formula for bornylene.
$$CH_2 \cdot CH-CH$$
$$| \quad CMe_2 \quad |$$
$$CH_2 \cdot CMe-CH$$

The paper includes an authorised extension of von Baeyer's scheme of nomenclature for dicyclic systems to tricyclic ones. Each tricyclic system contains two tertiary or quaternary carbon atoms in the ring, which are linked by bridges of carbon chains; these bridges, of which there are four in each tricyclic system, are represented by numbers which represent the number of atoms in each; the grouping of these 4 numbers constitutes the "characteristic"; if these bridges do not extend between the same carbon atoms in each case, the numbers representing the carbon atoms which act as origin and extremity of the bridge must be appended to the corresponding number in the characteristic. The application of this scheme can be seen in the above description of the condensation product of bornylene and ethyl diazoacetate.

D. F. T.

The Synthesis of the Glucosides of the Terpene Alcohols by means of Emulsin. JUHO HAMALÄINEN (*Biochem. Zeitsch.*, 1913, 52, 409—411).—The author has shown (this vol., i, 497, 639) that certain glucosides of the terpene alcohols are readily hydrolysed by emulsin. It seemed therefore possible that synthesis could be effected by the same agency. He has succeeded in obtaining in small quantities synthetically the following glucosides, by allowing the alcoholic solutions of dextrose and the alcohol to react in the presence of emulsin in ethyl alcoholic solutions : *l*-fenchyl-*d*-glucoside, *r-iso*borneol-*d*-glucoside, and *l*-borneol-*d*-glucoside. The formation of these glucosides can explain the action of emulsin in producing glycuronates of terpene-alcohols when injected into animals. A synthetic action of the ferment seems more probable than the formation of an anti-substance, as suggested by various investigators. S. B. S.

Synthesis of β-Geranylglucoside by means of Emulsin; Its Presence in Plants. ÉMILE BOURQUELOT and MARC BRIDEL (*Compt. rend.*, 1913, 157, 72—74).—β-*Geranylglucoside* is obtained by the action of emulsin on a suspension of dextrose in geraniol saturated with water, or, better, by its action on a solution of the alcohol and sugar in acetone and water. It was separated by the usual method (compare this vol., i, 663), and obtained as a colourless liquid, $[\alpha]_D - 25°49'$, not reducing Fehling's solution, precipitated by basic lead acetate, and rapidly hydrolysed in aqueous solution by emulsin. A glucoside similarly hydrolysed by emulsin to dextrose and geraniol and precipitated by basic lead acetate can be extracted by alcohol from *Pelargonium odoratissimum*. W. G

Cerebronic Acid. III. Its Bearing on the Constitution of Lignoceric Acid. PHŒBUS A. LEVENE and C. J. WEST (*J. Biol. Chem.*, 1913, 15, 193—195).—Cerebronic acid yields a normal acid of 24 carbon atoms which is identical with lignoceric acid.   W. D. H.

Azafrin. II. CARL LIEBERMANN and W. SCHILLER (*Ber*, 1913, 46, 1973—1986. Compare A., 1911, i, 391).—Although azafrin and bixin (Hasselt, A., 1911, i, 550) both give blue solutions in concentrated sulphuric acid, they are not identical. This is now shown by the fact that azafrin and methylazafrin give very characteristic colour reactions with a large number of other strong mineral or organic acids, with which bixin gives, at most, only transient and poor effects. One, two, or three molecules of an acid may enter into combination, but the compounds are not simple salts, since azafrin cannot be regenerated from them. Oxidation, reduction, substitution, hydroxyl and ketone reactions have either failed or led to still more complicated substances, but, from the analysis of the above compounds, it seems certain that azafrin has the formula $C_{37}H_{42}O_5$.

It is advisable not be prolong the extraction of azafranillo roots and stems, since benzene dissolves a small amount of a resin which hinders the crystallisation of the desired azafrin. The latter is purified by precipitation from alkaline solution, has m. p. 208°, and yields *methyl-azafrin*, $C_{38}H_{44}O_5$, in sparkling, reddish-yellow leaflets or needles, m. p. 191°, when treated with methyl sulphate. The following *compounds* with acids have been isolated: $B_3,2H_2SO_4$, $B,3HI$, $B,2HBr$, B,HCl, $B,HClO_4$, and $B,3CCl_3·CO_2H$, where B=azafrin or methylazafrin. They are blue or violet in colour, and dissolve in alkalis with never more than partial loss of acid. Phosphoryl chloride, meta-phosphoric acid, and nitric acid also give coloured solutions, but especially characteristic is the reaction with hot anhydrous formic acid, which gives a deep violet solution which may be diluted with water to a stable permanganate-coloured liquid. Glacial acetic acid is a useful indifferent solvent for azafrin, but after boiling the solution for a long time, water precipitates an entirely different substance.

Reduction of azafrin and methylazafrin with zinc dust and acids yields white, amorphous *products*, $C_{31}H_{46}O_4$ and $C_{32}H_{48}O_4$ respectively, whilst hydriodic acid and red phosphorus give rise to compounds which contain phosphorus. Ammonium persulphate yields a white, flocculent acid.   J. C. W.

The Hydrogenation of Pyromucic Acid. HEINRICH WIENHAUS and HERMANN SORGE (*Ber.*, 1913, 46, 1927—1931).—Only in a few cases in the furan group have reductions been effected by hydrogen. The author, in this preliminary announcement, describes tetrahydro-pyromucic acid obtained by the reduction of pyromucic acid with hydrogen and colloidal palladium.

Tetrahydropyromucic acid, $\begin{smallmatrix} CH_2·CH_2 \\ CH_2——O \end{smallmatrix}\!\!>\!CH·CO_2H$, was prepared by adding to the aqueous solution of pyromucic acid a little palladious

chloride solution and gum arabic, and shaking with hydrogen. The acid was purified by distillation, b. p. 131°/14 mm., and then crystallises in rhombohedra, m. p. 21°. It is much more stable than pyromucic acid towards potassium permanganate. The *sodium* salt crystallises in thin tablets; the *potassium, ammonium, barium,* and *silver* salts are all crystalline. When treated with phosphorus trichloride, the free acid is converted into the *chloride,* which reacts with strong ammonia solution, producing the *amide,* leaflets, m. p. 80°, b. p. 135—140°/20 mm. The same amide is formed when the ammonium salt is heated at 200° under pressure.   D. F. T.

A New Chromone Synthesis. ERNST PETSCHEK and HUGO SIMONIS (*Ber.,* 1913, **46,** 2014—2020).—When phenols are condensed with β-ketonic acid esters in presence of sulphuric acid, the products are coumarin derivatives (1 : 2-benzopyrones), but when phosphoric oxide is used, chromones (1 : 4-benzopyrones) are obtained. Ethyl acetoacetate itself has not yet led to definite products, but the method is being extended, particularly with a view to the synthesis of flavone from ethyl benzoylacetate and phenol.

For the preparation of 2 : 3-*dimethylchromone,* $C_6H_4{<}^{O-CMe}_{CO\cdot CMe}$, the dark mass obtained by mixing a solution of dry phenol in ethyl methylacetoacetate with phosphoric oxide is diluted with water, treated with half the quantity of sodium hydroxide required to neutralise the acid, saturated with salt, and extracted with ether. The extract is washed with alkali, dried, and evaporated. The yield is 25%. The compound forms large, transparent, yellow, monoclinic crystals $[a:b:c=1\cdot5201:1:1\cdot5681,\ \beta=73°19\cdot5']$, m. p. 97°. One litre of water dissolves 0·5 gram at 0°, 1·5 grams at 15°, and 4·5 grams at 100°, and the substance is volatile in steam. It forms a *dibromide,* $C_{11}H_{10}O_2Br_2$, in unstable, orange-yellow needles, m. p. 130°, and an *oxime,* $C_{11}H_{10}O:N\cdot OH$, by the direct action of hydroxylamine, in colourless, silky needles, m. p. 158·5°. The isomeric 3 : 4-*dimethylcoumarin oxime,* prepared from 3 : 4-*dimethylthiocoumarin,* m. p. 142°, has m. p. 222°. The oxime of the dimethylchromone yields a *dibromide,* m. p. 180—184°, which readily parts with one molecule of hydrogen bromide to form 2-*bromo-4-nitroso*-2 : 3-*dimethylcoumaran,* $C_6H_4{<}^{C(NO):CMe}_{O-----CBrMe}$, in colourless needles, m. p. 205°.

2 : 3-Dimethylchromone is easily oxidised by permanganate or hydrolysed by 3% sodium hydroxide, yielding salicylic acid. When heated with sodium ethoxide (compare Heywang and Kostanecki, A., 1902, i, 816) it is hydrolysed to *o-hydroxypropiophenone,*

$$OH\cdot C_6H_4\cdot COEt,$$
which forms a colourless, mobile, unpleasant smelling oil, b. p. 150°/80 mm. It is sparingly soluble in water, and the solution gives an intense reddish-violet coloration with ferric chloride. The *hydrochloride* of dimethylchromone, $C_6H_4{<}^{O(HCl)\cdot CMe}_{CO----CMe}$, is a white, crystal-

line substance, m. p. 88—92°. On nitration with fuming acid in cold concentrated sulphuric acid, 6-*nitro*-2 . 3-*dimethylchromone*, $NO_2 \cdot C_6H_3 \Big\langle {\overset{O-CMe}{\underset{CO \cdot CMe}{\vphantom{|}}}}$, is obtained in colourless prisms, m. p. 163°, which dissolve in potassium hydroxide with intense yellow colour. The isomeric 6-*nitro*-3 : 4-*dimethylcoumarin*, $C_{11}H_9O_4N$, from 3 : 4-dimethyl-coumarin has m. p. 172°. Both compounds yield 5-nitrosalicylic acid on oxidation. 7(?)-*Chloro*-6-*amino*-2 : 3-*dimethylchromone*, $C_{11}H_{10}O_2NCl$, is obtained when the nitro-compound is reduced by means of tin and hydrochloric acid. It has m. p. 245°, absorbs bromine, and yields a dark red chlorohydroxydimethylchromone.
p-Cresol and ethyl methylacetoacetate condense to form 2 : 3 : 6-*trimethylchromone* (annexed formula) in long, colourless, sparkling needles, m. p. 107°, which yield 5-methylsalicylic acid on hydrolysis with dilute alkali. Similarly, *m*-cresol yields 2 : 3 : 7(or 5)-*trimethylchromone*, in clusters of colourless needles, m. p. 96°. The oxidation to a methylsalicylic acid has met with difficulties. J. C. W.

A Simple Process for the Preparation of Flavones. Synthesis of Thioflavone. SIEGFRIED RUHEMANN (*Ber.*, 1913, 46, 2188—2197).—The author has succeeded in condensing β oxyaryl-cinnamic acids to flavones by heating their chlorides with aluminium chloride. Flavones which are substituted in position 8, ortho to the pyrone oxygen, do not show the fluorescence in concentrated sulphuric acid which is characteristic of these compounds in general. In the case of the hydroxyflavones, the removal of the hydroxyl group from the pyrone oxygen is accompanied by a constant depression of the melting point.

The condensation is carried out by adding phosphorus pentachloride to a suspension of the acid in dry benzene and warming until solution takes place, when aluminium chloride is introduced into the product. In this way β-phenoxycinnamic acid (T., 1900, 77, 986) gives an almost theoretical yield of flavone; β-*o*-tolyloxycinnamic acid (*loc. cit.*, 988) forms 8-*methylflavone*, $C_6H_3Me \Big\langle {\overset{CO \cdot CH}{\underset{O-CPh}{\vphantom{|}}}}$, in colourless needles, m. p. 170°, which are gradually decomposed by boiling concentrated potassium hydroxide into acetophenone; β-*m*-tolyloxycinnamic acid (*loc. cit.*, 1120) yields a mixture of 5- and 7-methylflavones; β-*p*-tolyl-oxycinnamic acid (*loc. cit.*, 989) gives 6-*methylflavone*, in colourless needles, m. p. 122—123°, and β-thymoxycinnamic acid (T., 1901, 79, 918) forms 5-*methyl*-8-iso*propylflavone*, $C_{19}H_{18}O_2$, which crystallises in colourless needles, m. p. 143—144°. For the preparation of the isomeride of the latter, ethyl phenylpropiolate was added to a solution of sodium in excess of carvacrol, the resulting yellow, viscous *ethyl β-carvacroxycinnamate*, $C_6H_3MePr \cdot O \cdot CPh:CH \cdot CO_2Et$, b. p. 225°/ 12 mm., was hydrolysed to β-*carvacroxycinnamic acid*, $C_{19}H_{20}O_3$, which formed well-defined, rhombic crystals from light petroleum, and lost carbon dioxide on heating above 103°, and this acid was treated as

above. 8-*Methyl*-5-*isopropylflavone* forms colourless prisms, m. p. 149—150°.

Similarly, β o-methoxyphenoxycinnamic acid (T., 1900, **77**, 1181) was converted into 8-*methoxyflavone*, $C_{16}H_{12}O_3$, which crystallised in colourless, silky needles, m. p. 199—200°, and formed 8-*hydroxy-flavone*, $C_{15}H_{10}O_3$, in colourless needles, m. p. 249—250°, by hydrolysis with concentrated hydriodic acid in a sealed tube. Finally, β-phenylthiolcinnamic acid (*ibid.*) was condensed in the same way to *thioflavone*,

$$C_6H_4 < \begin{matrix} CO \cdot CH \\ S—CPh \end{matrix}, $$ which forms white needles, m. p. 129—130°, and dissolves in warm, concentrated hydrochloric acid. The sulphonium salt and the platinichloride are, however, decomposed by water.

J. C. W.

Thiotetronic Acid and Derivatives. ERICH BENARY (*Ber.*, 1913, **46**, 2103—2107. Compare A., 1910, i, 434, 579).—The results of Anschütz and Bertram (A., 1903, i, 271) suggest that the hitherto unknown thiotetronic acid might be obtained through the interaction of ethyl sodiomalonate and acetylthiolacetyl chloride.

Acetylthiolacetic acid, $SAc \cdot CH_2 \cdot CO_2H$, is obtained by mixing thioglycollic acid and acetyl chloride, when a vigorous reaction ensues; the acid, b. p. 158—159°/17 mm., which can also be obtained by the interaction of thioacetic acid and chloroacetic acid in alkaline solution, gives a deep blue colour with ferric chloride solution, and is converted by phosphorus pentachloride into *acetylthiolacetyl chloride*, a pungent liquid, b. p. 93—95°/20 mm. The chloride cooled in ethereal solution reacts with ethyl sodiocyanoacetate, yielding *ethyl acetylthiol-acetylcyanoacetate* [α-cyano-β-hydroxy-γ-acetylthiol-Δ°-butenoate],

$$SAc \cdot CH_2 \cdot C(OH){:}C(CN) \cdot CO_2Et,$$
colourless needles, m. p. 70—71°, which indicates its enolic character by a red coloration with ferric chloride and by its acidity. Under similar conditions with ethyl sodioacetoacetate, the *sodium* derivative of *ethyl acetylthiolacetylacetoacetate* is obtained; the free ester is a heavy, yellow oil which passes very readily with elimination of alcohol into α-*acetylthiotetronic acid*, $\begin{matrix} CH_2 \cdot C(OH) \\ S———CO \end{matrix} > C \cdot OAc$, an acidic substance,

needles, m. p. 86—88°; *phenylhydrazone*, yellow needles, m. p. 173—174°, of feeble acid properties. In an analogous manner the interaction of acetylthiolacetyl chloride with ethyl sodiomalonate yields oily *ethyl acetylthiolacetylmalonate*, which on dissolving in sodium hydroxide solution and reprecipitation by acid eliminates a molecule of alcohol with formation of *ethyl thiotetron-α-carboxylate*,

$$\begin{matrix} CH_2 \cdot C(OH) \\ C———CO \end{matrix} > C \cdot CO_2Et,$$ needles, m. p. 122—123°; this reacts acid and gives a blood-red coloration with ferric chloride. On boiling with water for an hour, the ester is converted into *thiotetronic acid*,

$$\begin{matrix} S—CH_2 \\ CO \cdot CH \end{matrix} > C \cdot OH,$$ colourless needles, m. p. 115—117°, which behaves as a monobasic acid and gives a deep red coloration with ferric chloride;

the *silver* salt was prepared. With sodium nitrite, its aqueous solution produces a deep violet coloration. D. F. T.

Isomerism with Diacid Quaternary Ammonium Bases of the Coniine Group. Asymmetric Nitrogen 46. EDGAR WEDEKIND and F. NEY (*Ber.*, 1913, **46**, 1895—1899. Compare Wedekind, A., 1912, i, 509, 948).—Although many investigations have been made, in only one case (E. and O. Wedekind, A., 1910, i, 834) have the two isomeric forms of a diquaternary ammonium salt, in which the nitrogen atoms are asymmetric, been isolated. Endeavours have now been made to effect this isolation of the isomerides by using compounds containing an active asymmetric carbon atom. The addition of menthyl indoacetate to ditertiary bases is not satisfactory. It was found, however, that the aim could be achieved by the application of diacid bases derived from coniine.

*Ethylene-bis-*d-*coniine,*

$$CH_2 \overset{CH_2 \cdot CHPr^a}{\underset{CH_2---CH_2}{<}} N \cdot CH_2 \cdot CH_2 \cdot N \overset{CHPr^a \cdot CH_2}{\underset{CH_2---CH_2}{<}} CH_2,$$
b. p. 200—203°/19 mm., $[a]_D$ +81·09°, obtained by warming together for three hours a mixture of ethylene bromide with a quadrimolecular proportion of *d*-coniine, reacts with benzyl bromide, producing a mixture of diquaternary ammonium salts with an amine-ammonium salt, but the solubility differences in the products are too small to permit separation. With benzyl iodide the chief product, when the reaction occurs unassisted, is the amine-ammonium salt, decomp. at 178°, but if excess of warm molten benzyl iodide is introduced into the warm ditertiary base the product consists mainly of two diquaternary ammonium salts which can be separated by extraction with a mixture of alcohol and acetone; the more soluble and more abundant isomeride (termed *a*-), prisms, decomp. at 130—131°, has $[a]_D$ +40·42°, whilst the β-isomeride, cubical crystals, decomp. at 214°, has $[a]_D$ +15·42°, the solutions in both cases being observed in methyl alcoholic solution.

From theoretical reasons, three isomerides might be expected, represented by the schemes $(N+,C+) \ldots (N+,C+)$, $(N-,C+) \ldots (N-,C+)$, and $(N+,C+) \ldots (N-,C+)$. The *a*- and β-forms isolated are believed to be represented by the first two structures, the isomeride of the third configuration being too unstable to exist under the conditions of the experiment and so passing into the first form. This view is confirmed by the fact that the isomeride of higher rotation, and therefore of the first configuration, preponderates in the reaction product.

*Trimethylene bis-*d-*coniine,* obtained in an analogous manner from coniine and trimethylene bromide, has b. p. 200—201°/17 mm.; unfortunately, its diquaternary salts with benzyl bromide, benzyl iodide, and methyl iodide are amorphous, whilst with allyl iodide the product, which is at first amorphous, on keeping under ether becomes partly crystalline, but very easily undergoes decomposition. That the last substance is the expected *trimethylenebisallylconiinium iodide* was proved by analysis of the corresponding *platinichloride.* D. F. T.

The Behaviour of 2-Methylindole towards Aldehydes and Formic Acid. MAX SCHOLTZ (*Ber.*, 1913, **46**, 2138—2146).—The

interaction of 2-methylindole with aldehydes in alkaline media is strikingly different from its behaviour in acid or neutral solution (Fischer, A., 1887, 265; Freund and Lebach, A., 1905, i, 663).

If equimolecular quantities of 2-methylindole and benzaldehyde are treated with sodium hydroxide solution, a reaction occurs in which the solvent is implicated, for the product is *ethoxyphenyl-2-methylindolyl-methane*, OEt·CHPh·C$\underset{\text{OMe}}{\overset{\text{C}_6\text{H}_4}{<}}$NH, colourless leaflets, m. p. 123°.

A similar reaction with *p*-tolualdehyde in place of benzaldehyde yields *ethoxy-p-tolyl-2-methylindolylmethane*, $C_6H_4Me\cdot CH(OEt)\cdot C_9H_8N$, colourless prisms, m. p. 101°. If methyl alcohol is applied as solvent instead of ethyl, the product is *methoxy-p-tolyl-2-methylindolylmethane*, $C_6H_4Me\cdot CH(OMe)\cdot C_9H_8N$, colourless prisms, m. p. 153°.

Furfuraldehyde, 2-methylindole, and ethyl alcohol under similar conditions yield *ethoxyfuryl-2-methylindolylmethane*,
$$C_4OH_3\cdot CH(OEt)\cdot C_9H_8N,$$
colourless needles, m. p. 158°. With methyl alcohol as solvent, *methoxyfuryl-2-methylindolylmethane*, $C_4OH_3\cdot CH(OMe)\cdot C_9H_8N$, grey prisms, m. p. 108°, is obtained.

The product from anisaldehyde, 2-methylindole, and ethyl alcohol is *ethoxy-p-anisyl - 2 - methylindolylmethane*, $OMe\cdot C_6H_4\cdot CH(OEt)\cdot C_9H_8N$, colourless tablets, m. p. 133°; with methyl alcohol the product is *methoxy-p-anisyl-2-methylindolylmethane*, colourless leaflets, m. p. 151°.

o-Chlorobenzaldehyde, 2-methylindole, and ethyl alcohol yield *ethoxy-o-chlorophenyl-2-methylindolylmethane*, $C_6H_4Cl\cdot CH(OEt)\cdot C_9H_8N$, tablets, m. p. 122°; methyl alcohol gives *methoxy-o-chlorophenyl-2-methyl-indolylmethane*, needles, m. p. 91°.

m-Nitrobenzaldehyde, 2-methylindole, and ethyl alcohol produce *ethoxy-m-nitrophenyl-2-methylindolylmethane*,
$$NO_2\cdot C_6H_4\cdot CH(OEt)\cdot C_9H_8N,$$
yellow leaflets, m. p. 130°; methyl alcohol gives *methoxy-m nitro-phenyl-2-methylindolylmethane*, yellow, rhombic prisms, m. p. 155°.

Nearly all the above products have a tendency to redden if kept in a moist condition.

The behaviour of *o*-nitrobenzaldehyde is curiously abnormal, for, whether methyl or ethyl alcohol is used as solvent, and sodium hydroxide or piperidine as alkali, the one product is *o-nitrophenyl-2-methylindolylcarbinol*, $NO_2\cdot C_6H_4\cdot CH(OH)\cdot C_9H_8N$, orange-red leaflets, m. p. 138°.

Salicylaldehyde also failed to react in the above general manner with methylindole and alcohol, for under the usual conditions the sodium salt of salicylaldehyde is deposited, whilst if water is added to retain this, *o*-hydroxyphenyldi-2-methylindolylmethane (Freund and Lebach, *loc. cit.*) separates. If, however, the mixture of salicyl-aldehyde and methylindole in alcohol is made alkaline by piperidine in place of sodium hydroxide, the piperidine nucleus enters into the reaction product, which is *piperidino-o-hydroxyphenyl-2-indolylmethane*, $C_5H_{10}N\cdot CH(C_6H_4\cdot OH)\cdot C_9H_8N$, colourless prisms, m. p. 201°.

p-Homosalicylaldehyde with piperidine and methylindole in alcoholic solution behaves similarly to salicylaldehyde, producing *piperidino-*

o-*hydroxy-m-tolyl-2-methylindolylmethane*,

$$OH \cdot C_6H_3Me \cdot CH(C_5H_{10}N) \cdot C_9H_8N,$$
colourless needles, m. p. 132°. These two piperidino-compounds were the only ones obtainable in a crystalline condition, the products from other aldehydes being oily.

That the 3-carbon atom of the pyrrole nucleus is not entirely deprived of its activity in alkaline media is evidenced by the occasional occurrence of traces of di-indolyl derivatives in the reaction product; indeed, with *p*-hydroxybenzaldehyde and cinnamaldehyde the products are entirely of this type. The former aldehyde with piperidine and 2-methylindole in alcoholic solution gives rise to *p-hydroxyphenyl-bis-2-methylindolylmethane*, $OH \cdot C_6H_4 \cdot CH(C_9H_8N)_2$, a crystalline powder, m. p. 237°; in a similar manner, by condensation of one molecule of aldehyde with two molecules of 2-methylindole, cinnamaldehyde produces *styryl-bis-2-methylindolylmethane*,

$$CHPh{:}CH \cdot CH(C_9H_8N)_2,$$
yellow needles, m. p. 226°.

A solution of 2-methylindole in formic acid in a short time becomes deep red, and the addition of water then causes the separation of 2-*methylindolyl-2-methylindolidenemethane*,

$$N{<}^{C_6H_4}_{CMe}{>}C{=}CH{-}C{<}^{C_6H_4}_{CMe}{>}NH,$$
as the *formate*, red needles, m. p. 104°, from which the free *base*, an orange-yellow powder, m. p. 230°, is liberated by ammonium hydroxide; *hydrochloride*; *hydrobromide*, fiery-red needles, m. p. 236°; *perchlorate*, red needles, decomp. at 260°.   D. F. T.

Colours of the Second Order: *holo-* and *meri-*Quinonoid Salts. JEAN PICCARD (*Ber.*, 1913, 46, 1843—1860).—The author has systematically examined the *holo-* and *meri-*quinonoid salts derived from a number of *N*-methyl- and *N*-phenyl-substituted benzidines and *p*-phenylenediamines, and comes to the conclusion that Nietzki's well known rule connecting the increase in the complexity of the molecule with the deepening of the colour from yellow through red and blue to yellowish-green requires modification.

Whereas the *meri-*quinonoid salts derived from benzidine and its diphenyl derivative are coloured respectively blue and yellowish-green, the *meri-*quinonoid salts of tetraphenylbenzidine are yellow.

The author explains this apparent exception as follows: When the complexity of the molecule has been gradually increased to such an extent that the colour has passed successively from yellow to red, blue, bluish-green, and finally yellowish-green, the further increase in the complexity causes a repetition of these colours in the same order; and from analogy with the interference colours the second series are termed colours of the second order.

The *meri-*quinonoid salts of tetraphenylbenzidine thus have a yellow colour of the second order.

Aqueous solution of *meri-*benzoquinonephenyldi-imonium salts are formed by the oxidation of *p*-aminodiphenylamine. The salts are bluish-red and are very unstable, decomposing rapidly in concentrated solution

with the formation of emeraldine. The yellow *holo*-quinonoid salts are still less stable.

Solutions of meri-*benzoquinonephenyldimethyldi-imonium* salts are obtained by oxidising *p*-dimethylaminodiphenylamine in acetic acid solution by means of ferric sulphate. They have a blue colour, whilst those of the *holo*-quinonoid salts are red or reddish-yellow according as they are formed by the union of the base with one or two molecules of the acid ; a blue *ferricyanide* was prepared by methods similar to those employed by Willstätter and Kalb (A., 1908, i, 475).

Benzoquinonediphenyldi-imine (Bandrowski, A., 1888, 269) combines with NN'-diphenyl-*p*-phenylenediamine· to form a quinhydrone *base*, crystallising in yellow leaflets, m. p. 130—135° ; the *holo*-quinonoid salts give red solutions, the *meri*-quinonoid salts greenish-blue ; the *holo*-quinonoid *picrate*, $C_{18}H_{14}N_2,C_6H_8O_7N_8$, forms dark red prisms, the *meri*-quinonoid *picrate*, $C_{86}H_{80}N_4,2C_6H_8O_7N_8$, long, green needles.

Solutions of the *meri*-quinonoid salts derived from tetraphenyl *p*-phenylenediamine are green, whilst those of the *holo*-quinonoid salts are blue ; the salts were not isolated.

On account of their instability. *holo*-diphenoquinonedi-imonium salts, which are yellow in colour, have hitherto not been isolated (compare Willstätter and Kalb, A., 1908, i, 986) ; the *picrate*,

$$C_{12}H_{10}N_2,2C_6H_8O_7N_3,$$
is obtained in pointed, brownish-yellow needles by oxidising benzidine dissolved in glacial acetic acid with aqueous chromium trioxide, and adding picric acid to the resulting solution.

The *holo*-quinonoid base derived from diphenylbenzidine is precipitated in an impure condition by the addition of sodium carbonate to aqueous solutions of the salts, which have been described by Kehrmann and Micewicz (A., 1912, i, 1020).

The green *holo*-quinonoid and yellow *meri*-quinonoid salts derived from tetraphenylbenzidine are obtained by oxidising the base with the requisite amount of chromium trioxide in glacial acetic acid solution ; addition of water and picric acid to these solutions precipitates a very unstable green holo- and a yellow meri-*diphenoquinone-tetraphenyldi-imonium picrate*,

$$C_6H_2O_7N\cdot NPh_2\text{:}C_6H_4\text{:}C_6H_4\text{:}NPh_2\cdot C_6H_2O_7N$$
$$NPh_2\cdot C_6H_5\cdot C_6H_5\cdot NPh_2$$
which crystallises in prisms, m. p. 130—134°.   F. B.

holo- and *meri*-Quinonoid Salts of Benzidine. JEAN PICCARD (*Ber.*, 1913, **46**, 1860—1862).—A reply to Madelung (A., 1911, i, 678). The author maintains that the *holo*-quinonoid salts of benzidine are yellow and not blue or violet as stated by Madelung.   F. B.

Hippenyl *iso*Cyanate [Benzoylaminomethylcarbimide]. THEODOR CURTIUS (*J. pr. Chem.*, 1913, [ii], **87**, 513—541).—A recapitulation and extension of earlier work (A., 1896, i, 36) The dibromide of phenylcarbimide, $NPhBr_2\text{:}CO$, which has been previously obtained in an impure condition by boiling benzoylazoimide with bromine in chloroform solution, is prepared by the direct union of bromine and

phenylcarbimide in chloroform solution at a low temperature. It has m. p. 144°, and if carefully heated sublimes undecomposed. When strongly heated, it loses hydrogen bromide, yielding *p*-bromophenyl-carbimide. Benzoylaminomethylcarbimide, $COPh\cdot NH\cdot CH_2\cdot N\text{:}CO$, prepared by heating hippurylazoimide in benzene, chloroform, or carbon tetrachloride solution, has m. p. 96—98° according to the rapidity of heating, combines with methyl and ethyl alcohols to form the urethanes previously described (*loc. cit.*), and when boiled with water yields *s*-dibenzoylaminodimethylcarbamide together with a *substance*, m. p. 130°. It combines with benzamide to form *s*-*benzoylamino-methylbenzoylcarbamide*, $COPh\cdot NH\cdot CH_2\cdot NH\cdot CO\cdot NH\cdot COPh$, which has m. p. 221°, and has also been obtained by heating hippurylazo imide with benzamide in xylene solution.

p-*Bromohippurylazoimide*, prepared from p-*bromohippurylhydrazide* (needles, m. p. 226°) in a similar manner to that employed in the preparation of hippurylazoimide from hippurylhydrazide, crystallises in long, lustrous, silky needles, m. p. 98°, and is converted by boiling in benzene solution into p-*bromobenzoylaminomethylcarbimide*, $C_6H_4Br\cdot CO\cdot NH\cdot CH_2\cdot N\text{:}CO$, which crystallises in broad needles, m. p. 114°, unites with hydrogen chloride in benzene solution yielding a *hydrochloride*, m. p. 235° with previous sintering, and combines with ethyl and methyl alcohols to form the corresponding *urethanes* of m. p. 174° and 214° respectively.

When boiled with water, benzoylazoimide yields only carbanilide, whilst hippurylazoimide gives rise to the following products : carbon dioxide, nitrogen, formaldehyde, hydrazoic acid and its ammonium salt, benzamide, benzoic acid, methylenediamine, ammonium hydrogen hippurate, *s*-dibenzoylaminodimethylcarbamide, and *s*-*benzoylhippuryl-methylenediamine*, $COPh\cdot NH\cdot CH_2\cdot NH\cdot CO\cdot CH_2\cdot NH\cdot COPh$, which crystallises in slender, silky needles, m. p. 234°, and is hydrolysed by boiling dilute sulphuric acid to benzoic acid, glycine, ammonia and formaldehyde In aqueous alcoholic solution, the decomposition of hippurylazoimide is much simpler, the sole products being dibenzoyl-aminodimethylcarbamide and the urethane,

$$COPh\cdot NH\cdot CH_2\cdot NH_2\cdot CO_2Et.$$
When boiled with water, *p*-bromohippurylazoimide yields di-*p*-bromo-benzoylaminodimethylcarbamide (Heil, *Diss, Heidelberg*, 1911), hydrazoic acid and its ammonium salt, formaldehyde, *p*-bromobenzamide, and *p*-bromohippuric acid. F. B.

Benzoylhydrazicarbonyl. OTTO DIELS and HARUKICHI OKADA (*Ber.*, 1913, **46**, 1870—1876. Compare A., 1912, i, 511, 918).— Benzoylhydrazicarbonyl reacts with acid chlorides, yielding compounds which are undoubtedly derivatives of the type

$$CO<\begin{smallmatrix} N\cdot COPh \\ N\cdot R \end{smallmatrix},$$
although the formation of metallic salts is best represented on the assumption that the hydrazi-compound has the tautomeric formula
$OH\cdot C<\begin{smallmatrix} N\cdot COPh \\ N \end{smallmatrix}$. Thus, with benzoyl chloride and aqueous potassium

hydroxide it yields dibenzoylhydrazicarbonyl (Stollé and Krauch, this vol , i, 97), which is hydrolysed by fuming hydrochloric acid to benzoic acid and benzoylhydrazicarbonyl, and by dilute sodium hydroxide to *s-dibenzoylhydrazide,* crystallising in lustrous, white needles, m. p. 238°.

Ethyl benzoylhydrazicarbonylcarboxylate, $CO<^{N \cdot COPh}_{N \cdot CO_2Et}$, prepared from benzoylhydrazicarbonyl and ethyl chloroformate, forms colourless crystals, m. p. 94°, and is hydrolysed by warm aqueous sodium hydroxide to *ethyl benzoylhydrazinecarboxylate,* $NHBz \cdot NH \cdot CO_2Et$, which forms lustrous, white plates, m. p. 127°.

On nitration with sulphuric acid and ethyl nitrate, benzoylhydrazicarbonyl is converted into p-*nitrobenzoylhydrazicarbonyl.* This crystallises in pale yellow leaflets, m p. 248°, and is reduced by zinc dust and formic acid to p-*aminobenzoylhydrazicarbonyl,* which forms lustrous, silky, colourless leaflets, m. p. 144°, and yields a *sulphate* (decomp. 238°), *hydrochloride,* and *nitrate.* The amino-compound is decomposed by fuming hydrochloric acid at 130° into aniline and hydrazine hydrochloride, and when heated with hydrazine hydrate is transformed into p-*aminobenzoylcarbohydrazide,*

$$NH_2 \cdot C_6H_4 \cdot CO \cdot NH \cdot NH \cdot CO \cdot NH \cdot NH_2,$$
which crystallises from water in lustrous, white leaflets (decomp. 198°), is hydrolysed by hydrochloric acid to *p* aminobenzoic acid and carbohydrazide, and may also be obtained directly from *p*-nitrobenzoylhydrazicarbonyl by the action of hydrazine hydrate at 80°.

<div align="right">F. B.</div>

Constitution of Benzoylhydrazicarbonyl. ROBERT STOLLÉ (*Ber ,* 1913, **46**, 1993—1994).—The reactions of dibenzoylhydrazicarbonyl (this vol., i, 97) agree with either the hydrazicarbonyl formula (I), which has been assigned by Diels and Okada to benzoylhydrazicarbonyl (preceding abstract), or with the dihydro-oxadiazole formula (II).

$$(I) \quad CO<^{NBz}_{NBz} \qquad (II) \quad {}^{NBz \cdot N}_{CO—O}>CPh.$$
The author proposes to combine nitrobenzoylhydrazicarbonyl with benzoyl chloride and benzoylhydrazicarbonyl with nitrobenzoyl chloride, when the compounds should be identical if formula (I) is correct

<div align="right">J. C. W.</div>

New Series of *iso*Pyrazolones. GEORGES FAVREL (*Compt. rend.,* 1913, **156**, 1912—1914).—It has been shown previously that the γ-chloroacetoacetates react with diazo-chlorides to give the α-alkylhydrazones of γ-chloro-αβ diketobutyrates (A., 1907, i, 796). The latter are now shown to be converted by the action of aqueous solution of sodium hydroxide into alkyl*iso*pyrazolonecarboxylates.

Ethyl phenyliso pyrazolonecarboxylate, $NPh<^{N = C \cdot CO_2Et}_{CH_2 \cdot CO}$, m. p. 258—260°, obtained by the action of aqueous sodium hydroxide solution on the α-phenylhydrazone of ethyl γ-chloro-αβ-diketo-

butyrate, $CH_2Cl\cdot CO\cdot C(N_2HPh)\cdot CO_2Et$, crystallises in long, brilliant, faintly yellow needles from boiling alcohol. The *methyl* ester, m. p. 85—87°, forms small, colourless needles.

*Ethyl o-tolyl*isopyrazolonecarboxylate, m. p. 66—68°, forms feebly yellow crystals with difficulty from alcohol. The *methyl* ester, m. p. 178°, forms whitish crystals soluble in methyl alcohol.

*Ethyl p-tolyl*isopyrazolonecarboxylate, m. p. 111—112°, forms yellow needles, and the *methyl* ester is a crystalline, yellow powder, m. p. 218—220°. All these products in alcoholic solution give intense blue colorations with ferric chloride, which are dissipated by acids. They are soluble in weakly alkaline or strongly acid, but not in dilute acid, solutions. T. A. H.

The Benzoylation of Iminazole [Glyoxaline] Derivatives. OTTO GERNGROSS (*Ber.*, 1913, **46**, 1908—1913).—The author finds that the introduction of acyl groups into iminazole and its homologues, which has hitherto been found impossible, can be affected by mixing the acyl chloride with a bimolecular proportion of the base in ether or benzene solution and shaking for a day or so. The hydrogen chloride formed separates in combination with the excess of base and the acylation proceeds smoothly. If necessary the excess of base can frequently be replaced by the corresponding quantity of pyridine. The benzoyl derivatives are very unstable, and in the course of the preparation great care must be taken for the exclusion of traces of moisture.

1-*Benzoylglyoxaline*, $\begin{smallmatrix} CH:CH \\ N=CH \end{smallmatrix}$>NBz, obtained by evaporation of the benzene solution after the above procedure, slowly crystallises in colourless needles, m. p. 19—20°; when exposed to the air it is rapidly converted by moisture into glyoxaline benzoate, plates, m. p. 99·5°.

1-*Benzoyl*-4(5)-*methylglyoxaline*, obtained in a similar manner, forms needles, m. p. 54—55°; when treated in alcoholic solution successively with silver nitrate and ammonium hydroxide solutions, a *substance* crystallising in needles is precipitated. On exposure to the atmosphere, the benzoyl compound is gradually converted into 4(5)-methylglyoxaline benzoate, plates, m. p. 92—93°.

1-*Benzoyl*-4 : 5-*dimethylglyoxaline*, prepared similarly, forms hexagonal plates, m. p. 74—75°. It is affected by the atmosphere.

Ethyl 1-*benzoyl*-4(5)-*methylglyoxaline*-5(4)-*carboxylate* forms needles, m. p. 43—45°.

1-Benzoylbenziminazole is obtainable in a similar manner to the previous compounds. Although the simultaneously produced benziminazole hydrochloride can be quantitatively re-converted into the original base, if it is preferred the excess of benziminazole can be replaced by pyridine. The benzoyl derivative is more stable than the preceding ones, for although it is hydrolysed by potassium hydroxide solution, it resists sodium carbonate; it gives a *benzoate*, prisms, m. p. 100°, when mixed in ethereal solution with benzoic acid. The precipitate observed by Bamberger and Berlé (A., 1892, 632) in the action of potassium hydroxide on the benzoyl compound was due to the presence of the alcoholate of 1 : 3-dibenzoylbenziminazole as impurity.

Benziminazole can be converted into 1-acetylbenziminazole (Bistrzycki and Przeworski, this vol., i, 103) in the same manner.

<div align="right">.   D. F. T.</div>

The Mechanism of the Scission of Iminazole [Glyoxaline] Derivatives by Benzoyl Chloride and Alkali. OTTO GERNGROSS (*Ber.*, 1913, **46**, 1913—1924).—The action of benzoyl chloride and an alkali hydroxide on glyoxaline, benziminazole, and their homologues in which the imino-group is unsubstituted, even at 0°, causes scission of the ring with formation of an aliphatic acid and a dibenzoylated diamine (Bamberger and Berlé, A., 1892, 632). If sodium carbonate is used in place of the hydroxide with benzoyl chloride and benzimin-azole, a formyldibenzoyl-*o*-phenylenediamine can be obtained, and with benzoyl chloride and water in solution in a mixture of benzene and ether, benziminazole gives a dibenzoylbenziminazole-2-ol; these two new products are evidently to be regarded as intermediate steps in the above scission, and the former compound is easily produced from the latter. It is therefore probable that the mechanism of the scission is similar to that of the scission by alkyl haloids and alkali (compare Meldola and Kuntzen, T., 1911, **99**, 1283), namely:

$$\begin{array}{ccc}
\underset{\text{-N}}{\overset{\text{-NBz}}{>}}\text{CH} \longrightarrow C_6H_4\underset{\text{-N}}{\overset{\text{NBz}}{<}}\text{OH} \longrightarrow C_6H_4\underset{\text{NBz}}{\overset{\text{NBz}}{<}}\text{OH·OH} \\
\text{(I.)} \qquad\qquad\qquad \text{(II.)} \qquad\qquad \text{(III.)} \\
\text{Cl} \quad \text{Bz} \qquad\qquad\qquad \downarrow \\
\text{NHBz·C}_6\text{H}_4\text{·NHBz} \longleftarrow \quad \text{NHBz·C}_6\text{H}_4\text{·NBz·COH} \\
\text{(V.)} \qquad\qquad\qquad\qquad\qquad \text{(IV.)}
\end{array}$$
for the last three stages can thus be experimentally realised.

When benzoyl chloride is gradually added to an agitated and cooled aqueous solution of sodium carbonate and 4(5)-methylglyoxaline, a *substance*, tetragonal plates, m. p. 144° (decomp.), probably dibenzoyl-formyl-*αβ*-diaminopropylene, is obtained, which, when boiled with water or treated with cold sodium hydroxide solution, undergoes fission into dibenzoyldiamino-*αβ*-propylene and formic acid.

Experiments devoted to the isolation of the hypothetical additive compound (formula II above) of benzoylbenziminazole and benzoyl chloride were fruitless, the only new product being a small quantity of *benzoylbenziminazole hydrochloride*, needles, m. p. 195—200°, which is converted by alkali hydroxides into benziminazole.

1 : 3-*Dibenzoylbenziminazole-2-ol* (formula III above) is obtained by vigorously shaking for several hours an equimolecular mixture of benzoylbenziminazole and benzoyl chloride with a half-molecular pro-portion of water in a mixture of benzene and ether; the substance crystallises in cubes, and above its m. p., 135—140°, gradually re-solidifies to needles of *formyldibenzoyl-o-phenylenediamine* (formula IV), m. p. 157°; this substance on further heating also solidifies with evolution of carbon monoxide and formation of dibenzoyl-*o*-phenylene-diamine, which finally melts at 306° (decomp.), due to the last stage in the series of changes. The opening of the ring expressed by the formulæ III—IV, which is thus caused by heat, can be effected more readily by merely shaking with cold water or warming with methyl

alcohol. Dibenzoylbenziminazole-2-ol when boiled with alcohol or mixed in the cold with alcohol containing hydrogen chloride or even a little benzoyl chloride is converted into the corresponding *ethyl ether*, $C_6H_4<^{NBz}_{NBz}>OH\cdot OEt$; when heated with propyl alcohol the ethyl radicle is displaced with formation of the propyl ether. Above its m. p., 139°, the ethyl ether undergoes conversion into an *isomeride*, needles, m. p. 152°, which regenerates the original form on mere recrystallisation. In addition to the above-mentioned method, 1 : 3-*dibenzoylbenziminazolol propyl ether*, prisms, m. p. 135—136°, can also be obtained by heating the parent hydroxy-compound with propyl alcohol containing a trace of hydrogen chloride ; in the absence of the hydrogen chloride the iminazole ring is forced open.

The action of benzoyl chloride and sodium carbonate solution on benziminazole yields a mixture of formyldibenzoyl-*o*-phenylenediamine and dibenzoyl-*o*-phenylenediamine, which can be separated by making use of the greater solubility of the former in light petroleum or benzene. The formyldibenzoyl-*o*-phenylenediamine on prolonged boiling with water or more quickly with acids or alkalis is converted into formic acid and dibenzoyl-*o*-phenylenediamine.

It is suggested that the opening of the quinoline and benzothiazole rings by benzoyl chloride and alkali (Reissert, A., 1905, i, 925) may be due to a similar series of changes. D. F. T.

*iso*Hydantoin, 2-Imino-4-ketotetrahydro-oxazole, and its Homologues. WILHELM TRAUBE and RICHARD ASCHER (*Ber.*, 1913, 46, 2077—2084).—The reaction of guanidine with esters of α-amino- and α-hydroxy-acids is more complex than with esters of halogen substituted aliphatic acids (Traube, A., 1911, i, 115), in that not only alcohol but ammonia is eliminated, for example, glycine ester yields glycocyamidine, whilst the esters of the hydroxy-acids yield a reduced oxazole derivative.

When ethyl glycollate is mixed with guanidine in alcoholic solution, heat is developed, and there shortly separates 2-*imino-4-ketotetrahydro-oxazole*, $NH{:}C<^{NH\cdot CO}_{O-CH_2}$, prisms, m. p. 246—247° (decomp.) ; *hydro-chloride*, rhombic tablets, m. p. 164° (decomp.) ; *silver* salt ; *copper* salt, bright blue. The similarity of this substance to ψ-thiohydantoin, for example, in its hydrolysis by alcoholic hydrogen chloride to 2 : 4-*diketo-tetrahydro-oxazole*, $CO<^{NH\cdot CO}_{O-CH_2}$, tablets, m. p. 89—90°, b. p. 173°/11 mm., and by barium hydroxide solution to ammonia, carbon dioxide and glycollic acid, causes the authors to suggest the name ψ- or *iso*-hydantoin for it.

Ethyl lactate also readily reacts with an alcoholic solution of guanidine, giving *methylisohydantoin* (2-*imino-4-keto-5-methyltetrahydro-oxazole*), leaflets, m. p. 226° ; *hydrochloride*, needles. In a manner analogous to the last, this substance undergoes hydrolysis to 2 : 4-*diketo-5-methyltetrahydro-oxazole*, a hygroscopic solid, m. p. 44—45° (decomp.), b. p. 156—161°/15 mm.

By an analogous reaction, ethyl mandelate yields *phenylisohydantoin* (*2-imino-4-keto-5-phenyltetrahydro-oxazole*), crystals, m. p. 256—257° (decomp); *nitrate*, prismatic crystals, decomp. at 133°; this on warming with dilute hydrochloric acid becomes hydrolysed, producing 2 : 4-*diketo-5-phenyltetrahydro-oxazole*, leaflets, m. p. 108°, which is hydrolysed by barium hydroxide solution to mandelic acid, ammonia, and carbon dioxide.

Methyl glycerate reacts readily with guanidine in methyl alcoholic solution, producing *hydroxymethylisohydantoin* (*2-imino-4-keto-5-hydroxy-methyltetrahydro oxazole*), $\mathrm{NH{:}C{<}^{NH\cdot CO}_{\quad O}>CH\cdot CH_2\cdot OH}$, prisms, m.p. 197°.

Ethyl aminoacetate and guanidine react vigorously when mixed in equivalent quantities, yielding glycocyamidine.

Ethyl ethoxyacetate and ethyl ethoxypropionate both readily enter into reaction with a concentrated alcoholic solution of guanidine, yielding *ethoxyacetylguanidine*, m. p. 162°, and *ethoxypropionyl-guanidine*, m. p. 196°, respectively. The formation of these compounds is interesting as an indication of the probable intermediate stage in the formation of the *iso*hydantoin derivatives described above, whilst the absence of the second phase of the condensation serves as a confirmation of the structure assumed for the products obtained from the esters of the hydroxy-acids.   D. F. T.

Syntheses of Thiohydantoin. II. SHIGERU KOMATSU (*Mem. Coll. Sci. Eng. Kyōto*, 1912, **5**, 13—18. Compare A., 1911, i, 683).— The author has modified his interpretation of the mechanism of the reaction whereby thiohydantoin and methylthiohydantoin are formed by the action of potassium thiocyanate on the respective α-amino-acids in the presence of acetic anhydride, and agrees with the view of Johnson and Nicolet (A., 1912, i, 53) that acetyl derivatives of the thiohydantoins are first formed which subsequently undergo hydrolysis. An attempt was made to substitute benzoic anhydride for acetic anhydride, but neither thiohydantoin nor benzoylthiohydantoin was formed.

When potassium thiocyanate and phenyl aminopropionic acid are heated on the water-bath in the presence of acetic anhydride, 2-*thio-3-acetyl-4-benzylhydantoin*, $\mathrm{CH_2Ph\cdot CH{<}^{CO{-}NH}_{NAc\cdot CS}}$, white needles, m. p. 165—166°, is formed, which, when treated with concentrated hydrochloric acid, is converted into 2-*thio-4-benzylhydantoin*, white needles, m. p. 175—177°. Desulphurisation by means of mercuric oxide in ammoniacal solution or by digestion with chloroacetic acid in aqueous solution transforms this into 4-benzylhydantoin, platy crystals, m. p. 185—186°, the *silver* salt of which was analysed (compare Wheeler and Hoffman, A., 1911, i, 498).

Potassium thiocyanate and tyrosine when similarly heated with acetic anhydride yield a viscous, yellowish-brown *acetyl* derivative from which, on hydrolysis, 2-*thio-4*-p-*hydroxybenzylhydantoin*,

$$\mathrm{OH\cdot C_6H_4\cdot CH_2\cdot CH{<}^{CO{-}NH}_{NH\cdot CS}},$$
m. p. 203—204° (decomp.), is obtained. Boiling aqueous chloroacetic acid transforms it into 4-*p*-hydroxybenzylhydantoin, m. p. 253—254° (decomp.) [Wheeler and Hoffmann, *loc. cit.*, give m. p. 257—258° (decomp.)].   H. W.

The So called Quinhydrone Salts of the Phenazonium Group. ARTHUR HANTZSCH (*Ber.*, 1913, **46**, 1925—1927).—Mainly polemical in reply to Kehrmann (this vol., i, 298, 522). The author repeats his statement that the former's view as to a quinhydrone structure for the dark green methylphenazonium iodide is incorrect.

As further evidence he cites the neutral character of the solution of this substance, whilst hydrophenazine salts are almost completely hydrolysed by water; the dilute aqueous alcoholic solution of the iodide has the same greenish-yellow colour as the true phenazonium salts; finally, on grinding with silver nitrate solution or with a suspension of silver sulphate in water, the iodide is converted entirely into a greenish-yellow nitrate or sulphate. These salts from their colour cannot be quinhydrone salts, and they contain no admixed dihydrophenazine salts, because otherwise ether would extract the corresponding dihydro-base from them.   D. F. T.

A Condensation Product from Phenylindanone and 1-Phenyl-3-methyl-5-pyrazolone. GEORG ROHDE and M. TENZER (*J. pr. Chem.*, 1913, [u], **87**, 541—544).—With the object of establishing the constitution of the red acid substance produced by the condensation of 1-phenyl-3-methyl-5-pyrazolone with phthalic anhydride (this vol., i, 297), the authors have attempted to prepare a similar compound, but of simpler constitution, by the condensation of the pyrazolone with benzylidenephthalide. The product formed by fusing the two latter compounds in equimolecular proportions is, however, not a carboxylic acid, but a phenyl methylpyrazolonylidenephenylindanone of the following formula:

$$\begin{array}{l} \text{N=CMe} \\ | \qquad \quad \Big\rangle\text{C:C}\Big\langle \dfrac{\text{C}_6\text{H}_4}{\text{CHPh}}\Big\rangle\text{CO,} \\ \text{NPh·CO} \end{array}$$
its formation being explained by the transformation of the benzylidenephthalide into 2-phenylindanone, which subsequently condenses with the pyrazolone. This view has been confirmed by the formation of the compound by condensing the pyrazolone with 2-phenylindanone in the presence of anhydrous sodium acetate at 130—135°.

3 : 1'-*Phenyl-3'-methyl-4'-pyrazol-5'-onylidene-2-phenylindanone* crystallises in red needles, m. p. 272°, dissolves in alkalis with a deep magenta coloration, and yields an *oxime* and *semicarbazone*. With sulphuric acid it develops a dark green coloration.   F. B.

Constitution of Anilopyrine. EZIO COMANDUCCI (*Boll. chim. farm.*, 1913, **52**, 436. Compare Comanducci, this vol., i, 296; Zampolli, this vol., i, 296).—Zampolli's criticism is based on errors contained in a preliminary publication of the author, which were corrected before the appearance of Zampolli's paper.   R. V. S.

Iminoindigotins. WALTER MADELUNG (*Ber.*, 1913, **46**, 2259—2264. Compare Binz and Lange, this vol., i, 769).—The mono- and di-imines

can be prepared by heating indigotin with the compound of zinc chloride and ammonia.

The monoimine is obtained in almost quantitative yield by gradually introducing indigotin into the ammonia compound fused at 200°, and maintaining at this temperature for half an hour. In the preparation of the di-imine a higher temperature (about 260°) and more prolonged heating are necessary.

Both imines have the same colour as indigotin, but are much more readily soluble in organic solvents. On reduction with alkaline hyposulphite, the monoimine yields a leuco-compound soluble in alkalis, whilst the di-imine is converted into an insoluble diamine. Advantage is taken of this difference in behaviour to separate the di-imine from the product of the fusion. The leuco-compounds resemble the imines in being readily hydrolysed.

When the monoimine is vatted and the resulting solution, after being heated, submitted to oxidation, a mixture of the monoimine and indigotin is produced. From this the author draws the conclusion that the leuco-compound of the monoimine is present in the vat in the following two forms:

$$C_6H_4{<}^{C(OH)}_{NH}{>}C{\cdot}C{<}^{C(NH_2)}_{NH}{>}C_6H_4 \text{ and }$$

$$C_6H_4{<}^{C(OH)}_{NH}{>}C{\cdot}CH{<}^{C(NH)}_{NH}{>}C_6H_4.$$ The monoimine crystallises with acetic acid (1 mol.).

Di-iminoindigotin, $C_{16}H_{12}N_4$, forms rosettes of microscopic crystals which decompose above 200°, giving off ammonia. It is more readily soluble in all solvents, and possesses more pronounced basic properties than the monoimino-compound. With mineral acids it forms sparingly soluble salts.   F. B.

The Action of Potassium Cyanide on Pyronine and Acridinium Dyes. PAUL EHRLICH and LUDWIG BENDA (*Ber.*, 1913, **46**, 1931—1951).—If the red aqueous solution of pyronine *G* (tetramethyldiaminoxanthylium chloride) is mixed with aqueous potassium cyanide at the ordinary temperature, a violet-red precipitate of tetramethyldiaminoxanthylium cyanide,

$$NMe_2{\cdot}C_6H_3{<}^{CH{-}}_{O(CN)}{>}C_6H_3{\cdot}NMe_2,$$
is obtained, which on warming at 65° for ten minutes becomes converted into *tetramethyldiamino-9-cyanoxanthen*,

$$NMe_2{\cdot}C_6H_3{<}^{CH(CN)}_{O{-}}{>}C_6H_3{\cdot}NMe_2,$$
which the authors designate pyronine-leucocyanide (compare Hantzsch and Osswald, A., 1900, i, 256); this substance forms almost colourless needles, m. p. 183°, which rapidly become green when exposed to light; its alcoholic solution on the addition of potassium hydroxide shows a beautiful violet fluorescence. Oxidation of the leuco-compound in hydrochloric acid solution by ferric chloride or lead dioxide, yields *cyano pyronine hydrochloride*, green crystals of metallic lustre; *nitrate*, green, crystalline powder; *chromate*, obtained by effecting the oxidation with dichromate, forms blue flocks; the salts of the base, which has the formula $C_{18}H_{17}ON_3$, give blue aqueous solutions which dye mordanted

cotton and silk, and are reducible to the leuco-compound. With sodium hydroxide solution or ammonium hydroxide in the cold, the salts give a pale blue precipitate, and on acidifying, hydrogen cyanide is evolved, whilst the colour disappears. When boiled with sodium hydroxide solution, complete loss of colour occurs with formation of a precipitate of tetramethyldiaminoxanthone, yellow needles, m. p. 242° (compare Biehringer, A., 1897, i, 73), which in alcohol gives a colourless solution with a violet fluorescence, and in sulphuric acid colourless with a strong blue fluorescence.

If the above tetramethyldiaminoxanthone is reduced by zinc dust and hydrochloric acid in warm aqueous alcoholic solution, *bispyronine,* olive-green crystals, separates as deep blue flocks of a double *salt* with zinc chloride, from which it is freed by dissolving in very dilute hydrochloric acid and salting out. The free base,

$$OCl < ^{C_6H_8(NMe_2)}_{C_6H_8(NMe_2)} > C—C < ^{C_6H_8(NMe_2)}_{C_6H_8(NMe_2)} > OCl,$$
which dissolves in alcohol to a violet solution, and in sulphuric acid to a blood-red, dyes mordanted cotton and silk violet; its violet solution in hydrochloric acid becomes colourless on reduction with zinc dust, but the original coloured substance is regenerated by oxidation with ferric chloride; the base was analysed as the *nitrate.*

3:6-Diamino-10-methylacridinium chloride (compare Benda, A., 1912, i, 651), for which the authors suggest the name *trypaflavin,* when neutralised with sodium carbonate and treated with potassium cyanide in aqueous solution gives an orange-yellow precipitate of the *cyanide*; on warming the mixture at 75°, the precipitate is converted into pale red 3 : 6-*diamino-5-cyano-10-methyldihydroacridine* (compare Kaufmann and Albertini, A., 1909, i, 606), which on oxidation in aqueous hydrochloric acid solution by ferric chloride or potassium dichromate passes into 3 : 6-*diamino-5-cyano-10-methylacridine* (*cyanotrypaflavin*), deep green prisms of metallic lustre which give a magenta-red aqueous solution; the aqueous solution on addition of the required mineral acid precipitates the *nitrate, hydrochloride,* and *sulphate* respectively, which crystallise in needles; the solutions can be reduced by zinc dust and acid to a colourless substance which regenerates the coloured base on oxidation. The hydrochloride suspended in dilute hydrochloric acid is converted by sodium nitrite into a blue *diazo*-compound resembling diazosafranine. If 3 : 6-diamino-5-cyano-10-methyldihydroacridine is warmed for forty hours with sulphuric acid, it is oxidised to 3 : 6-diamino-10-methylacridinium sulphate, together with a *sulphonic acid* of unknown constitution.

When the above diaminocyanomethylacridine is warmed with sodium hydroxide solution, the solution changes its colour from red to brownish-yellow, and 3 : 6-*diamino-10-methylacridone,* colourless needles, when pure, m. p. 308° (decomp.), slowly deposits; this dissolves in hydrochloric acid to a deep yellow solution, and in hot water or alcohol to a colourless solution with a violet fluorescence; the hydrochloric acid solution on diazotisation gives a red *diazo*-compound, which couples with *R*-salt to a sparingly soluble red *substance.* Reduction of diaminomethylacridone with sodium amalgam in alcoholic solution and re-oxidation by ferric chloride in acid

solution produces diaminomethylacridinium chloride in poor yield. Reduction in hydrochloric acid by zinc dust, however, gives the *zinc chloride* double salt, red needles with metallic lustre, of *bistrypaflavin*, $NMeCl \begin{subarray}{l} C_6H_3(NH_2) \\ C_6H_3(NH_2) \end{subarray} > C \cdot C < \begin{subarray}{l} C_6H_3(NH_2) \\ C_6H_3(NH_2) \end{subarray} > NMeCl.$

The formation of this substance is believed to depend merely on the reduction of the pinacone compound which is previously produced (compare Decker and Dunant, A., 1909, i, 433). The addition of nitric acid to a solution of the zincochloride causes the separation of the *nitrate* of the base, orange-red needles; the orange-red aqueous solution of this yields a blue diazo-compound.

3 : 6-Tetramethyldiamino-10-methylacridinium *p*-toluenesulphonate (used in place of the chloride, that is, acridinium-orange, for convenience) reacts with an aqueous solution of potassium cyanide, giving first an orange-red precipitate of the corresponding *cyanide*, which on warming passes into a black green *substance*; this on oxidation in hydrochloric acid solution by ferric chloride gives *cyanoacridinium-orange*, $NMe_2 \cdot C_6H_3 < \begin{subarray}{l} C(CN) \\ NMeCl \end{subarray} > C_6H_3 \cdot NMe_2,$ green crystals soluble in water to a violet colour; *nitrate*, reddish-brown flocks. Reduction of this substance by zinc dust and hydrochloric acid produces a colourless solution, from which oxidation regenerates the original substance as the *chromate* if potassium dichromate is used as oxidising agent. The action of hot potassium hydroxide solution on cyanoacridinium orange causes the formation of *tetramethyldiamino-10-methylacridone*, colourless needles, m. p. 275—276°; *hydrochloride*, yellow needles; the colourless alcoholic solution exhibits a strong violet fluorescence, whilst in sulphuric acid a very strong bluish-green fluorescence is observed. By reduction in dilute hydrochloric acid with zinc dust, tetramethyldiamino-10-methylacridone is converted into *bis-acridinium-orange zincochloride*, red needles with metallic lustre, which, like the previous example, is probably produced by intermediate formation of a pinacone compound; *nitrate*, green crystals with a bronze lustre. The substance is reducible by zinc dust and hydrochloric acid to a yellow solution with green fluorescence, which can be reoxidised to the red solution of the original substance.

Thiopyronine, in an analogous manner, is converted by potassium cyanide into a blue colouring matter.

From a consideration of the colours of the products obtained with potassium cyanide and of the colours of the original pyronine or acridine dye, the conclusion is drawn that the grouping $>$C·CN in orthoquinonoid dyes exerts the same effect as a cyclic nitrogen atom $>$N on the colour; also, that in the cyano-compounds, a rearrangement occurs with formation of a para-quinonoid structure. The latter view is confirmed by experimental results which are to be published later, for example, a striking colour difference exists between 3 : 6-diamino-10-methylacridinium chloride and its 2 : 7-dimethyl derivative, the latter of which is structurally prevented from any such rearrangement.   D. F. T.

Products of the Internal Condensation of Hydrazinedithio-carbophenylamide. MAX BUSCH and WILHELM SCHMIDT (*Ber.*, 1913, **46**, 2240—2248).—The authors have attempted to prepare a derivative of aminocarbodi-imide, $NH:C:N\cdot NH_2$, by the removal of hydrogen sulphide from hydrazinedithiocarbophenylamide (*s*-diphenylthiocarbamylhydrazide), $N_2H_2(CS\cdot NHPh)_2$, by heating with mercuric oxide in alcoholic solution. The product consisted, however, of *tetrahydro-thiodiazoledianil* [*diphenyliminotetrahydrothiodiazole*], $\begin{array}{c}NH\cdot C(NPh)\\NH\cdot C(NPh)\end{array}\!\!>\!S$,
which crystallises in lustrous, white leaflets, m. p. 240°, and can also be obtained, together with the anilinothiolthiodiazole described below, by maintaining the hydrazide in a fused condition for a few minutes at a temperature not exceeding 200°

The thiodiazole has been previously prepared by Walther (A., 1906, i, 831), who assigned to it the formula $NPh:C:N\cdot NH\cdot CS\cdot NHPh$, whilst Freund and Wischewiansky (A., 1894, i, 97), who obtained it by the action of carbonyl chloride on the hydrazide, considered it to be a phenyliminophenylthiourazole of the constitution
$$\begin{array}{c}CS\cdot NPh\\NH\cdot NH\end{array}\!\!>\!C:NPh.$$
Walther's formula is excluded on account of the absence of additive properties, whilst Freund and Wischewiansky's formula is inadmissible because the substance does not possess distinct acid properties and is not oxidisable to a disulphide.
Evidence in support of the authors' formula is furnished by the behaviour of the thiodiazole on oxidation, whereby a red *azo*-compound, *diphenyliminodihydrothiodiazole*, $\begin{array}{c}N\cdot C(NPh)\\N\cdot C(NPh)\end{array}\!\!>\!S$, crystallising in stout, lustrous, dark violet to brownish-red needles, m. p. 113°, is produced. The oxidation is best carried out by heating an alcoholic solution of the thiodiazole with hydrochloric acid and amyl nitrite.

On treatment with nitrous acid the thiodiazole forms a *nitrosoamine*, which is converted by boiling with alcohol or benzene into the above azo-compound. That the sulphur atom of the azo-compound is contained in the ring is proved by its stability towards mercuric oxide, no action taking place even at 140°.

When boiled with concentrated hydrochloric acid. *s*-diphenylthiocarbamylhydrazide loses aniline, yielding *anilinothiolthiodiazole*,
$$\begin{array}{c}N\text{---}N\\C(SH)\cdot S\end{array}\!\!>\!C\cdot NHPh \quad \text{or} \quad \begin{array}{c}N\text{---}NH\\C(SH)\cdot S\end{array}\!\!>\!C:NPh,$$
which crystallises in white needles, and has been previously described by Freund and Imgart (A., 1895, i, 400) as a phenyldithiourazole, $\begin{array}{c}NH\cdot CS\\NH\cdot CS\end{array}\!\!>\!NPh.$
Anilinothiolthiodiazole reacts with methyl iodide and alcoholic potassium hydroxide, yielding *anilinomethylthiolthiodiazole*,
$$\begin{array}{c}N\text{---}N\\C(SMe)\cdot S\end{array}\!\!>\!C\cdot NHPh.$$
This crystallises in lustrous, colourless, glassy needles or large columns,
m. p. 127°, and has also been obtained by the removal of hydrogen sulphide from methyl thiocarbanilinodithiocarbazinate,

$$SH \cdot C(NPh) \cdot NH \cdot N \vdots C(SH) \cdot SMe.$$
Anilinobenzylthiolthiodiazole, $C_{15}H_{13}N_3S_2$, prepared in a similar manner, using benzyl chloride, forms pale yellow needles, m. p. 141°. That the above alkyl derivatives contain an imino-group has been shown by the preparation of a *nitrosoamine*, $C_9H_8ON_4S_2$, crystallising in needles, m. p. 84—85°, by the action of nitrous acid on the methyl derivative.

When heated at 100° with benzyl chloride and alcoholic potassium hydroxide, the methyl derivative is converted into *benzylanilino-methylthiolthiodiazole*, $C_{16}H_{15}N_3S_2$, which forms transparent prisms, m. p. 85°, and yields a *hydrochloride*, m. p. 169°.

The diacetyl derivative of anilinothiolthiodiazole, m. p. 252°, described by Freund and Imgart (*loc. cit.*), readily loses one of its acetyl groups on crystallisation of alcohol. The acetyl group which is so readily removed must be attached to the sulphur of the atom, and the monoacetyl derivative, thus formed, accordingly receives the

formula $\begin{matrix} N\!\!-\!\!-\!\!N \\ \| \quad\quad \rangle\!C\cdot NPhAc \\ C(SH)\cdot S \end{matrix}$ or $\begin{matrix} N\!\!-\!\!NAc \\ \| \quad\quad \rangle\!C \vdots NPh. \\ C(SH)\cdot S \end{matrix}$

In view of the above results the dithiourazoles described by Freund and Imgart must be considered as amino- or imino-tetrahydrothio-diazoles, whilst the aminothiourazoles are probably di-iminotetrahydro-thiodiazoles.   F. B.

Colour Bases of the Quinoneimide Dyes. I.

FRIEDRICH KEHRMANN, EM. HAVAS, and EUGÈNE GRANDMOUGIN (*Ber.*, 1913, 46, 2131—2138).—An investigation of the quinoneimide colouring matters, which brings to light certain analogies with the triphenylmethane colours. The occurrence of chemical change was detected spectro-scopically.

If a solution of safranine in water is treated with alkali and a layer of ether placed on the surface, the two red layers exhibit quite different absorption spectra; the same difference holds for the two layers in the case of the alkylated safranines, but the colours of the ether-soluble bases are in all cases strikingly similar. As the ammonium bases are insoluble in water, the ethereal solutions must contain the imino-base; on shaking with water partial hydration occurs, and a portion of the imino-base passes from the ether as the azonium base and imparts to the water the colour of the original salt. These azonium bases, which conduct the electric current, precipitate ferric hydroxide from ferric solutions, and are generally more stable than the analogous triphenylmethane bases, can also be obtained by the action of moist silver oxide. The equilibrium $NH_2R + H_2O \longrightarrow NH_3R\cdot OH$ also shows its effect in the action of much potassium hydroxide, when the excess of hydroxyl ion causes practically all the coloured substance to pass into the ethereal layer as the imino-base. To the substance soluble in water is attributed the structure

$$NH_2 \cdot C_6H_3 \begin{matrix} \xrightarrow{\quad\quad N} \\ NPh(OH) \end{matrix} C_6H_3 \cdot NH_2,$$
corresponding with the salts, for example,

$$NH_2 \cdot C_6H_3 \diagdown \overset{N}{\underset{NPhCl}{\diagdown}} \diagup C_6H_3 \cdot NH_2,$$
and to the base soluble in e$_t$her either

$$NH_2 \cdot C_6H_3 \diagdown \overset{N}{\underset{NPh}{\diagdown}} \diagup C_6H_3 : NH \text{ or}$$

$$NH_2 \cdot C_6H_3 \diagdown \overset{N}{\underset{NPh}{\diagdown}} \diagup C_6H_3 \cdot NH, \text{ preferably the former as it better}$$
expresses the analogy to the parent substance ammonia in which the valency passes from three to five in salt-formation.

Indamine, the simplest quinoneimide dye, closely resembles safranine in spectrum, thus indicating similarity in constitution, namely, $NH_2 \cdot C_6H_4 \cdot N : C_6H_4 : NH$; when shaken with water, however, it does not undergo any appreciable hydration to the corresponding ammonium base, indicating the less basicity of ammonium nitrogen compared with azonium nitrogen.

Tetraethylsafranine, with dilute potassium hydroxide or moist silver oxide, yields only the azonium base, which is insoluble in ether, but as with crystal-violet, on treatment with concentrated alkali, an ethyl radicle is eliminated with formation of triethylsafranine.

With the thiazine dyes, the introduction of successive methyl groups as with safranine, produces an additive effect in the shifting of the absorption band. Methylene-blue like tetraethylsafranine undergoes scission of one and even two methyl groups under the action of potassium hydroxide. The other ethylated thiazines when treated with alkali yield the ether soluble imino-bases, which on shaking with water pass into the thionium bases with simultaneous assumption of the blue colour characteristic of the salts.

D. F. T.

Bisthiohydantoins. GEORG FREERICHS and H. HÖLLER (*Annalen*, 1913, **398**, 256—264).—*Bisthiohydantoin*,

$$\overset{CH_2 - CO}{\underset{S \cdot C(:NH)}{\diagdown}} N \cdot N \diagup \overset{CO - CH_2}{\underset{C(:NH) \cdot S}{\diagdown}},$$
prepared by boiling bisthiocarbamide with aqueous chloroacetic acid, is a colourless, crystalline powder and possesses more pronounced acid properties than thiohydantoin itself. It is easily soluble in alkali hydroxides and carbonates and in aqueous ammonia; the *potassium* salt, $C_6H_6O_2N_4S_2,2KOH$, and *barium* salt, $C_6H_6O_2N_4S_2,Ba(OH)_2$, are crystalline substances. By treatment with methyl or ethyl iodide and $N/2$-potassium hydroxide, an alcoholic solution of bisthiohydantoin is readily converted at the ordinary temperature into NN-*dimethylbisthiohydantoin*, $C_8H_{10}O_2N_4S_2$, m. p. above 270°, colourless needles, or NN-*diethylbisthiohydantoin*, m. p. 224°, neither of which has acidic properties.

Bisthiocarbamide reacts in a similar manner with α-bromopropionic acid and with α-bromobutyric acid. 4 : 4'-*Dimethylbisthiohydantoin*,

$$\overset{CHMe \cdot CO}{\underset{S \cdot C(:NH)}{\diagdown}} N \cdot N \diagup \overset{CO - CHMe}{\underset{C(:NH) \cdot S}{\diagdown}}, \text{ m. p. above 280° (decomp.), forms}$$

a *barium* salt, $C_8H_{10}O_2N_4S_2,Ba(OH)_2$, an NN-*dimethyl* derivative, m. p.

255—256°, and NN-*diethyl* derivative, m. p. 187°.   4 : 4'-*Diethyl-bisthiohydantoin*, m. p. 225—226°, forms a *barium* salt,

$$C_{10}H_{14}O_2N_4S_2,Ba(OH)_2,$$
an NN-*dimethyl* derivative, m. p. 216—217°, and NN-*diethyl* derivative, m. p. 154°.   C. S.

The Anomalies of Uric Acid Solubility (Colloidal Uric Acid). HEINRICH SCHADE and E. BODEN (*Zeitsch. physiol. Chem.*, 1913, 86, 238—243. Compare this vol., i, 404).—Polemical in reply to Lichtwitz (this vol., i, 657).   W. D. H.

Action of Hydrazine on the 2 : 4-Dichlorophenylhydrazones of Ethyl α-Chloro- and α-Amino-glyoxylates and the Decomposition of Phenylazoacetoacetamide by Chlorine. Formation of the 2 : 4-Dichlorophenylhydrazone of α-Chloroglyoxylamide and its Basic Derivatives. CARL BÜLOW and PETER NEBER (*Ber.*, 1913, 46, 2032—2045. Compare this vol., i, 207).—The 2 : 4-*dichloro-phenylhydrazone* of α-*hydrazinoglyoxylhydrazide*,

$$C_6H_3Cl_2 \cdot NH \cdot N{:}C(NH \cdot NH_2) \cdot CO \cdot NH \cdot NH_2,$$
is formed when hydrazine hydrate acts on an alcoholic solution of the 2 : 4-dichlorophenylhydrazone of ethyl α-chloroglyoxylate under definite conditions which are fully described in the original. It forms straw-yellow leaflets, which rapidly decompose on exposure to air and light, which darken at 155°, and have m. p. 160° (decomp.). It gives an orange-red colour with cold concentrated sulphuric acid which becomes pale, dirty yellow on warming. When warmed with benzaldehyde in alcoholic solution, it yields the corresponding *benzylidine* derivative, $C_6H_3Cl_2 \cdot NH \cdot N{:}C(NH \cdot N{:}CHPh) \cdot CO \cdot NH \cdot N{:}CHPh$, yellow needles, m. p. 218° (decomp.).

When an alcoholic solution of the 2 : 4-dichlorophenylhydrazone of ethyl α-aminoglyoxylate is warmed with hydrazine hydrate, the 2 : 4-*dichlorophenylhydrazone* of α-*aminoglyoxylhydrazide*,

$$C_6H_3Cl_2 \cdot NH \cdot N{:}C(NH_2) \cdot CO \cdot NH \cdot NH_2,$$
is obtained in long, pale brown needles, m. p. 230° (decomp.). In contrast to the "hydrazidrazone hydrazide" described above, this substance only gives a pale yellow colour with concentrated sulphuric acid, from which the conclusion is drawn that the hydrazino-group attached to the α-carbon atom is the cause of the delicate halochromic property. The presence of the hydrazino-group is established by the preparation of the *benzylidine* derivative,

$$C_6H_3Cl_2 \cdot NH \cdot N{:}C(NH_2) \cdot CO \cdot NH \cdot N{:}CHPh,$$
yellow needles.

The 2 : 4-*dichlorophenylhydrazone* of α-*aminoglyoxylacetylhydrazide*, $C_6H_3Cl_2 \cdot NH \cdot N{:}C(NH_2) \cdot CO \cdot NH \cdot NHAc$, is formed when a mixture of the 2 : 4-dichlorophenylhydrazone of ethyl α-aminoglyoxylhydrazide and acetic anhydride is allowed to evaporate at the ordinary temperature. It forms white crystals, m. p. 233°. Its constitution is established by the fact that it does not yield a benzylidine derivative when boiled with benzaldehyde in alcoholic solution, and that it immediately yields a cloudy solution when sodium nitrite solution is added to a solution of it in dilute acid.

An attempt was made to confirm this conclusion in the following manner. The 2 : 4-*dichlorophenylhydrazone* of *ethyl α-acetylaminoglyoxylate*, $C_6H_3Cl_2 \cdot NH \cdot N{:}C(NHAc) \cdot CO_2Et$, white needles, m. p. 153° after previous softening, was prepared by the action of cold acetic anhydride on the 2 : 4-dichlorophenylhydrazone of ethyl α-aminoglyoxylate. When an alcoholic solution of this substance was warmed with hydrazine hydrate, a *product*, $C_{10}H_9ON_5Cl$, white needles, m. p. 205°, was obtained, which yielded a *benzylidene* derivative, and had the formula (1)

$$C_6H_3Cl_2 \cdot NH \cdot N{:}C \cdot N{:}CMe$$
$$\qquad\qquad\qquad CO-N \cdot NH_2, \text{ or}$$

$$(2)\ C_6H_3Cl_2 \cdot N \cdot N{:}C \cdot CO \cdot NH \cdot NH_2$$
$$\qquad\qquad MeC{=}N,$$
and was formed from the intermediate hydrazide,

$$C_6H_3Cl_2 \cdot NH \cdot N{:}C(NHAc) \cdot CO \cdot NH \cdot NH_2.$$

The 4-*chlorophenylhydrazone* of *ethyl α-aminoglyoxylate*,

$$C_6H_4Cl \cdot NH \cdot N{:}C(NH_2) \cdot CO_2Et,$$
is formed by the action of alcoholic ammonia on the 4-chlorophenyl-hydrazone of ethyl α-chloroglyoxylate (*loc. cit.*). It has m. p. 158°, and can be distilled without decomposition.

The 2 : 4-dichlorophenylhydrazone of ethyl α-chloroglyoxylate is best obtained by the action of chlorine on a solution of ethyl phenylazo-acetoacetate in acetone. The advantage gained by the substitution of acetone for chloroform (*loc. cit.*) is that the mother liquors from one preparation can be used as solvent for a succeeding preparation, and this procedure has a favourable effect on the yield.

The 2 : 4-*dichlorophenylhydrazone* of *α-chloroglyoxylamide*,

$$C_6H_3Cl_2 \cdot NH \cdot N{:}CCl \cdot CO \cdot NH_2,$$
m. p. 232°, is obtained when chlorine is passed into a solution of phenylazoacetoacetamide in glacial acetic acid or alcohol. It is readily soluble in potassium hydroxide. Piperidine converts it into a *substance*, m. p. 136—136·5°, which, at a higher temperature, decomposes suddenly with evolution of a volatile oil. With pyridine, it yields pale flesh-coloured *needles*, m. p. 220—221°. Investigation of these compounds is not completed. The 2 : 4-dichlorophenylhydrazone of ethyl α-amino-glyoxylamide, previously described (*loc. cit.*), is more conveniently obtained by the action of cold alcoholic ammonia on the above amide, and has m. p. 176° instead of 170° as previously given. It forms a *platinichloride*, crystallising in small, yellow octahedra, reduces boiling gold chloride solution, and gives a mirror with cold ammoniacal silver nitrate.

The 2 : 4-*dichlorophenylhydrazone* of *α-hydrazinoglyoxylamide*,

$$C_6H_3Cl_2 \cdot NH \cdot N{:}C(NH \cdot NH_2) \cdot CO \cdot NH_2,$$
is obtained by the action of hydrazine hydrate on an alcoholic solution of the 2 : 4-dichlorophenylhydrazone of α-chloroglyoxylamide. It has m. p. 157°, and gives an orange coloration with concentrated sulphuric acid. With an alcoholic solution of benzaldehyde, it yields the corresponding *benzylidene* derivative,

$$C_6H_3Cl_2 \cdot NH \cdot N{:}C(NH \cdot N{:}CHPh) \cdot CO \cdot NH_2,$$
yellow needles, m. p. 205°.

In order to determine which of the two amino-groups in the 2 : 4-di-

chlorophenylhydrazone of α-aminoglyoxylamide is more loosely held, this substance was energetically treated with an excess of hydrazine hydrate, when the 2 : 4-dichlorophenylhydrazone of α-aminoglyoxyl-hydrazide was obtained, thus showing the amino-group of the –CONH$_2$ radicle to be the more readily replaceable.   H. W.

Azo-dyes Derived from 2-Hydroxy-3-naphthoic Acid. ANUKUL CHANDRA SIRCAR and EDWIN ROY WATSON (*J. Soc. Chem. Ind.*, 1913, **32**, 642—644).—In a previous paper (A., 1912, i, 1037) the authors have described attempts to prepare dyes similar in constitution to benzeneazosalicylic acid, which would possess the same all-round fastness as this dye, but with the colour deepened to red, violet, blue or black. These attempts were not, however, successful as the colour was deepened towards maroon and brown, instead of towards violet and blue as desired. Since many azo-dyes of not more complicated structure possess the desired shades, the authors have examined a list of the well-known azo-dyes prepared from naphtholsulphonic acids, from which they are led to the conclusion that the relative position of the hydroxyl- and chromophore-group is the determining factor in the colour of the dye, the *ortho*-position favouring red, violet, and blue shades, and the *para*-position giving brown shades. A series of dyes have therefore been prepared by coupling diazonium salts with 2-hydroxy-3-naphthoic acid, the hydroxyl group thus being in the ortho-position to the azo-group. The shades obtained are very satisfactory, including fiery-red, claret, cherry-red, brownish-purple, bluish-purple and black. The dyeings on chrome-mordanted wool are quite satisfactory as regards fastness to light and acid test, but are not so resistant to soaping, alkalis, and milling as they were expected to be.

Naphthalene-α-1-azo-2-hydroxy-3-naphthoic acid, prepared from diazotised α-naphthylamine and 2-hydroxy-3-naphthoic acid, forms greenish-red, rhombic prisms, m. p. 236°, whereas Möhlau and Kriebel (A., 1896, i, 242) gave m. p. about 182°.
m-*Xylene-1-azo-2-hydroxy-3-naphthoic acid,*
$$C_6H_3Me_2 \cdot N:N \cdot C_{10}H_5(OH) \cdot CO_2H,$$
crystallises in deep red needles, m. p. 240—242°.

p-*Ethoxybenzene-1-azo-2-hydroxy-3-naphthoic acid,*
$$OEt \cdot C_6H_4 \cdot N:N \cdot C_{10}H_5(OH) \cdot CO_2H,$$
deep red, needle-shaped crystals with green reflex, has m. p. 231° after softening at a somewhat lower temperature.
m-*Nitrobenzene-1-azo-2-hydroxy-3-naphthoic acid,*
$$NO_2 \cdot C_6H_4 \cdot N:N \cdot C_{10}H_5(OH) \cdot CO_2H,$$
prepared from diazotised *m*-nitroaniline and 2-hydroxy-3-naphthoic acid, separates from nitrobenzene in beautiful red needles, which do not melt at 275°. The corresponding *dye* from *p*-nitroaniline forms fine hair-like, red needles, which do not melt at 285°.

Benzeneazobenzene-1-azo-2-hydroxy-3-naphthoic acid,
$$NPh:N \cdot C_6H_4 \cdot N:N \cdot C_{10}H_5(OH) \cdot CO_2H,$$
is formed when a diazotised solution of *p*-aminoazobenzene (Hewitt, T., 1909, **95**, 1394) is dropped into an alkaline solution of 2-hydroxy-3-naphthoic acid. It crystallises in magenta-red needles with a green reflex and does not melt below 275°.

Diazotised disulphonaphthalene-β-azo-α-naphthylamine combines with an alkaline solution of 2-hydroxy-3-naphthoic acid to yield the *sodium* salt of *disulphonaphthalene-β-azonaphthalene-α-1-azo-2-hydroxy-3-naphthoic acid*, $C_{10}H_5(SO_3Na)_2 \cdot N{:}N \cdot C_{10}H_6 \cdot N{:}N \cdot C_{10}H_5(OH) \cdot CO_2Na$, which could not be converted into the free acid by boiling with any mineral acid, and forms a black powder. Similarly, *sodium benzidine-bis-1-(azo-2-hydroxy-3-naphthoate)*, $C_{12}H_8[N{:}N \cdot C_{10}H_5(OH) \cdot CO_2Na]_2$, is prepared by coupling a diazotised solution of benzidine with an alkaline solution of 2-hydroxy-3-naphthoic acid. It forms a green powder from which the corresponding free acid is not obtained by means of boiling mineral acids.

The colorations produced when the dyes are dissolved in alkalis or in concentrated sulphuric acid together with the shades produced on unmordanted or chrome-mordanted wool are also described. H. W.

Azo-colouring Matters of Phenyl*iso*ooxazolone. ANDRÉ MEYER (*Compt. rend.*, 1913, **156**, 1992—1995. Compare A., 1911, i, 341).—As the azo-derivatives previously prepared by the author (*loc. cit.*) contained no salt-forming groups and so were unsuited for dyeing purposes, he has now obtained various compounds chemically suitable for dyes, and has compared them with the corresponding pyrazolone compounds.

Sodium phenylisooxazoloneazobenzene-p-sulphonate,

$$C_9H_6O_2N \cdot N_2 \cdot C_6H_4 \cdot SO_3Na, 2H_2O,$$

golden-yellow spangles, obtained by applying a diazotised solution of sulphanilic acid, dyes silk golden-yellow in a bath containing acetic acid.

Sodium phenylisooxazoloneazo-m-xylene-o-sulphonate, an orange, crystalline powder, with $2H_2O$, dyes silk and wool a deep orange-yellow.

Sodium phenylisooxazolone-1-azonaphthalene-4-sulphonate forms orange-brown spangles with $2H_2O$; it dyes silk and wool a reddish-maroon.

Sodium phenylisooxazolone-8-azonaphthalene-2:6-disulphonate, orange crystals with $2H_2O$.

The following substantive dyes were prepared by combining a molecule of a tetrazotised solution of benzidine with a molecule of phenyl*iso*oxazolone, and subsequently coupling the free diazo-radicle with a molecule of a phenol or an amine.

Sodium phenylisooxazoloneazodiphenylazonaphthylaminesulphonate, $C_9H_6O_2N \cdot N_2 \cdot C_6H_4 \cdot C_6H_4 \cdot N_2 \cdot C_{10}H_5(NH_2) \cdot SO_3Na$, obtained by applying naphthionic acid for the second coupling reaction, has a red colour changing to blue on addition of acid; it dyes cotton a scarlet-red.

Sodium phenylisooxazoloneazo-o-ditolylazo-1-amino-8-naphthol-3:6-disulphonate is a reddish-violet powder, changed to bluish-violet by a mineral acid, which dyes a deep violet.

Sodium phenylisooxazoloneazodianisylazo-8-amino-1-naphthol-3:5-disulphonate dyes fabric violet.

Sodium phenylisooxazoloneazodiphenylazosalicylate is a deep brown powder, which dyes cotton orange.

The above dyes are not nearly as fast to light as the pyrazole analogues, the substantive colours being even less stable than the

acid colours mentioned first ; ultraviolet radiation affected the colours much more rapidly than ordinary light. The replacement of the imino-group in such compounds by an oxygen atom evidently provokes a weakening towards photochemical influence according with the lessening in stability towards ordinary chemical agents.   D. F. T.

Existence of Phenyldi-imide. STEFAN GOLDSCHMIDT (*Ber.*, 1913, 46, 2300. Compare this vol., i, 768).—In ethereal solution *p*-bromophenyldi-imide decomposes mainly into *p*-bromobenzene and nitrogen ; quinol and a small amount of a colourless, crystalline substance are also produced in the decomposition.   F. B.

The Density and Volume of Some Protein Solutions. AMEDEO HERLITZKA (*Zeitsch. Chem. Ind. Kolloid*, 1913, 12, 309).— Polemical (compare Chick and Martin, this vol., i, 40 ; Herlitzka, A., 1910, ii, 1013 ; Gayda, A., 1912, i, 399).   J. F. S.

Changes in the Physical Condition of Colloids. XV. Electrochemical Investigations on Acid Protein. KAICHIRO MANABE and JOH. MATULA (*Biochem. Zeitsch.*, 1913, 52, 369—408).— The investigations are a continuation of those of Pauli. The present authors have been chiefly concerned in the determination of the diminution of hydrogen and chlorine ion concentration when hydrochloric acid is added to carefully dialysed solutions of proteins. The hydrogen ion concentrations were determined in the ordinary manner, with the employment of a shaking electrode devised by Pauli, which is figured in the text. The chlorine ion concentration was determined by shaking the solution under investigation with calomel and mercury, and preparing from this mixture a calomel electrode in the ordinary way. The *E.M.F.* was determined when this was balanced against a calomel electrode containing a definite concentration of potassium chloride ($N/10$ or N). A figure is given in which the *E.M.F.* produced is plotted against the hydrogen ion exponent of the mixture under investigation measured against both N and $N/10$-potassium chloride. The form of vessel used for these investigations is also figured in the text. In the cases of albumins, or ox-serum, the addition of acids up to a concentration of $0.03N$ is accompanied by an increased binding of the free hydrogen atoms ; there are, however, only a relatively small number of chlorine ions bound at the same time, and an equality between the hydrogen and chlorine ions bound is only reached in higher concentrations of the acids. If the difference between the bound chlorine and hydrogen ions is plotted against the hydrochloric acid concentration, it will be found that it gradually reaches a maximum and then falls. The maximum corresponds with the maximum of viscosity of the mixture. These results are in accordance with the theory of Pauli, according to whom an albumin hydrochloride is formed, which dissociates in solution giving rise to albumin and chlorine ions ; the high viscosity of the solutions is due to the former. With the addition of increasing amounts of hydrochloric acid, the ionic dissociation of the albumin salt is depressed, and the viscosity

diminishes; an equality between the bound chlorine and hydrogen ions is then also gradually attained. The whole of the hydrogen ions added are never completely bound, and the amount of hydrolytic dissociation of the albumin salt has therefore also been ascertained. For this purpose, the hydrogen ion concentration was determined in an oxserum solution containing $0.02N$-hydrochloric acid in undiluted condition and when diluted with twice and four times its bulk of water. From the numbers obtained, it was calculated that the hydrolytic dissociation amounted to 4.4% in the twice diluted solution, and to 15.3% in the four times diluted solution. The results obtained with gelatin are somewhat different to those obtained with albumins. In this case, there is but little binding of the chlorine ions, even in higher concentrations of acids; the explanation offered in this case is, that the chloride is strongly dissociated even in presence of a large excess of acid. This does not, however, explain the diminution of the viscosity in the higher concentrations; it is suggested that the acid causes, in this case, a degradation of the protein. The effect of the addition of salts to the acid protein solutions was also investigated. This addition causes a small increase in the bound hydrogen ions in low concentrations of acids ($0.005N$-HCl). Such an increase cannot, however, be detected with certainty in the higher concentrations. It is assumed that in this case the salt attaches itself to the acid protein by means of accessory valencies. The actions possible in this case are discussed in some detail. S. B. S.

The Tyrosine Content of Proteins. OTTO FOLIN and WILLEY DENIS (*J. Biol. Chem.*, 1913, 14, 457—458).—Polemical. A reply to Abderhalden and Fuchs (this vol., i, 409). The authors insist that their tyrosine figures are more correct than those hitherto recorded.
W. D. H.

The Factors Concerned in the Solution and Precipitation of Euglobulin. (Miss) HARRIETTE CHICK (*Biochem. J.*, 1913, 7, 318—340).—Re-determination of the isoelectric point of euglobulin shows that it coincides with the point of most rapid agglutination, namely, at a hydrogen ion concentration of about 3×10^{-4} normal. Solution and dispersion of euglobulin by electrolysis is influenced by the nature (especially the valency) of the constituent ions. There are two general types: (1) electrical type of solution in which the dispersion is accompanied by the acquisition of an electric charge by the protein molecules; and (2) molecular type in which the dissolved protein is electrically neutral.

When euglobulin is denaturated by heat, it no longer possesses the property of forming the molecular type of solution. The reaction of acid and alkaline solutions of euglobulin is greatly affected by the addition of electrolytes; the influence of electrolytes in causing precipitation is affected by changes in reaction. Euglobulin in common with caseinogen and vegetable globulins presents an interesting analogy with heat denaturated protein, but differs from it in its capacity to form solutions with electrolytes in which the protein particles are electrically neutral. W. D. H.

Do Gliadin and Zein Yield Lysine on Hydrolysis? Thomas B. Osborne and Charles S. Leavensworth (*J. Biol. Chem.*, 1913, **14**, 481—487).—Small quantities of lysine (as picrate) were separated from the hydrolytic products of gliadin from wheat which had been prepared with great care. Zein yielded none.   W. D. H.

Phonoporphyrin, a New Degradation Product of Hæmin. Oscar Piloty and Hermann Fink (*Ber.*, 1913, **46**, 2020—2026).—In continuation of their work on the molecular size of hæmin and hæmoglobin (A., 1912, i, 923), the authors have further investigated the reduction of hæmin by hydrogen iodide, and have shown that, in addition to mesoporphyrin, a second substance, *phonoporphyrin*, may be isolated, and that the total weight of products thus obtained is 90% of that theoretically derivable from hæmin. Their previous conclusion that the molecular weight of hæmin is 1303 is thus confirmed. The occurrence of phonoporphyrin among the decomposition products of hæmin seems to have been previously observed by Nencki and Zaleski (A., 1901, i, 434), Zaleski (A., 1903, i, 217), and Fischer and Meyer-Betz (this vol., i, 111), but the substance was not further investigated.

When hæmin is boiled with glacial acetic acid, hydriodic acid (D 1·96), red phosphorus and a little water, and the mixture, after removal of phosphorus, poured into a large bulk of water, a mixture of mesoporphyrin and phonoporphyrin is obtained from which the former may be removed by repeated extraction with large quantities of boiling dilute hydrochloric acid. The residual phonoporphyrin, after purification by solution in sodium hydroxide and precipitation with acetic acid, consists of a dark brown, amorphous powder, analyses of which agree most nearly with the formula $C_{34}H_{36}O_7N_4$ or

$$C_{36}H_{40}O_7N_4.$$
It is not obtained when mesoporphyrin is acted on by hydrogen iodide under the above conditions, and hence cannot be formed as an intermediate product of the formation of mesoporphyrin from hæmin.

When boiled with 9% methyl alcoholic hydrochloric acid, phonoporphyrin yields the corresponding *methyl* ester, $C_{36}H_{40}O_7N_4$ or $C_{38}H_{44}O_7N_4$, which forms minute, brown particles showing no distinct crystalline form, and does not soften at 225°. The similarly prepared *ethyl* ester, $C_{38}H_{44}O_7N_4$ or $C_{40}H_{48}O_7N_4$, decomposes at 255°.

Oxidation of phonoporphyrin in sulphuric acid solution with chromic acid gives methylethylmaleinimide and hæmatic acid, $C_8H_9O_4N$.

H. W.

Histone and its Preparation. Walter H. Eddy (*Biochem. Bull.*, 1913, **2**, 419—440).—Histone, obtained by precipitating aqueous extracts of thymus with ammonia, is different from that obtained by saturation with sodium chloride. The former is not soluble in water, and contains more nitrogen; the latter is soluble in water, and contains combined chlorine.

The preliminary use of alcohol to precipitate histone and the other proteins in the glands is preferable to direct water-extraction. Bang's

contention that ammonia does not precipitate histone in the absence of salts is incorrect; their presence, however, facilitates the process.

W. D. H.

Chondroitin sulphuric Acid. PHŒBUS A. LEVENE and FREDERICK B. LA FORGE (*J. Biol. Chem.*, 1913, **15**, 155—160).—For the first time all the components of this acid were isolated and identified; they are those assumed on indirect evidence by Schmiedeberg, namely, sulphuric acid, acetic acid, glycosamine and glycuronic acid. Schmiedeberg's view of the molecular structure of the molecule needs revision, and the new formula is set out in full. It assumes a glucosidic union of two chondrosin molecules, which explains the reason why chondrosin is a reducing agent, and chondroitin-sulphuric acid is not.

W. D. H.

Sphingomyelin. I. The Presence of Lignoceric Acid among the Hydrolytic Products of Sphingomyelin. PHŒBUS A. LEVENE (*J. Biol. Chem.*, 1913, **15**, 153—154).—Thudichum considered that the principal fatty acid in sphingomyelin was isomeric with stearic acid. This is not so; the acid in question has the composition $C_{24}H_{48}O_2$, melts at 81°, and forms an ethyl ester melting at 55—56°; hence it is lignoceric acid. W. D. H.

The Components of Sphingomyelin. PHŒBUS A. LEVENE (*J. Exper. Med.*, 1913, **18**, 679—680).—By the hydrolysis of this phosphatide the author has obtained in addition to lignoceric acid (preceding abstract) a base, $C_{15}H_{31}O_2N$, which is isolated in the form of its sulphate, m. p. 225°. S. B. S.

Myokynine. DANKWART ACKERMANN (*Zeitsch. Biol.*, 1913, **61**, 373—378. Compare this vol., i, 181).—Myokynine may be prepared from horse as well as from dog muscle. Myokynine dichloride from the dog muscle has $[a]_D^{20} - 11\cdot09°$, that from horse muscle has $[a]_D^{20} - 13\cdot5°$.

Myokynine can be esterified by means of ethyl alcohol and dry hydrogen chloride; it accordingly contains a carboxyl group. It does not give a pyrrole reaction when distilled with zinc dust. Since an unbranched chain of four carbons in presence of basic nitrogen usually forms pyrrole under these conditions, the presence of such a grouping in myokynine is doubtful. E. F. A.

Did Von Wittich Antedate Ostwald in the Definition of Enzyme Action? WILLIAM N. BERG (*Biochem. Bull.*, 1913, **2**, 441—445).—Quotations from von Wittich's writings of 1872-1 show that his conception of enzyme action was much the same as that of Ostwald. He was probably also the first to describe the adsorption of pepsin by solid proteins, such as fibrin. Abderhalden and others who have utilised the method of recent years have not referred to this.

W. D. H.

Amyloclastic Action of Malt and the Reaction of the Medium. HENRI VAN LAER (8th Inter. Cong. App. Chem., 1912, 14, 203—213).—The influence of the addition of varying quantities of acid and alkali on malt extracts of different origin has been studied.

The inhibition resulting from the presence of an excess of acid or alkali is due to the formation of an inactive compound between the enzyme and the acid or alkali. The diminution in the activity of diastase acting in presence of an excess of hydrogen or hydroxyl ions is due to three principal causes: (1) The destruction of a portion of the enzyme—this is non-reversible; (2) the temporary inactivity of part of the enzyme; (3) the increase in the activity due to the disappearance of some of the ions due to the influence of the steadiers (buffers).

Diastase has an amphoteric character, and its specific properties depend on both the acid and basic groups which it contains.

E. F. A.

The Nature of Diastase (Amylase). HENRI VAN LAER (Bull. Acad. Roy. Belg., 1913, 395—451).—A critical examination of previous work on the nature of diastase leads to the conclusion that the enzyme converting soluble starch into maltose is to be regarded as constituted by the association of a colloidal organic nitrogen compound with electrolytes, so allowing the former to act as a catalytic agent, provided always that the reaction of the medium is defined within narrow limits.

Diastase as it exists in cereals differs from the enzyme as used in solution. In the cereal, it is partly present as an insoluble zymogen in combination with protein substances which are capable of attack by pepsin; in solution, the enzyme is free and unaltered either by papain or pepsin.

The organic complement of diastase is digested by a solution of pepsin in hydrochloric acid. It is also modified by phosphotungstic acid like other proteins.

In solutions of diastase the dissolved matter is the more active as the amount of nitrogen in solution increases. The amount of pentosan present bears no relation to the activity of the enzyme. The conclusions are confirmed by extracting powdered diastase with successive equal amounts of water.

In dried preparations the enzyme slowly becomes inactive.

The nitrogen complement of diastase behaves as an amphoteric substance.

The mineral matter is essential for activity, but there is a maximum in the amount of neutral salts, above which any further increase will not cause increased enzyme activity.

At present all the established facts relative to the dynamics of diastatic action are best interpreted on the basis of the properties of emulsoids.

E. F. A.

The Relationship Between the Active and Inactive Condition of a Ferment and its Surface Tension. M. J. GRAMENIZKI (Biochem. Zeitsch., 1913, 52, 142—154).—Taka-diastase

solutions, as the author has already shown, partly recover the activity which has been lost by heating when they are kept. It is now shown that the surface-tensions of the solutions diminish on heating, but again increase on keeping. From these facts, the conclusion is drawn, that there is a connexion between the fermentative activity of a solution and its surface tension. S. B. S.

Saccharification of Starch by Koji Diastase in Presence of Acids and Salts. F. ANDO (*8th Inter. Cong. App. Chem.*, 1912, **14**, 13—24).—Experiments made with an extract of Koji diastase and potato starch in presence of a variety of mineral salts and acids are described. The presence of neutral and acid salts, with the exception of acid calcium phosphate, is up to a certain point favourable to the enzyme. Excess of the salts retards action except in the case of manganese salts.

Alkaline salts, with the exception of potassium phosphate, retard the saccharification. Small quantities of mineral acids accelerate action ; organic acids uniformly retard it. Action takes place in solutions of 30% alcohol. E. F. A.

Some Conditions Affecting the Activity and Stability of Certain Ferments. JOHN H. LONG and WILLIAM A. JOHNSON (*J. Amer. Chem. Soc.*, 1913, **35**, 895—913).—It is suggested that for diastasic comparisons, the starch paste should be made from starch prepared in the laboratory from sound ripe potatoes, and subsequently well washed. In experiments in which 0·1 gram of sodium chloride was present in each 100 c.c. of digesting mixture, it was found that amylolytic activity is greatest when about 25 mg. of sodium hydrogen carbonate are also added ; sodium hydrogen carbonate in larger quantity retards the action without destroying any of the ferment, whilst the addition of sufficient acid to neutralise the hydrogen carbonate destroys the ferment at once. Glycerol extracts of the pancreas are very stable, but rapidly lose amylotic power after dilution, especially if kept at 40° ; the presence of traces of sodium chloride exerts a considerable protecting effect. Experiments with the glycerol extract indicate that the pancreatic diastase is exceedingly sensitive towards even traces of mineral acid, such as hydrochloric acid, but that salt again exerts a protecting action ; the effect of the acid, which is more marked than that of alkali, is probably due to immediate destruction of the enzyme, as neutralisation fails to restore the original activity. D. F. T.

The Nature of Enzyme Action. III. The Synthetic Action of Enzymes. WILLIAM M. BAYLISS (*J. Physiol.*, 1913, **46**, 236—266).— Reactions in the system glycerol, dextrose, glycerol-glucoside and water, as accelerated by emulsin, follow the laws deduced from mass action for an equilibrium in a reversible system, catalysed by a single enzyme. The equilibrium position is the same from whichever end it is approached ; the glucoside produced is the β-form, and the same which is hydrolysed by emulsin. The reaction-rate is directly proportional (not linear, how-

ever) to the concentration of the enzyme. The final equilibrium is independent of this concentration.

Brailsford Robertson's "synthesis of paranuclein by pepsin" is not a synthesis, nor is it produced by pepsin; the substance formed is not paranuclein. It is a colloidal precipitation, and has no connexion with enzyme action.

Apparent deviations from the law illustrated should be properly investigated, and the reasons for divergence sought. It is unwise to invent new enzymes to explain difficulties.   W. D. H.

The Lipases Contained in Pancreatic Cysts. KONRAD BOURNOT (*Biochem. Zeitsch.*, 1913, 52, 155—171).—The lipases from the fluids of pancreatic cysts are similar to other animal lipases. The liquids can be filtered through paper without loss of lipolytic activity. This continually diminishes if the liquid is kept, but the residue obtained by evaporation at 20° preserves its lipolytic activity. Acids inhibit the lipolytic action, but alkalis in very low concentrations accelerate it. With small quantities of fluids (0·05—0·2 c.c.) there is a direct proportionality between the amount of enzyme and the fat saponified. For larger quantities of ferment the formulæ of Schütz and Arrhenius hold good. The Schütz law and Arrhenius' equation also agree with the time relations in fat hydrolysis and the oleic acid-glycerol fat synthesis within certain limits. Still better agreement is obtained, however, with the employment of contents calculated from the adsorption isotherm $K = X/E^m$. The maximal hydrolysis of triolein obtained was 93·5%, and the maximal synthesis in the presence of excess of glycerol was 42% of the oleic acid.   S. B. S.

The Lipase of Chelidonium Seeds. KONRAD BOURNOT (*Biochem. Zeitsch.*, 1913, 52, 172—205).—Like the ricinus lipase, the chelidonium lipase is insoluble in water, but is, to a large extent, soluble in the oils extracted by ether from the seeds. It is also somewhat soluble in a mixture of oleic acid and alcohol. Whereas, however, the ricinus lipase acts most readily on addition of acids, the chelidonium ferment acts best in the presence of water alone. Even $N/50$-acetic acid has an inhibitory effect on its action. The maximal hydrolysis obtained was 92—95%. The lipases of ricinus and chelidonium are similar, in ·that they do not readily hydrolyse the esters of the monohydroxy-alcohols. As the molecular weights of the fatty acids increase, the esters are more rapidly attacked by the chelidonium lipase; thus, *iso*butyl oleate and amyl palmitate undergo hydrolysis to the extent of 15—33%. The lipase, furthermore, can cause a rapid and almost complete synthesis of the esters of the higher fatty acids, which action is in marked contrast to the less complete hydrolysis of the same esters caused by the ferment. Possibly the larger quantities of water have an inhibitory action when the water of the substrate cannot form an emulsion. The *iso*butyl oleate synthesis accords with a unimolecular reaction, and there is a direct proportionality between the rate and quantity of enzyme present. The maximal synthesis is 92%. The maximal triolein synthesis is 47—50%. In the latter cases, the same final equilibrium is obtained in synthesis and hydrolysis. The final equilibrium here will depend

on the amount of water present. The seeds can be heated for fifteen minutes at 100° without any very marked deterioration of the ferment.　　　　　　　　　　　　　　　　　　　　　　　　S. B. S.

Action of Boric Acid on Zymase; Comparison with the Action of Phosphates. HENRI AGULHON (*Compt. rend.*, 1913, 156, 1855—1858).—The author has previously shown (A., 1909, i, 621) that boric acid is remarkably inactive towards diastases in general, and has examined its action on zymase. For this purpose, sucrose or dextrose was mixed with a constant quantity of zymase in the presence of varying amounts of boric acid, the course of the reaction being followed by determining from time to time the loss in weight due to the carbon dioxide evolved. The inhibiting action of boric acid is observable even with only 10 mg. of acid per 100 c.c., whilst with one gram of acid per 100 c.c. fermentation is no longer possible. On the other hand, living yeast derived from the same source is capable of fermenting a portion of the sugar supplied to it even in the presence of boric acid of the concentration 2 in 100, from which it appears that the membrane presents contact of the boric acid with the zymase.

The inhibiting action of boric acid cannot be attributed solely to its acidity, since monosodium phosphate, which possesses the same degree of acidity as boric acid, exerts a slight favouring action. The nature of the electronegative radicle is also important. This is shown by a series of comparative experiments with borax, trisodium phosphate, trisodium citrate, and sodium carbonate, in which only the borax is found to have a marked inhibiting effect. This effect is, however, less than that observed with boric acid, so that it appears that the favouring action of the alkali compensates in some measure the inhibiting action of the electronegative radicle.　　　　　　　　　　　　　　　　H. W.

Physiological Chemistry

The Work Done by the Lungs at Low Oxygen Pressures. ARCHIBALD V. HILL (*Proc. physiol. Soc.*, 1913, xxvii—xxviii; *J. Physiol.*, 46).—By calculation, from known data, of the work done by the lungs in secreting oxygen (if Haldane's views are accepted) it is found that the work done per minute by the lungs is only 0·8 cal. If therefore the lung cells can secrete oxygen at all, and if they be assumed to possess an "efficiency" in performing the mechanical work of oxygen secretion of only 20%, they should, nevertheless, be well able to perform this work with an activity no greater per gram than that of the body as a whole.　　W. D. H.

Carbon Dioxide Excretion Resulting from Muscular Work following Forced Breathing. GEORGE O. HIGLEY (*Biochem. Bull.*, 1913, 2, 390—392).—The sudden increase in the excretion of

carbon dioxide after the beginning of work is due to better ventilation of the lungs; the continuation of the increase is due to ventilation of the blood and tissues also. After forced breathing, followed by muscular work, the new rate of excretion is sharply defined; the further increase as the result of work is not so prompt, and comes on gradually. Some differences of detail occur according to the duration of the forced breathing.   W. D. H.

The Influence of Barometric Pressure on the Excretion of Carbon Dioxide in Man. G. O. HIGLEY (*Biochem. Bull.*, 1913, **2**, 393—402).—The degree of influence of barometric pressure on the excretion of carbon dioxide differs in different subjects. It is evidently a minor factor, the effect of which is liable to be masked by other influences, diet, exercise, etc.   W. D. H.

The Effect of Altitude on Mesectic Curves. JOSEPH BARCROFT (*Proc. physiol. Soc.*, 1913, xxx—xxxi ; *J. Physiol.*, **46**).—In subjects at rest living at a high altitude there is a reduced carbon dioxide tension in the blood, and acidosis. These so nearly balance each other that the dissociation curve remains mesectic (that is, normal). This statement is illustrated by the necessary data and calculations.
     W. D. H.

The Relation of the Blood-salts to Cardiac Contraction. ERNEST G. MARTIN (*Amer. J. Physiol.*, 1913, **32**, 165—183).—Calcium and sodium are not regarded as antagonistic, but each has a definite function. Calcium promotes (as Howell stated) the conversion of stable into unstable energy-yielding material; sodium (as proposed by Lingle) serves as the immediate stimulus to bring about the actual dissociation, and so to initiate the heart-beat. Neither is an exclusive agent; the preparation of dissociable material is much hampered by the accumulation of waste products, and is therefore aided by abundant supplies of oxygen or by sodium carbonate; carbon dioxide in moderate quantities, and perhaps sugar, act as direct stimulants to cardiac tissue much as sodium acts.
     W. D. H.

Hæmolysis by Silicic Acid. M. LIEBERS (*Arch. Hygiene*, 1913, **80**, 43—55).—In the system blood + silicic acid + complement, hæmolysis often takes place. The silicic acid cannot, however, always replace an ordinary amboceptor. Certain complements show the same complementing action towards sheep corpuscles charged with silica as towards the same corpuscles charged with an ordinary amboceptor. The more coarsely colloidal or turbid solutions of silica cause agglutination, and the blood does not then lake so readily when treated with the complement. The ordinary immune amboceptor in the original Wassermann reaction cannot be replaced by silica.   S. B. S.

Lipolytic Action of the Blood. FRANCIS H. THIELE (*Biochem. J.*, 1913. **7**, 275—286).—Blood and chyle contain an enzyme which can hydrolyse lecithin, but not neutral fat. When blood and chyle fat

are incubated together, the neutral fat forms an absorption compound with the protein, and is then non-extractable by ether. This compound can be broken up by peptic digestion, by alcohol, and by heating. The formation of the complex occurs in the corpuscles; serum has no such effect. It is not due to hæmoglobin, and is probably brought about by an enzyme.   W. D. H.

Variations in Glycæmia during Inanition. HENRY BIERRY and (Mlle.) LUCIE FANDARD (*Compt. rend.*, 1913, **156**, 2010—2013).— The authors have already shown (this vol., i, 426) that the injection of adrenaline can induce perturbations in the glycæmia of an animal, and now bring evidence of the considerable effect on the content of sugar in the blood of dogs caused by inanition. The quantity of free sugar is fairly constant for the first twelve days, then may occasionally increase considerably, but finally decreases. The combined sugar, which is liberated on hydrolysis, commences to increase in quantity about the twelfth day and continues to increase until death.   D. F. T.

The Action of the Thromboplastic Substance in the Clotting of Blood. F. W. MACRAE and A. G. SCHNACK (*Amer. J. Physiol.*, 1913, **32**, 211—218).—Calcium-free (oxalated) peptone plasma may be made to clot by the addition of calcium-free solutions of thromboplastic substance (kephalin), provided the excess of oxalate is removed by dialysis. The action of the kephalin is demonstrated more easily if some thrombin is added previously to the dialysed oxalate plasma in an amount insufficient in itself to overcome the effect of antithrombin. This result is opposed to the theory of Morawitz that the thromboplastic substance acts as a kinase in conjunction with calcium, but accords with Howell's view that kephalin facilitates clotting by neutralising antithrombin.
    W. D. H.

Blood-relationship of Animals as Displayed in the Composition of the Serum-proteins. II. A Comparison of the Sera of Ox, Sheep, Hog, Goat, Dog, Cat, and Guinea-pig with Respect to their Content of Various Proteins. J. HOMER WOOLSEY (*J. Biol. Chem.*, 1913, **14**, 433—439).—The following table summarises the average results obtained:

	Percentage of the total proteins in the sera of						
	Ox.	Sheep.	Hog.	Goat.	Dog.	Cat.	Guinea-pig.
"Insoluble" globulin...	8·1	6·4	6·0	6·5	7·7	6·5	4·2
Total globulin	29·0	17·0	36·0	22·0	18·0	30·0	16·0
Total albumin	70·0	82·0	64·0	75·0	81·0	69·0	84·0

    W. D. H.

The Activation of Blood-serum. CORNELIS A. PEKELHARING (*Zeitsch. physiol. Chem.*, 1913, **85**, 341—345).—When blood-serum is kept, its power to coagulate fibrinogen lessens. Morawitz attributes this to a change of thrombin into a metathrombin. Such serum

can be reactivated by adding alkali, and then neutralising; the author advances the view that the loss of activity is due to the development of inhibitory substances, and that these are destroyed by alkali. He also disagrees with Landsberg, who regards the loss of activity as due to adsorption of the thrombin by the serum proteins; and quote experiments to support his view. Among other things proved is the fact that dialysis of the serum removes the inhibitory substance or substances. Activated serum on keeping loses its activity more rapidly than serum which has not been treated with alkali.   W. D. H.

The Digestive Enzymes of Cold- and Warm-blooded Animals. I. The Pepsin of the Hake and Dog. A. RAKOCZY (*Zeitsch. physiol. Chem.*, 1913, **85**, 349—371).—The pepsin of hake and dog are not identical, but show the following differences: Hake pepsin digests fibrin, serum protein, and caseinogen well, but it is less active towards edestin, and especially towards egg-albumin and elastin than dog's pepsin. Hake pepsin is adapted to work at a lower acidity than dog's pepsin; there are also differences in milk-curdling power, adsorption by elastin, velocity of action, and in optimum temperature. Hake's pepsin is only slightly inhibited at freezing point.   W. D. H.

The Pepsin–Chymosin Question. WILLEM VAN DAM (*Zeitsch. physiol. Chem*, 1913, **86**, 77—84).—Polemical against Rakoczy's views.   W. D. H.

The Influence of Preliminary Heating on Peptic and Tryptic Digestion. A. H. BIZZARRO (*J. Physiol.*, 1913, **46**, 267—284).— During peptic digestion, Sörensen's formaldehyde method shows that amino-acid groupings are liberated slowly, and after many days' action the time varies for different proteins. Preliminary heating of egg-white to 120—140° makes subsequent tryptic proteolysis more active; the same is true for fibrin, caseinogen, and beef; but the opposite for gelatin. The amino-acid groupings in tryptic solutions increase after fifteen hours' digestion.   W. D. H.

Pancreatic Digestion. (Miss) GERTRUDE D. BOSTOCK (*Zeitsch. physiol. Chem.*, 1913, **85**, 471—492).—A study of the influence of alkali on the partition of nitrogen in the digestion of fibrin by pancreatin shows that the powers to dissolve and to split proteins are two different things. The most favourable degree of alkalinity for protein solution is between 1·2 and 1·8% of sodium carbonate. Protein cleavage is hindered by 0·6% sodium carbonate, but between 0% and 0·3% no differences were noted. An optimum concentration for cleavage was not found. The cleavage during protein tryptic digestion is as unfavourably influenced by 0·6 to 1·2% of sodium carbonate as is protein cleavage during autolysis.
                                    W. D. H.

The Influence of Carbon Dioxide on Chlorine Metabolism. ERNST LAQUEUR and J. SNAPPER (*Biochm. Zeitsch*, 1913, **52**, 41—59). —It has been shown by Hamburger that chlorine passes from the

body fluids into tissue cells when the mixture is treated with carbon dioxide *in vitro*. Experiments carried out with rabbits, which were allowed to inhale air rich in carbon dioxide, failed to reveal a similar action *in vivo*, as no chlorine retention was found to take place after such inhalations, as should be expected if chlorine passed from the blood serum into the formed elements. It is assumed that the body possesses some compensatory mechanism which prevents this from taking place. S. B. S.

The Nitrogen-sparing Action of Salts, Especially of Sodium Acetate, in the Case of Carnivorous Animals. ERNST PESCHECK (*Biochem. Zeitsch.*, 1913, **52**, 275—330).—Numerous experiments are given in detail, in which sodium acetate and other salts were added to basal diets given to dogs, in which the nitrogen balance was, in some cases, complete, in other cases positive, and in still other cases negative. The results of previous experiments were confirmed, which tended to show that sodium acetate causes nitrogen retention, this action being specially marked when the nitrogen balance is a negative one. The salt is without action on the amount of nitrogen excreted in the fœces. Sodium citrate, sodium lactate, and magnesium acetate appear to exert a similar action. The author supposes that the action is due to the alkali added, which can be used for neutralisation of acids in the body, instead of the ammonia set free by the deamidisation of the proteins. S. B. S.

[Nitrogenous Metabolism.] EDUARD GRAFE (*Zeitsch. physiol. Chem.*, 1913, **85**, 347—348).—Polemical. A final reply to Abderhalden and Lampé (compare this vol., i, 547, 671). W. D. H.

The Normal Protein Metabolism of the Rat. OTTO FOLIN and J. LUCIEN MORRIS (*J. Biol. Chem.*, 1913, **14**, 509—515).—The new micro-chemical analytical methods enable small quantities of urine to be dealt with, such as are excreted by the rat. Rat's urine closely resembles that of man. The high percentage of uric acid is remarkable, for the rat's tissues lack the uric acid-forming enzymes, although the liver destroys it. W. D. H.

Intermediary Metabolism of Carbohydrates and Proteins. The Mutual Interconversion of α-Amino-acids, α-Hydroxy-acids, and α-Ketonic Aldehydes. HENRY D. DAKIN and HAROLD W. DUDLEY (*J. Biol. Chem.*, 1913, **14**, 555—561; **15**, 127—143).—By a suitable choice of experimental conditions it is possible to convert α-amino- and α-hydroxy-acids into α-ketonic aldehydes at low temperatures; lactic acid and alanine. for example, yield methylglyoxal. When methylglyoxal is acted on by enzymes (glyoxalases) found in the body, *d*- and *l*-lactic acid are formed. When given to the glycosuric animal, glyoxal and both lactic acids yield dextrose. Methylglyoxal is therefore believed to be an intermediate product in the mutual interconversion of alanine, lactic acid, and dextrose (compare Proc., 1913, **29**, 156). W. D. H.

The Value of Lactose and Galactose after Partial Exclusion of the Liver (Eck's Fistula). LUDWIG DRAUDT (*Arch. expt. Path. Pharm.*, 1913, 72, 457—474).—After an Eck's fistula the nutritive value of lactose and galactose falls; the liver fails to convert them into glycogen, and the sugars circulate in the blood and leave the body by the urine. 　　　　　　　　　　　W. D. H.

The Formation of Fat from Carbohydrate. SERGIUS MORGULIS and JOSEPH H. PRATT (*Amer. J. Physiol.*, 1913, 32, 200—210).—The present observations on dogs confirm the results of others with other animals, that feeding on carbohydrates leads to fat formation with the accompaniment of a high respiratory quotient. 　　　　　　　　　　　W. D. H.

Fat Absorption. II. Absorption of Fat-like Substances other than Fats. W. R. BLOOR (*J. Biol. Chem.*, 1913, 15, 105—117).—Neither petroleum hydrocarbons nor unsaponifiable esters (wool-fat) are absorbed. Neither class of compounds is reducible to a water-soluble form in the intestine. Hence it is extremely probable that fats can only be absorbed in water-soluble form, and that saponification is a necessary preliminary to absorption. 　　　　　　　　　　　W. D. H.

The Absorption of Nitrogenous Products. OTTO FOLIN and WILLEY DENIS (*J. Biol. Chem.*, 1913, 14, 453—455).—Polemical. A reply to Abderhalden and Lampé (A., 1912, ii, 1189). W. D. H.

Nutrition of the Embryo-chick III. The Assimilation of Egg-white. HUBERT W. BYWATERS and W. BARRETT ROWE (*Proc. physiol. Soc.*, 1913, xxxiii—xxxiv; *J. Physiol.*, 46).—During incubation the ratio of albumin to ovomucoid in the white of the egg remains constant. Either the two proteins are absorbed at the same rate or the albumin alone is absorbed, and then fresh albumin is formed from the ovomucoid. The ovomucoid contains the same proportion of carbohydrate throughout. Probably the first explanation is the correct one. 　　　　　　　　　　　W. D. H.

An Important Chemical Difference between the Eggs of the Sea Urchin and those of the Star-fish. ALBERT P. MATHEWS (*J. Biol. Chem.*, 1913, 14, 465—467).—Cholesterol is absent or nearly so in the starfish egg. It could not be found in the eggs of *Asterias forbesii*. It is present in considerable amount in the sea urchin eggs. The phosphatide of the starfish contains about 10% of a reducing sugar in firm combination and also sulphuric acid. 　　　　　　　　　　　W. D. H.

The Influence of Hypertonic Solution on the Rate of Oxidations in Fertilised and Unfertilised Eggs. JACQUES LOEB and HARDOLPH WASTENEYS (*J. Biol. Chem.*, 1913, 14, 469—480).—The unfertilised eggs of sea urchins which have undergone artificial membrane formation die if not treated with a hypertonic solution,

but the solution does not increase the rate of oxidations either in unfertilised or fertilised eggs. Such solutions increase the rate of oxidations in unfertilised eggs if they have not undergone membrane formation. Weak bases added to normal sea-water cause membrane development, and affects the rate of oxidation in unfertilised eggs as when they are added to hypertonic sea-water. Complete cytolysis of the unfertilised eggs by saponin raises the rate of oxidation to the same height as fertilisation, showing that cytolysis of the surface of the egg is the essential feature in fertilisation.

W. D. H.

The Influence of Bases on the Rate of Oxidations in Fertilised Eggs. JACQUES LOEB and HARDOLPH WASTENFYS (*J. Biol. Chem.*, 1913. **14**, 459—464).—Bases influence the rate of oxidations differently in the fertilised and unfertilised eggs of *Strongylocentrotus purpuratus*. Strong bases accelerate this rate in the fertilised egg only if their concentration is over $10^{-3}N$; this suppresses development of the egg. Weak bases accelerate the rate slightly in the fertilised egg. No conclusion as to the seat of oxidation in the egg is warranted.

W. D. H.

Biochemistry of Protozoa. II. THEODOR PANZER (*Zeitsch. physiol. Chem.*, 1913, **86**, 33—42).—The parasitic protozoon *Goussia gadi*, which lives in the swim-bladder of certain fishes and also in shellfish, was investigated.

The composition and constants of the fatty substances present show them to be different from those in the host. No sugar or related substance was found. The keratin-like protein in the spore-capsules is free from sulphur and phosphorus. After hydrolysis, lysine, histidine, arginine, tyrosine, glycine, and glutamic acid were separated.

W. D. H.

The Action of Tissues on Hexoses. PHŒBUS A. LEVENE and GUSTAV M. MEYER (*J. Biol. Chem.*, 1913, **15**, 65—68).—Kidney tissue was obtained aseptically, and in its presence dextrose, *d*-mannose, and *d*-fructose were all converted into *d*-lactic acid. The action is the same, but not quite so powerful as that of leucocytes.

W. D. H.

The Biochemical Conversion of Methylglyoxal into Lactic Acid and the Formation of the Different Lactic Acids in Nature. CARL NEUBERG (*Biochem. Zeitsch.*, 1913, **51**, 484—508).—Animal tissue extracts contain an aldehydomutase, which readily converts methylglyoxal into lactic acid. The reaction takes place best when the reaction mixture contains calcium hydrogen carbonate, which prevents the mixture from becoming too acid. This process is carried out in the following way: 1·40 grams of calcium carbonate are added for each 0·72 gram of methylglyoxal present in solution in the organ extract; the former is added, and the liquid is saturated with carbon dioxide before addition of the aldehyde. After remaining in the incubator, the mixture is heated

and filtered, and an aliquot portion is evaporated to a small bulk. Hot alcohol is added, the precipitated substances were filtered off, the filtrate is again evaporated, treated with alcohol, and again evaporated. These processes are continually repeated until no precipitate is produced on addition of alcohol. The amount of lactic acid formed can be estimated by determining the amount of calcium in an aliquot part of the final filtrate; for determination of the rotation the zinc salt can be made from this liquid. Control estimations should be made with the methylglyoxal and tissue extract separately, both of which yield small quantities of a soluble calcium salt when treated by the above process, and a correction can be thus introduced into the result.

The conversion of methylglyoxal into lactic acid is never quantitative, but reaches sometimes 75%. Certain maceration juices of top yeasts are also capable of producing lactic acid from methylglyoxal, but not aqueous extracts of the same. The lactic acid thus produced is inactive. On the other hand, muscle and liver extracts produce the l-acid, which is not the naturally occurring form. The theory of the formation of this active form is discussed by the author in some detail. He assumes that by the addition and scission of the elements of water optically active substances can be produced from forms such as methylglyoxal, which are themselves inactive, and that such active substances are formed as intermediary products in various biochemical changes. These views are illustrated by numerous examples and formulæ.   S. B. S.

The Preparation from Animal Tissues of a Substance which Cures Polyneuritis in Birds Induced by Diets of Polished Rice. I. EVELYN A. COOPER (*Biochem. J.*, 1913, 7, 268—274).— A fraction rich in the anti-neuritic substance can be precipitated by ether from the fats and lipoids (alcoholic extract) of horse-flesh. The substance is insoluble in alcohol, benzene, chloroform, ether, and ethyl acetate, but is moderately soluble in water. It is absorbed to some extent by animal charcoal, and is destroyed readily by alkali. Quinine and cinchonine exert a temporary curative action in these birds, but lose this power after being heated at 125° for six hours; the effect is regarded as due to traces of the anti-neuritic substance from the cinchona bark. Alcohol given to the birds in small doses does not affect the onset of polyneuritis when a diet of polished rice is taken. This suggests that alcoholic neuritis is not due to a lessened capacity of the body to utilise the anti-neuritic substance.   W. D. H.

Lipolytic Action of the Tissues. FRANCIS H. THIELE (*Biochem. J.*, 1913, 7, 287—296).—The tissues possess a true lipolytic enzyme, but, except in the case of the pancreas, it hydrolyses phosphatides and jecorins, but not ordinary fats. It acts in an alkaline or acid medium. There is no evidence of a kinase in the spleen.
        W. D. H.

The Influence of Anæsthetics on the Oxydones. FRÉD. BATELLI and (Mlle) LINA STERN (*Biochem. Zeitsch* 1913. **52**, 226—252. Compare Vernon, this vol., i, 220).—The "oxydones" are the insoluble catalysts contained in animal tissues, which accelerate the oxidation of certain substances. Below certain concentrations, anæsthetics have no action on the succinic oxydone; at a certain critical concentration they exert an inhibitory influence, which is not far removed, except in the case of antipyrine, from a limiting concentration at which the ferment becomes quite inactive. Similar phenomena were observed by Vernon in the case of the phenylenediamine oxydone. All anæsthetics have the power of precipitating nucleoproteids from aqueous solution; this precipitation is only marked when a certain critical concentration is reached, and is complete in a slightly higher concentration. These two concentrations, except in the cases of phenol and *o*-cresol, are almost identical with the concentrations necessary for inhibition and complete inactivation of the oxydone. They also vary, in both cases, with the temperature. The influence of the anæsthetics on the activity of the succinic oxydone is not much stronger when they are present during the actual oxidation than when the tissue has been treated by them and then washed. The destruction of the oxydone is therefore an irreversible process. There is, as Vernon has already shown, a parallelism between narcotic action and capacity to destroy oxydones, which is far more marked than the parallelism between the narcotic action and coefficient of distribution between oil and water. There is also a parallelism between the capacity for destroying oxydones and the hæmolytic action, the toxicity, and capillary activity. The authors draw the conclusion that these activities are due rather to actions on the proteins than to the actions on lipoids   S. B. S.

The Influence of Aldehydes on the Oxydones FRÉD. BATELLI and (Mlle) LINA STERN (*Biochem. Zeitsch* , 1913. **52** 253—270).—The aldehydes are similar in their action on oxydones to the anæsthetics, the method of action of which is described in the preceding paper. There is a critical concentration at which inhibition is effected, which is not far removed from the limiting concentration of total inactivation. Both vary with the temperature; the destructive action on the oxydones, furthermore, is an irreversible one. These critical and limiting concentrations do not coincide, however, with the incipient and complete precipitation of the nucleoproteins in the case of liver extracts, but, as a general rule, they nearly coincide with the capacity of the aldehyde to form a precipitate with the soluble proteins after acidification with acetic acid. Again, the authors draw the conclusion that the destruction of oxydones is due rather to action on the proteins than to action on the lipoids.   S. B. S.

The Sympathetic System Does Not Possess the Same Chemical Composition as the Axial Nervous Tissue and the Cranial or Spinal Nerves. N ALBERTO BARBIERI (*Compt. rend.*, 1913, **157**, 69—72).—By successive extraction with carbon

disulphide, distilled water, alcohol, ether, and boiling alcohol the author has made a comparative analysis of the tissue of the sympathetic system and of the axial nervous tissue and the cranial and spinal nerves, and finds that the first-named differs in chemical composition from the others. Of its total extract 66% is composed of oil and stearin. It is completely void of nervous serum and of cerebroin and cerebrin.   W. G.

Carbon Dioxide Production in Nerve Fibres. SHIRO TASHIRO (*Amer. J. Physiol.*, 1913, **32**, 107—136).—All nerve fibres give off carbon dioxide. A nerve of the spider crab at rest produces $6\cdot7 \times 10^{-7}$ gram per 10 mg. per ten minutes. The figure for frog's sciatic is $5\cdot5 \times 10^{-7}$. The amount is increased in activity to 16×10^{-7} (crab) and $14\cdot2 \times 10^{-7}$ (frog). This is due to a vital active process, which is reduced by anæsthetics, both in nerves and seeds.   W. D. H.

The Cerebro-spinal Fluid in Nervous Diseases. I. ROBERT V. STANFORD (*Zeitsch. physiol. Chem*, 1913, **86**, 43—50).—The high specific gravity of the cerebro-spinal fluid in cases of progressive paralysis is regarded as of diagnostic importance.   W. D. H.

The Cerebro-spinal Fluid in Nervous Diseases. II. Nitrogen. ROBERT V. STANFORD (*Zeitsch. physiol. Chem.*, 1913, **86**, 219—233) — The amount of nitrogen follows the specific gravity; it is increased in progressive paralysis, and in certain other mental diseases, but not so greatly. In epilepsy this is not the case as a rule.
                                                        W. D. H.

The Action of Electrolytes on the Heart. GEORGE R. MINES (*J. Physiol.*, 1913, **46**, 188—235).—The experiments were made on the frog's heart, simultaneous records of the contractions and of their electrical accompaniment being taken. The character of the electrocardiogram and the changes it undergoes are discussed at length. Among the points of interest noted is that the electrical changes may continue after all movements have ceased, as when calcium is absent from the perfusing fluid. This has already been noticed in the mammal's heart by Locke and Rosenheim.
                                                        W. D. H.

The Action of Pituitrin and β-Amino-4 ethylglyoxaline (Histamine) on the Action of the Heart. W. EINIS (*Biochem Zeitsch.*, 1913, **52**, 96—117).—The experiments were made on the isolated hearts of frogs and rabbits. In the rabbit's heart single small doses of pituitrin cause a slight increase in the frequency, larger doses a diminution. Repeated doses also cause a diminution In hearts brought to a standstill by want of oxygen, pituitrin causes a transient activity. β-Amino-4-ethylglyoxaline causes a diminution of frequency by inhibition of the stimulus. On the mammalian heart pituitrin causes a diminution of frequency, followed by a more or less marked rise; there is a diminution in

the height of contraction, followed by a recovery to the normal, or even higher than the normal. The diminution in the frequency and height of contraction may be ascribed to the chloretone contained in the preparation used. β-Amino-4-ethylglyoxaline causes an increase in the frequency in the mammalian heart to two or three times the normal after a slight preliminary transient diminution. The final value is below normal. It also causes a marked increase in the height of contraction.   S. B. S.

The Action of the Diastatic Ferment on Glycogen within the Cell. III. ERNST J. LESSER (*Biochem. Zeitsch.*, 1913, 52, 471—485).—During the winter months glycogen does not disappear quickly from the liver during incubation of the intact organ. If, however, the organs are ground up so as to destroy the structure, the glycogen rapidly disappears; in fact, it is hydrolysed as rapidly as it is in the intact organs taken from animals during the months of May and June, when the glycogen is labile. The difference is probably due to the difference of the diffusibility of the ferment through the cells, which enables it to come into contact with the glycogen, and not to the presence of blood-diastase, as the same results are obtained with the organs which have been perfused and rendered blood-free, as with the organs directly removed from the body (compare Ivar Bang, this vol., i, 552, 553).   S. B. S.

The Action of Antiglycosuric Medicaments and Liver Glycosuria. III. The Perfusion of the Liver with Blood under the Influence of Different Reagents. ERNST NEUBAUER (*Biochem. Zeitsch*, 1913, 52, 118—141. Compare A., 1912, ii, 962).—The results were obtained by oncometric experiments on rabbits' livers. An increase of volume of the organ follows the intravenous or subcutaneous injection of adrenaline, and the intravenous injection of the infundibular portion of pituitary body, of strophanthin, of cocaine (after subcutaneous injection of adrenaline), after asphyxia produced by stoppage of the trachea, after faradic stimulation of the central end of the vagus in the neck and the stimulation of the splanchnic. There is contraction or inhibition of expansion of the liver, after intravenous injection of the glandular portion of the pituitary body, after veronal, chloral hydrate, ergotoxin, after venesection, and after stimulation of various kinds of the peripheral end of the vagus. Phloridzin and cocaine have no specific action on the liver volume. Caffeine and diuretin cause repeated alterations in the kidney volume. The liver volume changes run as a rule parallel with the height of the blood-pressure, behaving in this respect like the limbs, but unlike the spleen. Those treatments of the animals which produce hyperglycæmia in the liver through vaso-constriction in the splanchnic vessel system cause, generally, expulsion of the sugar, whereas those treatments which antagonise this stasis in the liver, antagonise also glycosuria. The rule is, however, not absolute; diminution of the liver volume produced by insufficient arterial blood supply, for example, can also be accompanied by expulsion of sugar, which also takes place in a stasis produced by anoxybiotic conditions.   S. B. S.

The Oxidation Products of Cholesterol in the Animal Organism (Portal and Hepatic Veins). V. ISAAC LIFSCHUIZ (*Biochem. Zeitsch.*, 1913, **52**, 206—213).—The absence of oxycholesterol from the liver might be explained, either on the assumption that the liver cannot take up this substance, or that it takes it up from the blood-stream and changes it into other products which do not give the oxycholesterol reactions. From analyses of the blood of the portal and hepatic veins, and of blood which had been artificially perfused through the liver, the second of the above explanations seems to be correct, for the hepatic vein contains less oxycholesterol than the portal vein, and unperfused blood less than perfused blood.   S. B. S.

The Effect of Changes in the Circulation of the Liver on Nitrogen Metabolism. SAMUEL A. MATTHEWS and E. M. MILLER (*J. Biol. Chem.*, 1913, **15**, 87—104)—After an Eck fistula is established, urea in the urine is largely replaced by ammonia, and toxic effects have been described as the result of increased ammonia in the blood. In the present experiments a large number of the dogs died of inanition, but in some the augmented excretion of ammonia over long intervals did not even produce ill health. Such dogs, however, are susceptible to meat intoxication. In animals which survive a long time the formation of adhesions may bring about a partial return of portal blood to the liver.   W. D. H.

Physiology and Pathology of the Kidney Functions. WILHELM BAETZNER (*Archiv expt. Path. Pharm.*, 1913, **72**, 309—315).—In experiments on animals it was found contrary to the statements of Bock that in water diuresis a regularly increasing rise in phosphorus elimination takes place.   W. D. H.

Action of Leucocytes on Hexoses. IV. The Mechanism of Lactic Acid Formation. PHŒBUS A. LEVENE and GUSTAV M. MEYER (*J. Biol. Chem.*, 1913, **14**, 551—554).—The present paper confirms the work of Dakin and Dudley (this vol., i, 565; also corroborated by Neuberg, this vol., ii, 564) on the existence of glyoxalases. In the present experiments bacteria were rigidly excluded. Leucocytes and kidney tissues were used, and produced the conversion of methylglyoxal into *dl*- and *d*-lactic acid. This confirms the view that the formation of *d*-lactic acid from the various *d*-hexoses is conditioned by the intermediate formation of methylglyoxal:

$$OH \cdot CH_2 \cdot CH(OH) \cdot CHO \longrightarrow CH_3 \cdot CO \cdot CHO \longrightarrow$$
$$CH_3 \cdot CH(OH) \cdot CO_2H.$$

W. D. H.
The Physiology of the Thyroid. F. BLUM (*Zeitsch. physiol. Chem*. 1913, **85**, 428—429).—Introductory to a series of papers to follow later.   W. D. H.

Self-digestion of the Thymus. ELI K. MARSHALL, jun. (*J. Biol. Chem.*, 1913, **15**, 81—84).—In self-digestion of the thymus, the

enzymes present are not capable of decomposing all the nucleic acid within any reasonable length of time; the portion left undecomposed appears to be identical with that prepared from the fresh gland. W. D. H.

Physical Chemistry of Muscle-plasma. FILIPPO BOTTAZZI (*Biochem. Bull*, 1913, **2**, 379—385).—Muscle-plasma as seen under the ultra-microscope is full of many brilliant, small particles (myosin) and a small number of coarse particles; the latter are composed of fat, glycogen, and nuclear and sarcoplasmic fragments. The liquid portion contains salts, extractives, and protein in true solution. When freed from the granules, the plasma is optically homogeneous, but on adding acid or heating to 55°, true precipitation of a dissolved muscle protein (myoprotein) occurs.

The fine plasma granules are degradation products from the muscular fibrils. They tend to flocculate spontaneously, and the so-called heat coagulation which occurs between 38° and 54° is due to rapid aggregation. Myoprotein is not completely coagulated by heat even at 80°; it is totally precipitated by dialysis. Tables of the composition and physical constants of muscle plasma are appended. The osmotic pressure is high, and the reaction always acid. The maximum production of acid substances occurs soon after the muscles are separated from the body, and it is these which cause the high osmotic pressure. The surface tension is also higher than that of blood-serum. W. D. H.

Fasting Studies. XI. Composition of Muscle from Fasting Dogs. HENRY C. BIDDLE and PAUL E. HOWE (*Biochem. Bull*, 1913, **2**, 386—389).—The tables given show an increase in water, and a decrease in nitrogen and creatine as a result of fasting. In the heart (one observation only) the nitrogen falls and the creatine rises. W. D. H.

Carnosine Content of the Muscles of Mammals. MARIE MAUTHNER (*Monatsh.*, 1913, **34**, 883—900).—The present investigation was undertaken with the object of deciding whether carnosine is the sole component of the carnosine fraction obtained by Gulewitsch (A., 1900, i, 516) from the muscles of mammals, and also in the hope of discovering an exact method for the estimation of carnosine. The following are the main conclusions:

(i) If a carnosine fraction is obtained from meat extract by addition of lead acetate and silver nitrate, separation of the precipitated matter, addition of silver nitrate and barium hydroxide to the filtrate and decomposition of the precipitate so obtained by means of hydrogen sulphide, it is frequently possible to separate the carnosine in the form of the sparingly soluble, blue, crystalline copper compound described by Gulewitsch. A quantitative separation is, however, never obtained, and there are many indications that, in addition to carnosine itself, a modification or decomposition product of it is often present which does not possess the power of dissolving copper hydroxide.

(ii) Estimations by the picrolonic acid method of the histidine obtained by hydrolysis of carnosine fractions by hydrochloric or sulphuric acids show that 80—90% of the nitrogen present in the latter is contained in the form of carnosine or of a closely allied compound.

(iii) The same result is obtained by the separation of the base from carnosine fractions in the form of a sparingly soluble, yellow, crystalline *picrolonate*, which, according to ultimate analysis and to the amount of picrolonic acid separable from it by addition of hydrochloric acid, is a mono-sodium compound of carnosinedipicrolonate, $C_{29}H_{29}O_{13}N_{12}Na$.   H. W.

The Occurrence of Alcohol-resistant Carmine-red and Brown-red Pigments in the Skin of Bony Fishes. EMIL BALLOWITZ (*Zeitsch. physiol. Chem.*, 1913, **86**, 215—218).—The red pigments referred to occur in the chromatophores, and are distinct from a yellow lipochrome which is soluble in alcohol.   W. D. H.

The Presence of Boron in Milk and Eggs. GABRIEL BERTRAND and HENRI AGULHON (*Compt. rend.*, 1913, **156**, 2027—2029. Compare A., 1910, ii, 241; 1912, ii, 854; this vol., i, 423).—From the very frequent occurrence of this element in animals and vegetables the authors raise the question as to whether the element may not play, like iron and manganese, an indispensable part (possibly catalytic) in the living cell. They have extended their investigation to milk (human, ass, goat, and cow) and to eggs (fowl, pigeon, wild duck, turkey, and goose), with distinct positive results in each case. Analysis indicates the presence of 0·08, 0·1, and 0·2 mg. of boron in 1 litre of human, ass's, and cow's milk respectively, and 1 mg. of boron in 1 kilogram of dried material from the egg of the fowl, turkey, or goose.   D. F. T.

The Alcohol Content of Milk after Ingestion of Alcohol and under the Influence of Tolerance. WILHELM VOLTZ and JOHANNES PAICHTNER (*Biochem Zeitsch.*, 1913, **52**, 73—95).—After a short period of toleration the amounts of alcohol appearing in the milk in the case both of cows, and of a woman, who ingested moderate quantities, are practically negligible. When cows are fed on residues from distillation processes, which seldom contain more than 0·1 to 0·3% alcohol, only, at the outside, a few milligrams .of alcohol can be ingested daily by infants fed on the milk from such animals, quantities, in fact, which are absolutely without action.   S. B. S.

Action of Hydrogen Peroxide on the Amylase of Human Milk. L. LAGANE (*Compt. rend.*, 1913, **156**, 1941—1943).—Starch paste is not liquefied by cow's or goat's milk before or after boiling, but a slight liquefaction occurs with either of these milks in a fresh state in presence of hydrogen peroxide. Fresh human milk, on the contrary, liquefies starch paste, and this action is greatly accelerated in presence of hydrogen peroxide, although the latter

does not enable boiled human milk to effect liquefaction. Similarly, the saccharification of starch paste by fresh human milk takes place more rapidly in presence of hydrogen peroxide, but this action is less marked than the acceleration of liquefaction. Control experiments of various kinds indicate that the acceleration is due to direct action of the peroxide on the amylase, or possibly to indirect action through peroxydases in the milk. T. A. H.

The Critical Solution Point of Urine. WILLIAM R. G. ATKINS and THOMAS A. WALLACE (*Biochem. J.*, 1913, 7, 219—230).—In normal urines the rise in critical solution point is about eight times as great as the depression of freezing point. In very dilute urines, and when excess of salts are present, this is greater; in the presence of dextrose or excess of urea it is less. The relationship between the rise of the critical solution temperature and the depression of the freezing point furnishes a useful datum in the examination of urine. W. D. H.

Toxic Bases in the Urine of Parathyroidectomised Dogs. W. F. KOCH (*J. Biol. Chem.*, 1913, 15, 43—63).—Digested proteins have a very toxic effect after parathyroidectomy; the toxic substances which arise either in intestinal or parenteral digestion pass into the urine, in which secretion several bases were found, among which β-amino-4-ethylglyoxaline, choline, and methylguanidine were identified. In animals in which no feeding occurred, the violent symptoms observed are attributed to disintegration of the body-protein. Histological examination reveals active degeneration of the cell-nuclei. The parathyroid secretion is regarded as concerned with anabolic processes closely related to the building up of nucleins. W. D. H.

The Chemical Composition of the So-called " Colloidal " Nitrogenous Substances obtained from Human Urine by Precipitation with Zinc Salts. H. THAR and J. BENESLAWSKI (*Biochem Zeitsch.*, 1913, 52, 435—438).—Salkowski has shown that alcohol produces a precipitation in concentrated human urine which contains nitrogen, is non-dialysable, and was supposed to consist of oxyproteic acid and similar substances. These same substances can also be obtained by precipitation with zinc sulphate. They have been investigated in greater detail by the authors, who now show that the precipitate contains chiefly uric acid and purine bases, contaminated with small quantities of urea, ammonia, and other constituents of the urine. S. B. S.

Acapnia and Shock. HENRY H. JANEWAY and EPHRAIM M. EWING (*Biochem. Bull.*, 1913, 2, 403—406).—The conclusion is drawn from experiments on dogs that the reduction of the carbon dioxide of the blood is not an important factor in the production of shock induced by hyper-respiration, but that the essential influence is an interference with the venous return to the heart. In experiments on the intestines, shock is due to manipulation of the gut, and not to

any lessening of carbon dioxide in the blood produced thereby. Aëration of the intestines without the addition of carbon dioxide does not produce shock.   W. D. H.

Beri-beri. VII. The Vitamine Fraction from Yeast and Rice Polishings. CASIMIR FUNK (*J. Physiol.*, 1913, **46**, 173—179).
—The vitamine fraction from yeast was separated into three substances: (1) with formula $C_{24}H_{19}O_9N_5$, (2) with formula $C_{20}H_{22}O_9N_5$, and (3) nicotinic acid. The first substance mixed with the third is stated to have some curative effect on pigeons suffering from polyneuritis.
The vitamine fraction from rice polishings was separated into two fractions: (1) with formula $C_{26}H_{20}O_9N_4$, and (2) nicotinic acid. The deductions as to their curative power are not yet published.
                                        W. D. H.

The Theory of Diabetes. I. Sarcolactic Acid in Diabetic Muscle. ROLLIN T. WOODYATT (*J. Biol. Chem.*, 1913, **14**, 441—451. Compare this vol., i, 559).—Muscles of glycogen-free animals form some sarcolactic acid (about 30% of the normal). This cannot come from glycogen, but must arise from preformed sugar or directly from amino- or fatty acids. The muscles of a severe human case of the disease formed even less than that of fully phloridzinised dogs. This suggests an impaired power to dissociate dextrose on the part of the muscles, as they are bathed in an abnormally high quantity of sugar. With D : N (dextrose : nitrogen) ratios of 3·65 : 1 post-mortem analyses of dog's muscles and livers show no glycogen. With ratios 2·8 or 3·0 : 1 this is not necessarily the case, and it cannot be assumed that with a constant D : N ratio of this magnitude an animal is free from glycogen.   W. D. H.

The Part Played by Acids in Carbohydrate Metabolism. II. Starvation Diabetes. HERBERT ELIAS and L. KOLB (*Biochem. Zeitsch.*, 1913, **52**, 331—361. Compare this vol., ii, 215).—The object of the investigation was to ascertain whether the diabetes produced by administration of carbohydrates during starvation is due to acidosis. This, from experiments on young dogs, appears to be the case for the following reasons. The starvation diabetes is accompanied by increased acidity of the blood, as determined by Spiro and Pemsel's method, and by an increased carbon dioxide tension in the alveolar air, as estimated by a modification of Wolffberg's technique The diabetes is always accompanied also by hyperglycæmia, which indicates that it cannot be ascribed to renal insufficiency; neither is it due to any action of the suprarenals, as it also occurs after bilateral splanchiotomy. Furthermore, the diabetes is depressed by administration of alkali, which also reduces the blood sugar to the normal. The diabetes appears to be due, therefore, to some disturbance in the intermediary metabolism, and is to a great extent to be ascribed to acidosis.   S. B. S

The Sugar Consumption in Normal and Diabetic (Depancreated) Dogs after Evisceration. JOHN J. R. MACLEOD and R. G. PEARCE (*Amer. J. Physiol.*, 1913, **32**, 184—199).—No differences occur in the consumption of sugar in the muscles and heart of depancreated dogs and normal dogs. This is opposed to the statements of Starling and Knowlton. W. D. H.

Gluconeogenesis. III. The Fate of *iso*Butyric, *iso*Valeric, and *iso*Hexoic Acids in the Diabetic Organism, with Consideration of the Intermediary Metabolism of Leucine and Valine. A. I. RINGER, EDWARD M. FRANKEL and L. JONAS (*J. Biol. Chem*, 1913, **14**, 525—538).—In experiments on phloridzinised dogs it was found that *iso*butyric acid and *iso*butyl alcohol give rise to dextrose, probably by undergoing demethylation and so giving rise to normal fatty acids (propionic acid). *iso*Valeric acid does not give rise to dextrose, but to large quantities of acetoacetic acid, acetone, and β-hydroxybutyric acid. *iso*Hexoic acid gives rise to dextrose, probably by demethylation to valeric acid and subsequent oxidation to propionic acid. In certain cases *iso*butyric acid possesses marked antiketogenic properties. It is suggested that *iso*valeric and *iso*butyric acids are normal intermediary products in the katabolism of leucine and valine respectively. W. D. H.

Gluconeogenesis. IV. The Fate of Succinic, Malic, and Malonic Acids in the Diabetic Organism, with Consideration of the Intermediary Metabolism of Aspartic Acid, Glutamic Acid, Proline, Lysine, Arginine, and Ornithine. A. I. RINGER, EDWARD M. FRANKEL and L. JONAS (*J. Biol. Chem.*, 1913, **14**, 539—550).—In phloridzinised dogs, succinic, malic, and perhaps malonic acids give rise to extra dextrose. Succinic acid is an intermediary substance in the metabolism of glutamic acid, ornithine, and proline, which accounts for their conversion into dextrose. Malonic acid may arise in part from the katabolism of aspartic acid; lysine in its katabolism may pass through a glutaric acid stage, which accounts for its non-conversion into dextrose. W. D. H.

Gluconeogenesis. V. The Rôle of Pyruvic Acid in the Intermediary Metabolism of Alanine. A. I. RINGER, E. M. FRANKEL and L. JONAS (*J. Biol. Chem.*, 1913, **15**, 145—152).—In phloridzinised dogs pyruvic acid is capable of yielding extra dextrose in the diabetic organism. In some cases the amount was much less than arises from similar amounts of alanine and lactic acid. Pyruvic acid cannot therefore be considered a necessary intermediary product in the conversion of alanine into lactic acid, and alanine cannot be considered to undergo oxidative deaminisation. W. D. H.

The Biochemical Relation between Pyruvic Acid and Dextrose. HENRY D. DAKIN and N. W. JANNEY (*J. Biol. Chem.*, 1913, **15**, 177—180).—Results similar to those obtained by Ringer (see preceding abstract). W. D. H.

The Influence of Thyroid- and Parathyroid-ectomy on Carbohydrate Metabolism. SOICHIRO- MIURA (*Biochem. Zeitsch*, 1913, **51**, 423—442).—The onset of alimentary galactosuria in cats is not markedly influenced either by unilateral thyroid or parathyroidectomy. Neither does this exert any influence on the sugar and nitrogen excretion in cases of phloridzin diabetes. Even, therefore, in an animal from which the thyroids and accessory glands have been extirpated, phloridzin causes new sugar formation at the expense of the proteins. Some weeks after the extirpation, however, the sugar/nitrogen ratio increases, as the nitrogen excretion sinks, and is not accompanied with a corresponding decrease of sugar formation. Adrenaline-glycosuria is markedly diminished in animals which have been deprived some weeks before of their thyroid glands and have been treated with phloridzin. S. B. S.

The Influence of Chloral Hydrate on Various Experimental Forms of Hyperglycæmia. AAGE TH. B. JACOBSEN (*Biochem. Zeitsch.*, 1913, **51**, 443—462).—In the case of rabbits, chloral hydrate causes hyperglycæmia, and increases hyperglycæmia produced by adrenaline, *piqûre*, and venesection. This increased action is most marked when the chloral exerts a strong narcotising action. In cases where the animals are only slightly influenced by the chloral, it is often impossible to state whether there has been an increase of hyperglycæmia or not. From the results it is impossible to determine whether the *piqûre* hyperglycæmia is due to adrenaline diabetes. S. B. S.

The Influence of Fever on the Elimination of Creatinine. VICTOR C. MYERS and G. O. VOLOVIC (*J. Biol. Chem.*, 1913, **14**, 489—508).—Fever increases creatinine excretion; so also in rabbits does artificial hyperthermia; hence the result is due to the rise of temperature which accelerates the normal metabolic processes. In toxic fevers, creatine is also generally found, but usually after the crisis. W. D. H.

Is Narcosis due to Asphyxiation? JACQUES LOEB and HARDOLPH WASTENEYS (*J. Biol. Chem.*, 1913, **14**, 517—523).—Chloral-hydrate, ethyl urethane, chloroform, and various alcohols produce complete narcosis in the fertilised eggs of the sea urchin, whilst they lower hardly at all the rate of oxidation in the egg. W. D. H.

Transformation of Calomel into Soluble Salts of Mercury in Digestive Media. H. ZILGIEN (*Compt. rend.*, 1913, **156**, 1863—1864).—Aqueous solutions of lactic acid, ammonia, or previously prepared ammonium lactate do not convert calomel into soluble salts of mercury; if, on the other hand, ammonia is added to a suspension of calomel in water containing lactic acid, a considerable quantity of soluble mercury salts is immediately formed, the amount of which does not increase when the mixture is preserved. A similar result is obtained with nascent ammonium

chloride, although the previously prepared substance is inactive. The soluble salt obtained is probably mercuric chloride. Sodium chloride, whether previously prepared or nascent, is inactive. Similar results are obtained with salts of bismuth, etc., so that probably a general principle is here involved.

In the dog the conversion of calomel into soluble salts of mercury occurs in the stomach only, mercuric sulphate being formed in the intestine. Administration of ammonia in suitable quantity causes a considerable increase in the amount of calomel transformed.

<div align="right">H. W.</div>

The Inactivation of the Hæmolytic Action of Ethyl Alcohol by Normal Serum Albumin. ALBERT FISCHER (*Biochem. Zeitsch.*, 1913, **52**, 60—72). — Normal serum inhibits hæmolysis by ethyl alcohol; sodium fluoride serum has a more powerful action in this respect than the serum which separates from a coagulum. Serum albumin also inhibits the hæmolytic action, the process being one of adsorption. Bases are strongly adsorbed by serum albumin, whereas with acids there is a negative adsorption.

<div align="right">S. B. S.</div>

The Mechanism of the Union of Digitalis-like Heart Poisons. VIKTOR WEIZSACKER (*Arch. expt. Path. Pharm.*, 1913, **72**, 347).—Merck's digitalin acts twenty-five times more strongly than strophanthin. The difference in activity of various preparations depends largely on the amount of active substances in combination, but the depression of cardiac activity depends on the concentration of the toxic molecules in the cell; combinations are formed in the cells.

<div align="right">W. D. H.</div>

The Distribution and Excretion of Digitoxin when Administered Subcutaneously to Bufo vulg. CAMILL LHOTÁK VON LHOTA (*Biochem. Zeitsch.*, 1913, **52**, 362—368).—In the case of the toad, digitoxin acts in the first instance as a nerve poison, and only as a heart poison when it is administered in large doses. When administered subcutaneously, it is for the most part absorbed, although a certain portion remains for a long time unabsorbed at the place of injection. The absorbed drug can be detected in the muscular tissue, in the cloacal fluid, and in the urine, in which about 10% of the substance administered is slowly excreted. The greater part of the absorbed drug cannot, however, be detected in the body, and appears to be destroyed. Keller's reaction was employed for the estimation of the digitoxin.

<div align="right">S. B. S.</div>

The Action of Ergotoxine. HENRY H. DALE (*J. Physiol.*, 1913, **46**, 291—300).—Ergotoxine does not reverse the motor effects of adrenaline by producing high tonus of plain muscle (blood vessels, uterus); it may even lower tone, and yet replace a motor adrenaline effect by an inhibitory one. Stimulation of the splanchnic nerves, after an adequate dose of ergotoxine, may cause a fall of blood-pressure although the suprarenal glands are removed.

Much of the paper is devoted to a discussion of the detection of sympathetic vaso-dilator nerves. There is no evidence apart from that furnished by the action of ergotoxine for a mixed motor-inhibitory supply to arteries in general. W. D. H.

[Physiological Action of] Certain Derivatives of Quinine. KNUD SCHROEDER (*Arch. expt. Path. Pharm.*, 1913, **72**, 361—386). —Towards Infusoria and Plasmodia, monobromoquinine and dibromoquinine are almost twice as strongly active as quinine; and dehydroquinine has about half the activity; the alkaloid, $C_{19}H_{22}O_3N_2Cl_2$, is inactive. These substances act in a similar relative way on bacteria, but not so strongly. Equimolecular doses of the quinine derivatives mentioned have the same antipyretic effect as quinine. They do not affect nitrogenous metabolism in rats, subcutaneous injection causes local necrosis, the various substances producing this in varying degrees. Dehydroquinine and quinine differ in so much as the vinyl group, $CH:CH_2$, of the quinine is changed into $C:CH$ in the first-named material; this alteration is believed to be responsible for the change in activity. W. D. H.

Action of Morphine on the Circulation. E. ANDERFS (*Arch. expt. Path. Pharm.*, 1913, **72**, 331—346).—In both dogs and rabbits morphine causes the heart to slow, although the arterial pressure may be unaltered or even slightly rise. In dogs this is due to central vagus stimulation; in rabbits there is, in addition, a peripheral stimulation due to decrease in negative intrapleural pressure Curare produces the same effect in rabbits, but in dogs, where it does not alter the intrathoracic pressure, there is no synergic action if both drugs are given together. W. D. H.

[Physiological Action of] Strophanthidin. A. GROBER (*Arch. expt. Path. Pharm*, 1913, **72**, 317—330).—Strophanthin acts in rabbits about 3·6 times as toxically as strophanthidin when given intravenously. Death is produced by both drugs by central respiratory paralysis. In minimal lethal doses, strophanthidin acts more quickly and instantaneously, whereas in the case of strophanthin death is preceded by dyspnœa, which lasts for some minutes. On the isolated frog's heart, both poisons act in the same concentration (1 in 1,500,000) in causing standstill of the ventricle. W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Oxidation of Petroleum, Paraffin, and Benzene by Bacteria. NICOLAAS L. SÖHNGEN (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **15**, 1145—1151).—Although most of the bacteria which oxidise hydrocarbons are unable to decompose fatty acids, some species

belonging to the mycobacteria are able to split fats by the secretion of lipase. Many species, such as *Bacillus fluorescens liquefaciens, B. pyocyaneus, Micrococcus paraffinae*, etc., were found in soil and canal water, and when cultivated in a medium containing tap water with 0·05% of ammonium chloride, 0·05% of dipotassium phosphate, and 1·0% of the hydrocarbon were able to oxidise the compound with great rapidity. Plate cultures showed the organisms to be extremely widely distributed, and it may rise to about 50,000 per gram of garden soil.

Pure cultures of the paraffin oxidising organisms decomposed, on an average, about 7·5 mg. of petroleum and 4 mg. of paraffin in twenty-four hours at 28° per square centimetre surface of the culture liquid. H. B. H.

A Comparative Study of the Metabolism of Pneumococcus, Streptococcus, Bacillus lactis erythrogenes, and Bacillus anthracoides. MARY LOUISE FOSTER (*J. Amer. Chem. Soc.*, 1913, **35**, 916—919. Compare this vol., i, 684).—A study of the proteolytic power of the various organisms. Two strains of *Pneumococcus* were very different in their power of affecting the protein molecule; increase of temperature from 37° to 40° favoured the reaction to such an extent that with the more active strain the phosphotungstic acid fraction was more than doubled, whilst the monoamine fraction is increased in the ratio 6 : 1. When milk was used as culture medium for *Streptococcus, Bacillus lactis erythrogenes*, and *B. anthracoides*, the liquid became alkaline and assumed a red colour and glue-like odour; no indication of lactic acid could be observed. The results indicate the probability of chemical similarity between organisms which morphologically are widely different. D. F. T.

Mechanism of the Acclimatisation of Yeasts to Formaldehyde. M. EMMANUEL POZZI-ESCOT (*Compt. rend.*, 1913, **156**, 1851—1852).—According to Effront, the acclimatisation of yeasts to formaldehyde is due to the destruction of the latter by an oxidising agent which develops in the yeast, the requisite oxygen being obtained from the air or from substances contained in the mixture; the substance produced by acclimatisation plays the part of selective catalyst, without which oxidation does not occur. The author considers this view to be improbable, and has carried out a series of experiments, in which he finds that (i) formaldehyde actually disappears, (ii) destruction takes place more readily in a medium rich in complex nitrogenous substances; if a poor barley wort is employed and the nitrogenous matter removed by means of tannin, fermentation becomes more difficult in the presence of a constant amount of formaldehyde; fermentation occurs more readily if a large initial quantity of yeast is used; (iii) combustion of formaldehyde is complete since formic acid cannot be detected; (iv) formaldehyde combines almost quantitatively with a wort rich in nitrogenous matter forming a labile compound, from which it can be recovered by energetic treatment. Fermentation, and conse-

quently acclimatisation, of the yeast are more difficult in proportion as the wort is poorer in organic nitrogen, and, with an artificial wort containing only ammonium phosphate, becomes very difficult.

The author is led to the conclusion that formaldehyde loses its antiseptic properties owing to the extreme ease with which it combines with groups containing nitrogen, and that the disappearance of the aldehyde corresponds simply with the consumption of the amino-compound formed by the yeast.   H. W.

The Formation of the Higher Alcohols from Aldehydes by Yeasts. I. The Conversion of Valeraldehyde into Amyl Alcohol. CARL NEUBERG and H. STEENBOCK (*Biochem. Zeitsch.*, 1913, 52, 494—503).—It has been already shown by Neuberg and his pupils that keto-acids can be converted by a ferment in yeasts into aldehydes. If these two classes of substances are intermediary products in alcoholic fermentation, it should be expected that the yeasts can convert aldehydes into alcohol. This is now experimentally shown to be possible, and yields of over 80% of the theoretical of amyl alcohol have been obtained from valeraldehyde when this aldehyde is present during alcoholic fermentation. The reaction is apparently a direct reduction, and not a conversion of aldehyde into an equal number of molecules of acid and alcohol by Cannizaro's reaction, as only small quantities of acid could be isolated, and the yield, furthermore, of the alcohol was too large to admit of this explanation. The higher alcohol was separated from the ethyl alcohol by fractional distillation.   S. B. S.

The Assimilability of Maltose by Yeasts. A. J. KLUYVER (*Biochem. Zeitsch.*, 1913, 52, 486—493).—It has been shown by Rose that certain yeasts will grow in culture media containing maltose, without producing fermentation, whereas they will not grow in dextrose solutions, although they will produce fermentation with this sugar when added to the medium containing maltose. These results were to a large extent confirmed by more extended researches of Lindner and Saito. The author now shows that certain yeasts will grow in Hayduck's medium containing some preparations of maltose, whereas they will not grow in the presence of maltose obtained from other firms. If, furthermore, the maltose samples which produce growth are purified by recrystallisation, they lose their power of producing growth. The results of Rose, Lindner, and Saito are therefore to be explained by the fact that the maltose they employed was not pure, but contained probably some protein substances derived probably from the diastase used in their preparation.   S. B. S.

The Protein Substances of Yeast. PIERRE THOMAS (*Compt. rend.*, 1913, 156, 2024—2027).—The only earlier work of an exact nature on this subject is that of Kossel (*Zeitsch. physiol. Chem.*, 1879, 3, 284; 1880, 4, 290) and of Schröder (A., 1902, i, 730). The author has succeeded, after partial autolysis of yeast, in isolating two protein substances; the first, which from its properties

appears to occupy a position between casein and the vitellin of egg-yolk, contains 16 2% nitrogen, 1·8% phosphorus, and 0·38% sulphur; it is soluble in dilute solutions of the alkali hydroxides and carbonates, but is precipitated by acids; rennet causes its coagulation, but less readily than it does caseinogen. If a solution of the protein in 1% sodium hydroxide is maintained at 37°, the phosphorus passes gradually into the mineral state, the extent of 58% being attained in five days (compare Plimmer and Scott, T., 1908, **93**, 1699).

The second substance, for which the author proposes the name *cerevisin*, closely resembles albumin; it is soluble in water, coagulable by heat, and not precipitable by acetic acid; the substance, which contains 16·3% nitrogen, 0·9% sulphur, and a trace of phosphorus, probably due to impurity, gives the usual precipitation and colour reactions.   D F. T.

Rôle of Reductase in Alcoholic Fermentation   S. D. Lvov (*Bull Acad. Sci. St. Pétersbourg*, 1913, 501—532).—Further experiments on the lines of those previously carried out by Palladin and the author (see this vol., i, 684) lead to the following results

The first stage, or one of the first stages, in alcoholic fermentation consists in the activation of two atoms of hydrogen with the aid of reductase. So far as is at present known, this active hydrogen may be formed either directly from the dextrose or as the result of the ionic dissociation of water; in the latter case the dextrose would be oxidised by the hydroxyl ions, whilst in the former this early stage would be represented by the equation

$$C_6H_{12}O_6 + R = (C_6H_{12}O_6 - 2H) + RH_2,$$
where R denotes the reductase. The hydrogen fixed temporarily on the reductase is necessary to the further course of normal fermentation. Failure of the distillate to yield the reaction for aldehydes with magenta and sulphurous acid indicates that the formation of aldehydes during the fermentation of sugar, if it actually occurs, is a more complex process than is assumed in Kostytschev's scheme (A , 1912, ii, 589, 860; this vol., i, 323).

Between the reducing and fermentative capacities of yeast strict parallelism is observed; the reductase gives up the hydrogen it fixes to an amount which stands in equimolecular relation to the diminution in yield of the products of fermentation.

A number of auto-fermentation experiments have also been made. The results of these show that the extraction during the process of reduction, of 2 gram-atoms of hydrogen by 1 gram-mol of methylene-blue, is accompanied by the evolution of an excess of 1 gram-mol of carbon dioxide   Hence a fermenting medium contains some substance which. in absence of sugar, is capable of liberating 1 mol of carbon dioxide when the conditions are such that the substance itself loses 2 atoms of hydrogen   This process is found to be enzymic in character, and is one-sided in that no corresponding excess is observed in the yield of alcohol. The excess of carbon dioxide is regarded as resulting from the decomposition of amino-acids, with parallel formation of aldehydes.

The conclusion is drawn that activation of the hydrogen under the influence of reductase is an all-important factor in the processes of fermentation, which are unable to take place in absence of reductase.   T. H. P.

Alcoholic Fermentation of Sugar. EDUARD BUCHNER and KURT LANGHELD (*Ber.*, 1913, 46, 1972).—Sugar was allowed to ferment with expressed or macerated yeast juice in presence of trisodium phosphate or disodium hydrogen phosphate in an extraction apparatus, through which a flow of ether was maintained. The presence of acetaldehyde in the solvent was detected by the formation of the *p*-nitrophenylhydrazone. A similar result was obtained by Kostytschev in the presence of zinc chloride (A., 1912, ii, 589).   J. C. W.

Alcoholic Fermentation. IV. Decomposition of Sugar by Dry Yeast in Presence of Zinc Chloride. S. KOSTYTSCHEV and A. SCHELOUMOV (*Zeitsch. physiol. Chem.*, 1913, 85, 493—506. Compare A., 1912, ii, 589, 860; 1913, i, 323, 434).—When sugar is fermented by yeast preparations in the presence of zinc chloride, the normal series of changes is disturbed and acetaldehyde formed. Parallel with this there is a marked restriction of the production of carbon dioxide. Various zinc salts act in a similar manner, most acetaldehyde being produced in presence of zinc iodide, bromide, or chloride, and less when zinc acetate, carbonate, or phosphate is used.

In the absence of zinc chloride, equal quantities of carbon dioxide and alcohol are obtained on fermentation, but after twenty-four hours about 25% of the sugar decomposed has not been converted into these products; it has probably been used to form hexose phosphate. After forty-eight hours' action, the whole of the sugar is converted into alcohol and carbon dioxide. In parallel experiments in which 0·15 gram of zinc chloride was added per 10 grams of yeast, the sugar is more rapidly decomposed, the fermented part of it being used to form other products. At first the amounts of carbon dioxide and alcohol are equal; after forty-eight hours the production of carbon dioxide is in excess.

When the amount of zinc chloride is doubled, a still larger proportion of the sugar decomposed is not fermented. With 1·2 grams of zinc chloride to 10 grams of yeast, no action takes place.

In a similar manner the addition of 0·5 gram of methylene-blue affects the fermentation. Only two-thirds of the sugar decomposed is fermented, although carbon dioxide and alcohol are produced in equal proportions. The fermentative energy is decreased.

The experiments indicate that the two end-products of fermentation are not formed simultaneously. Alcohol is partly replaced by acetaldehyde.   E. F. A.

Alcoholic Fermentation. V. Decomposition of Protein by Dry Yeast in Presence of Zinc Chloride. S. KOSTYTSCHEV and W. BRILLIANT (*Zeitsch. physiol. Chem.*, 1913, 85, 507—516. Compare preceding abstract).—Generally speaking, external factors act in

an opposite manner towards zymase fermentation and protein decomposition by yeast.

In the absence of sugar, zinc chloride very slightly accelerates the auto-decomposition of dry yeast protein. In the presence of sugar the reverse is the case, the proteolysis being slightly retarded, no doubt owing to the presence of the sugar and the acetaldehyde formed from it. In concentrated sugar solutions the retardation is more marked.

The retardation of the zymase fermentation by zinc chloride is thus not due to acceleration of the antagonistic proteolysis, but to a direct action on the zymase.   E. F. A.

Nitrogen Metabolism in Aspergillus niger. H. J. WATERMAN (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **15**, 1047—1057).—When grown in nutrient solution containing ammonium salts and dextrose or lævulose, the mould is found to give a high nitrogen : carbon ratio. This is attributed not to a simple adsorption of the nitrogen compound, but to its assimilation and immediate transformation into compounds insoluble in hot distilled water.

With increasing age the nitrogen : carbon ratio falls rapidly, and then remains practically constant.

An excretion of ammonia is observed, and this occurs irrespective of the nitrogen compound supplied; nitrate is reduced to ammonia, but not to free nitrogen. The addition of manganese salts increases the velocity of metabolism, whilst the substitution of rubidium for potassium in the nutrient solution is without effect. Where the amount of nitrogen is limited, there did not appear to be any assimilation of atmospheric nitrogen.

H. B. H.

Phosphorus Metabolism in Aspergillus niger. H. J. WATERMAN (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **15**, 1058—1063).—The ratio of phosphorus to assimilated carbon in old cultures was found to be constant. In the early stages of growth comparatively large quantities of phosphorus are taken up, but, in contradistinction to the same stage in nitrogen assimilation, this phosphorus does not appear to be transformed into organic compounds, such as lecithin or phytin, and can consequently be extracted with hot water. A retardation in spore-formation may be induced by the addition of excess quantities of phosphorus salts.

H. B. H.

Cleavage of Pyromykuric Acid by Mould Enzymes. ARTHUR W. DOX and RAY E NEIDIG (*Bioch,m. Bull.*, 1913, **2**, 407—408).— Various moulds cleave hippuric acid, and the products can be determined by Sörensen's formaldehyde method. If the synthesis of hippuric acid from benzoic acid in the body is due to an enzyme, the synthesis of corresponding derivatives from substituted benzoic acids may be attributed to the same cause, but there is no reason to suppose that a separate enzyme is necessary for each. This reasoning may be extended to analogous compounds, in which a

heterocyclic replaces the benzene nucleus. In the present experiments, in which pyromykuric acid was subjected to the influence of moulds, the cleavage produced was comparatively small, but this is no evidence that the enzyme is a specific one.   W. D. H.

Importance of Oxygen in the Germination of Peas. VL. P. MALTSCHEVSKI (*Bull. Acad. Sci. St. Pétersbourg*, 1913, 639—664).— The results of experiments on the germination of peas under various conditions bring out the following points.

In the case of living seeds, the action of oxygen in causing germination cannot be replaced by that of methylene-blue. The initial influence of the air in stimulating resting seeds under anærobic conditions is of great importance, and changes the character of the anærobic development of carbon dioxide. The alcoholic fermentation produced by seeds under strictly anærobic conditions is accompanied by another process, which leads to the evolution of carbon dioxide from another source, but furnishes no alcohol. Such process is apparently peculiar to living seeds, and is lacking or, at any rate, greatly enfeebled with dead seeds. In the investigation of the anærobiosis of seeds, it is essential to deprive the latter of oxygen even in the first stages of steeping. For the initiation of the germination of peas, absorption of atmospheric oxygen is necessary, not merely for supplying the energy liberated by the oxidation of substances existing in the resting seeds, but also for the formation of new compounds.   T. H. P.

Assimilation of Iron by Plants. WILHELM VAUBEL (*Chem. Zeit.,* 1913, **37**, 737).—Iron and ammonium nitrate interact with production of ferrous oxide, ferric hydroxide, and a small amount of a soluble compound, $Fe_2O_4(NO \cdot NH_4)_2$, or $Fe_2O_6(NO \cdot NH_4)_3$ (*ibid.*, 637; Kaufmann, A., 1901, ii, 554). It is suggested that iron is taken up by plants partly in this form. The compound only exists in solution, and decomposes when the solution is evaporated down. According to the concentration, the solution is colourless or dark grey; if yellow, ferric nitrate is present.   N. H. J. M.

The Oxidative Formation of Nitrous Acid in Extracts of Plants. ALEXIS BACH (*Biochem. Zeitsch.*. 1913, **52**, 418—422).— The author confirms the observation of Mazé, that nitrous acid is formed in plant extracts when exposed to the action of air. The nitrous acid thus produced is spontaneously destroyed. Nitrous acid is formed only in traces, if the extract is first heated. Reasons are given for assuming that nitrous acid is formed from the amino-acids present and not from nitrates, and against the assumption that the formation of iodine from potassium iodide is not due to the presence of nitrous acid, but is due directly to the existence of an oxydase in the tissues.   S. B. S.

Relationship of Bases and Mineral Acids in Plant Tissues. GUSTAVE ANDRÉ (*Compt. rend.*, 1913, **156**, 1914—1916).—In connexion with Warington's observation (A., 1900, ii, 569), that crops

usually show a deficiency of bases on the assumption that all the nitrogen enters the plant in the form of nitrates, the author points out that this is the case for barley (A., 1912, ii, 675, 803) and for linseed (A., 1913, i, 688), but not for spurrey (*loc. cit.*). In the last case the bases are in excess.   T. A. H.

Detection of Urea in Plants. ROBERT FOSSE (*Compt. rend.*, 1913, **156**, 1938—1941. Compare A., 1912, ii, 1203; 1913, i, 432). —Some objection might be taken to the work already done on this subject (*loc. cit.*) owing to the fact that the plant preparations in which urea was detected had been concentrated by heat in presence of acetic acid. The author has therefore repeated and extended the work by operating on plant preparations obtained by expression or maceration in the cold. From such products the xanthhydrol derivative of urea is readily precipitated. Urea has thus been detected in the following plants: *Aspergillus niger*, *Penicillium glaucum*, carrot, potato, spinach, endive, chicory, turnip, green haricot, peas, purslane, lettuce, pumpkin, maize grain, and in the embryos of wheat, rye, sunflower, beet, field-bean, lucerne, lentil, lathyrus, grain, pumpkin, horse-bean, dwarf-bean, *Trifolium incarnatum*, and common haricot. Examples of the three methods used in preparing the extracts are given.   T. A. H.

The Detection of Formaldehyde in Plants. HEINRICH FINCKE (*Biochem. Zeitsch.*, 1913, **52**, 214—225).—For these researches, the Grosse-Bohle reagent for the detection of formaldehyde was employed. This consists of a rosaniline salt in the presence of sulphites and free hydrochloric acid, and is to be distinguished from the ordinary magenta-sulphite solution for detection of aldehydes, by the presence of free mineral acid. It was found by the author to be capable of detecting formaldehyde in the dilution 1 in 500,000, giving with the aldehyde a violet colour. In numerous experiments on plants, no indication of the presence of formaldehyde was obtained with the use of this reagent; furthermore, formaldehyde could not be detected by the reagent after addition to certain living plants. The author draws the conclusion that his investigations throw no light on the correctness or otherwise of Bayer's assimilation hypothesis.   S. B. S.

The Reduction Ferments. IV. Vegetable Perhydrases. ALEXIS BACH (*Biochem. Zeitsch.*, 1913, **52**, 412—417).—It has been shown by the author that animal tissues contain a perhydrase which can reduce nitrates to nitrites in the presence of aldehydes. The existence of a similar vegetable ferment is now demonstrated, which can be obtained from potatoes by extraction with water and filtration of the extract. If this extract is kept under antiseptic conditions (in the presence of sodium fluoride) and in the absence of air, a co-ferment is gradually produced, which can replace the aldehyde in the above-described perhydrase reaction. The co-ferment which activates the animal perhydrase, and which is obtained by extraction of animal tissues by hot water, will not

activate the vegetable perhydrase, which also differs from the animal perhydrase in that it will not reduce methylene-blue. It has not yet been found possible to replace the co-ferment in the vegetable perhydrase reaction with amino-acids or keto-acids, and its exact nature is still undetermined. S. B. S.

Arsenic and Manganese in Young and Old Leaves. F. JADIN and A. ASTRUC (*Compt. rend.*, 1913, **156** 2023—2024. Compare A., 1912, ii, 478, 976).—The observation of Pichard (A., 1899, ii, 40) that manganese appears to become concentrated in those parts of a tree which are in vegetative activity, appears to depend for its correctness on the method of analysis.

According to their age, the different organs contain variable proportions of water and of mineral matter. The experimental results indicate that the amounts of arsenic and manganese in the old leaves of various trees examined are decidedly greater than in the young leaves, if the percentage is calculated on the weight of the fresh leaves. The difference becomes less marked if the percentage of the elements is referred to the dried organs, whilst if the percentages are calculated on the ash the case is actually reversed. D. F. T.

Variation of Carbohydrates in Leaves During Development. E. MICHEL-DURAND (*Compt. rend.*, 1913, **156**, 1926—1929. Compare Combes, A., 1909, ii, 426).—The author has determined the dry weight, reducing and non-reducing sugars, glucosides, dextrin, starch, non-nitrogenous extractive matter, amyloids, and cellulose in the leaves of *Fagus sylvatica*, *Ampelopsis hederacea*, and *Betula alba*, at various stages of development during the year. The results for *Betula alba* leaves are quoted in full in the original. The following conclusions are drawn from the whole of the results. There is a general diminution in carbohydrates towards the end of the season. After attaining a maximum dry weight in August to September, the leaves lose weight until and after they fall. The leaves of *Fagus* and *Betula* contain the maximum amount of reducing sugars when yellow; those of *Ampelopsis* when red; these are corresponding states, and after these stages the amount diminishes rapidly. Starch, when it exists, reaches a maximum while the leaves are green, and then diminishes gradually; yellow leaves contain only traces, but in *Fagus* it persists in the dead leaves until these are dry. Amyloids are at a maximum in *Betula* leaves when these are yellow, but in *Ampelopsis* leaves while they are still green. Cellulose diminishes steadily in *Ampelopsis* leaves, but increases steadily in *Betula* leaves. Rain and dew carry off some soluble carbohydrates from dead leaves. The diminution of carbohydrates in leaves as the season's growth proceeds is due partly to migration of these substances into the stem, partly to respiration, and partly to the effect of atmospheric water. The formation of soluble sugars towards the end of the season is favoured by low temperatures. T. A. H.

Organic Chemistry.

Formation of Methane by Catalysis, Starting with Carbon Monoxide and Water Vapour. Léo Vignon (*Compt. rend.*, 1913, **157**, 131—134. Compare A., 1911, i, 101; ii, 391).—An examination of the effect of the metals iron, nickel and copper, and the oxides of aluminium, magnesium and silicon as catalysts, at temperatures varying from 250° to 1250°, in the formation of methane from carbon monoxide and water vapour. They are all effective, but to a variable degree, nickel being the most active at 600°. The mechanism of the action is different for the various catalysts. In all probability iron and the oxides of aluminium and silicon act through the intermediate formation of a carbide, which is decomposed by the water vapour as fast as it is formed. W. G.

Pyrogenetic Decomposition of the Butadiene Hydrocarbons. Hermann Staudinger, R. Endle, and J. Herold (*Ber.*, 1913, **46**, 2466—2477).—Isoprene when passed through a tube heated at 750° is converted to the extent of 45—55% into a tar, which in appearance and composition closely resembles coal tar, and contains benzene, toluene, naphthalene, a-methylnaphthalene, anthracene, chrysene, etc. The rest of the isoprene is converted into butadiene and into hydrogen, methane, ethylene, or into retort carbon.

At 400° under similar treatment isoprene is partly unattacked, and partly polymerised to unsaturated hydrocarbons—terpenes. Very little gas is formed, but there is some amylene and β-methyl-Δ^{β}-butylene produced.

At 600—700° a mixture of unsaturated hydrocarbons results, which no longer contains terpenes, but resembles crude petroleum. At temperatures above 700°, aromatic compounds are formed; at 750° they are almost entirely, and at 800° they are, the only products.

At 700°, but in a vacuum of 20—25 mm, almost half the isoprene remains unchanged. Unsaturated compounds are formed, but no tar.

When isoprene or butadiene is prepared by pyrogenetic reactions it is advisable to work in a vacuum and to cool rapidly if a high yield is desired.

Isoprene is primarily condensed to hydroaromatic compounds. These polymerise further, or condense with isoprene to form substances which decompose into aromatic compounds, the side-chains being eliminated. The formation of the tar from acetylene and ethylene derivatives, which might have been formed primarily by the pyrogenetic decomposition of isoprene, is improbable, since these compounds are not formed at the lower temperatures, or on heating in a vacuum.

Butadiene may originate from the hydroaromatic substances or from amylene.

β-Methyl-Δ^{β}-butylene at 750° gives rise to butadiene, but this is obtained in much larger quantity on decomposing amyl alcohol. The alcohol yields relatively little tar; β-methyl-Δ^{β}-butylene gives a considerable quantity. In this case also hydrogen is separated from carbon, and there is no scission of carbon linkings with the formation of methane.

Butadiene also takes part in the formation of the aromatic tar, but it polymerises more slowly than isoprene, and the amount of tar products formed is therefore less.

Dimethylbutadiene behaves just as isoprene does at high temperatures, forming tar and small quantities of butadiene at 800°.

It is considered that the polymerisation of butadiene hydrocarbons plays only a small part in the formation of tar from coal. The tar is mainly formed by the dehydrogenation or decomposition of hydroaromatic substances.　　　　　　　　　　　　　　　　　E. F. A.

The Action of Sodium in Liquid Ammonia on the True Acetylenic Hydrocarbons of the Fatty Series, and a Method of Formation of Ethylenic Hydrocarbons. PAUL LEBEAU and MARIUS PICON (*Compt. rend.*, 1913, **157**, 137—139).—Sodium in liquid ammonia reacts with the acetylenic hydrocarbons of the fatty series quantitatively, giving the sodium derivative of these hydrocarbons (2 mols.) and the corresponding ethylenic hydrocarbon (1 mol.) according to the equation :

$$3C_3H_4 + 2NaNH_3 = 2C_3H_3Na + 2NH_3 + C_3H_6.$$

The products of the reaction are pure, and no secondary reactions were noticed.　　　　　　　　　　　　　　　　　W. G.

Ethylenic Isomerism of s-Dibromoethylene. H. VAN DE WALLE. (*Bull. Soc. chim. Belg.*, 1913, **27**, 209—217).—Crude s-dibromoethylene is best obtained in quantity by the action of zinc on an alcoholic solution of tetrabromoethane. It boils at 108—112°, and the two isomerides cannot be separated by fractional distillation on account of the spontaneous reversion of the different fractions to the equilibrium mixture. Attempts to separate them by fractional solidification and also by fractional precipitation by water of a solution of the crude bromo-derivative in acetic acid were unsuccessful. Their isolation can be effected, however, by taking advantage of the fact that each isomeride forms a binary mixture with alcohol. By repeated fractionation of a solution of the crude substance in absolute ethyl alcohol with careful exclusion of moisture, two binary mixtures can be isolated. The first of these has b. p. 75·6—75·9°/760 mm., and contains 64% of s-*dibromoethylene*, m. p. −6·5°. The second has b. p. 77·7—78°/760 mm., and contains 32·5% of s-*dibromoethylene*, m. p. −53°. The pure compound, m. p. −6·5°, has b. p. 108°, $D_4^{17\cdot5}$ 2·2667, $n_{H\alpha}^{17\cdot5}$ 1·54563, $n_D^{17\cdot5}$ 1·55054, $n_{(\gamma)}^{17\cdot5}$ 1·57381, whilst the other isomeride has b. p. 112·5°, $D_4^{17\cdot5}$ 2·2846, $n_{H\alpha}^{17\cdot}$ 1·53837, $n_{H\alpha}^{1\cdot}$ 1·53791, $n_D^{17\cdot}$ 1·54312, $n_D^{18\cdot}$ 1·54256, $n_G^{18\cdot5}$ 1·55406. Slight errors are probably involved in the determination of the density owing to rapid isomerisation which occurs with such facility that an equilibrium mixture is formed in the course of a few hours. On exposure to air and moisture, the dibromocompounds are readily decomposed with evolution of hydrogen bromide.

The equilibrium mixture of the two isomerides has $D_4^{17\cdot5}$ 2·2788, $n_{H\alpha}^{17\cdot5}$ 1·54092, $n_D^{17\cdot5}$ 1·54560, and thus contains about 33·5% of the modification, m. p. −6·5°.

The compounds are readily decomposed by alcoholic potassium

hydroxide according to the equation :

$$C_2H_2Br_2 + KOH = C_2HBr + KBr + H_2O,$$
the isomeride, m. p. −53°, being by far the more readily decomposable. **H. W.**

An Application of Young's Method for the Preparation of Absolute Alcohol. GEORGES CHAVANNE (*Bull. Soc. chim. Belg.*, 1913, 27, 205—209).—The author criticises Young's method of dehydrating aqueous alcohol by means of benzene, and has examined the effect of substituting s-dichloroethylene for the latter substance. The general course of the process is similar in each case. s-Dichloroethylene, b. p. 48·35°, yields with aqueous alcohol a ternary mixture, b. p. 44·4°, which has the composition, s-dichloroethylene 94·5%, alcohol 4·4%, water 1·1%. The binary mixture of s dichloroethylene and alcohol has b. p. 46·5° and contains 94·0% of the former, whilst the binary mixture of s-dichloroethylene and water, containing 98·1% of the former, has b. p. 45·3°. With the isomeric s-dichloroethylene, b. p. 60·25°, the ternary mixture has the composition, s-dichloroethylene 90·5%, alcohol 6 65%, water 2·85%, and b. p. 53·8°. The binary mixture of s-dichloroethylene and alcohol, containing 90·2% of the former, has b. p. 57·7°, whilst the corresponding mixture of s-dichloroethylene and water contains 96·65% of the former and has b. p. 55·3°. The following are the main conclusions :

(i) The loss of alcohol due to the formation of a ternary mixture is rather greater than when benzene is used if the isomeride, b. p. 48·35°, is employed, rather less in the case of the isomeride, b. p. 60·25°. The use of a mixture of equal weights of the two isomerides, corresponding approximately with commercial s-dichloroethylene, leads to a slightly greater loss of alcohol than is the case with benzene, whilst the employment of the equilibrium mixture gives results practically identical with those obtained with the aid of benzene.

(ii) In practice, a portion of the alcohol would also be removed in the form of a binary mixture. Such loss, however, would be less serious than that encountered when benzene is used, since the binary mixtures of alcohol and s-dichloroethylene are poorer in alcohol than the corresponding mixtures of alcohol and benzene.

(iii) The use of the dichloro-derivatives has the advantage that the b. p. of alcohol is 20·6° higher than that of the least volatile binary mixture. In this respect, the dichloro-derivatives are superior to benzene or n-hexane.

The author is led to the conclusion that the above method is not suited to the commercial preparation of absolute alcohol, since the losses are much greater than those involved by the use of lime.

H. W.

Composition of Certain Formates. CHARLES H. HAMPSHIRE and W. R. PRATT (*Pharm. J.*, 1913, 91, 138—142).—An examination of commercial specimens of the principal formates and an investigation of the methods of preparation gave the following results : Sodium formate sometimes consists of the anhydrous salt and sometimes of crystals of the dihydrate. Ferric formate has the formula,

$$Fe_3(OH)_2(HCO_2)_7,4H_2O,$$
assigned to it by Belloni (A., 1909, i, 283), and not $Fe_2(HCO_2)_6,H_2O,$

as stated in the B. P. Codex. Magnesium formate has the formula $Mg(HCO_2)_2,2H_2O$, and calcium formate the formula $Ca(HCO_2)_2$. Quinine formate is not anhydrous, but has the composition

$$C_{20}H_{24}O_2N_2,HCO_2H,H_2O.$$
When freshly prepared, strychnine formate contains $2H_2O$, but it effloresces quickly.   W. P. S.

Esters of Palmitic Acid. MARJORY STEPHENSON (*Biochem. J.*, 1913, **7**, 429—435).—Palmityl chloride, a colourless oil, b. p. 198—200°/15 mm., condenses with glycol in presence of pyridine with chloroform as a solvent to *ethylene dipalmitate*, $(C_{15}H_{31}\cdot CO_2)_2C_2H_4$, which crystallises in rosettes of fine needles, m. p. 65° (corr.).

Glyceryl tripalmitate (tripalmitin), prepared in a similar manner, crystallises in colourless, fine needles, m. p. 62° (corr.).

Mannityl hexapalmitate crystallises in rosettes of fine needles, m. p. 64·5° (corr.).

Dextrose pentapalmitate,

$$C_{15}H_{31}\cdot CO_2\cdot CH_2\cdot[CH\cdot O\cdot CO\cdot C_{15}H_{31}]_4\cdot CHO,$$

has m. p. 62°.   E. F. A.

The Action of Complex-forming Acids or their Salts on Platinum Ammonia Compounds. II. Reactions with Ethylthiolacetic Acid. LUDWIG RAMBERG (*Ber.*, 1913, **46**, 2353—2362. Compare this vol , ii, 607).—An intermediate product of the action of ethylthiolacetic acid on *cis*-dinitratodiammineplatinum is *nitrato-diammineplatinum ethylthiolacetate*, $Pt(NH_3)_2(NO_3)(CO_2\cdot CH_2\cdot SEt)$, which crystallises in large, colourless prisms, m. p. 188—189°. When distilled with dilute sodium hydroxide only one half of the ammonia is liberated. When, however, ethylthiolacetic acid is added to dissolve the compound and then, after an interval, it is distilled with sodium hydroxide, the whole of the ammonia is set free. When the above nitratodiammineplatinum ethylthiolacetate is boiled with concentrated acetic acid one molecule of ammonia is liberated, and *nitratomonammineplatinum ethylthiolacetate*, $CH_2\!\!<^{CO\cdot O}_{SEt}\!\!>P\!\!<^{NO_3}_{\cdot NH_3}$, is obtained. This crystallises in large, flat, colourless prisms, grouped in rosettes, m. p. 193—194° (decomp.).

On shaking *cis*-dinitritodiammineplatinum with an aqueous solution of ethylthiolacetic acid in a closed tube only a little dissolves, and some nitrous fumes are liberated on opening the tube. If, however, sodium ethylthiolacetate is substituted for the free acid and the mixture is boiled in an open vessel, the main product is *sodium dinitrito-(bisethylthiolacetato)-platinoate*, $(CO_2Na\cdot CH_2\cdot SEt)_2Pt(NO_2)_2,2H_2O$, which is also obtained on adding sodium nitrite to α-platinoethylthiolacetate; it forms small, colourless crystals.

trans-Dichlorodiammineplatinum reacts with ethylthiolacetate to form a colourless, complex substance of the composition

$$Pt_2(NH_3)_4Cl_3(CO_2\cdot CH_2\cdot SEt)(CO_2H\cdot CH_2\cdot SEt),$$
which evolves ammonia only slowly when distilled with sodium hydroxide, and decomposes on boiling with acetic acid into *trans*-dichloro-

diammineplatinum, *trans*-diammineplatinum bisethylthiolacetate, and ethylthiolacetic acid. Hence the formula given should probably be doubled.

Ethylthiolacetic acid combines with *trans*-dinitratodiammine-platinum to the compound $Pt(NH_3)_2(NO_3)_2 2CO_2H\cdot CH_2\cdot SEt, H_2O$; this crystallises in colourless rosettes of prismatic crystals, m. p. 115—116°.

Ethylthiolacetic acid and *trans*-sulphatodiammineplatinum combine to form the *additive product*, $Pt(NH_3)_2SO_4, 2CO_2H\cdot CH_2\cdot SEt$, which crystallises in colourless tablets or prisms. It reacts with potassium platinochloride, K_2PtCl_4, forming platinoethylthiolacetate, which reacts with hydrogen chloride, forming *monochloro-(bisethylthiolacetato)-platinoic acid*, $(CO_2H\cdot CH_2\cdot SEt)PtCl(CO_2\cdot CH_2\cdot SEt)$, and *trans*-dichloro-diammineplatinum, $Pt(NH_3)_2Cl_2$. The former compound crystallises in greenish-yellow aggregates, m. p. 166—167°.

The above sulphate reacts with barium hydroxide, yielding colourless, microscopic needles of *trans*-diammineplatinum bisethylthiol-acetate, which can also be obtained from the corresponding iodide on boiling with silver ethylthiolacetate. It has m. p. 200—203° (decomp.).

trans-Dinitritodiammineplatinum and sodium ethylthiolacetate react very slowly, yielding the same sodium dinitrito-(bisethylthiolacetato)-platinoate as was derived from the *cis*-derivative. E. F. A.

Lactonisation of α-Ketonic Esters. HENRI GAULT (*Compt rend.*, 1913, 157, 135—137. Compare A., 1911, i, 709).—By a study of its compounds with hydrazine and ammonia the author has definitely established the constitution of the neutral substance, b. p. 176—177°/13 mm., obtained by saturating ethyl pyruvate with hydrogen chloride in the cold, as being the ethyl ether of the enolic form of ethyl α-keto-γ-valerolactone-γ-carboxylate,

$$CO_2Et\cdot CMe {<}^{O--CO}_{CH:C\cdot OEt}$$
(compare A., 1912, i, 237). It unites with hydrazine (1 mol.) to form the *lactone hydrazide*, $NH_2\cdot NH\cdot CO\cdot CMe{<}^{O--CO}_{CH:C\cdot OEt}$, m. p. 146°, and a small quantity of a crystalline *compound*, m.p. 230° (decomp.), is obtained at the same time. With excess of hydrazine it gives the *hydrazinolactone hydrazide*, $NH_2\cdot NH\cdot CO\cdot CMe{<}^{O--C(OH)\cdot NH\cdot NH_2}_{CH:C\cdot OEt}$, m. p. 180° (decomp.).

Ammonia reacts similarly in the cold, giving an *amide*, m. p. 190°, and a second *compound*, m. p. 245° (decomp.).

The compound, m. p. 230°, obtained in the action with hydrazine (1 mol.) and the compound, m. p. 245°, obtained in the action with ammonia are shown to be derivatives of ethyl α-chloro-γ-keto-α-methyl-glutarate, formed during the aldolisation of the pyruvic ester.

W. G.

Catalytic Preparation of Ketones Over Oxides of Iron. ALPHONSE MAILHE (*Compt. rend.*, 1913, **157**, 219—221).—Both ferrous and ferric oxides can replace cadmium oxide (compare this vol., i, 828) as catalysts in the preparation of simple or mixed ketones from their acids. The oxides are kept at a temperature of 430—490°. The acids employed may be aliphatic or aromatic, or mixtures of the two, and, as in the case of cadmium oxide, *iso*valeric and *iso*butyric acids give the worst yields. The yields are given for numerous ketones.

W. G.

The Mechanism of the Formation of Acrose. ERNST SCHMITZ (*Ber.*, 1913, **46**, 2327—2335).—At the time of their identification of α-acrose as *dl*-fructose, Fischer and Tafel suggested that the accompanying β-acrose present in smaller amount in the product from dibromopropaldehyde and from glycerose was a sugar probably allied to sorbose. From the occurrence of a ketose it is obvious that the process cannot be a simple aldol condensation of glyceraldehyde, but that at some stage of the change an aldehyde group must become transformed into a ketonic one; this probably occurs in the triose molecule, as the conditions of the condensation are not such as to cause a rearrangement in the hexose molecule; it has also been shown (Wohl and Neuberg, A., 1901, i, 12) that the trioses are easily interconvertible under these conditions, because whether aldehyde-free glycerose or pure glyceraldehyde is applied for the condensation, β-acrose is always produced.

By the condensation of pure glyceraldehyde, obtained conveniently by the hydrolysis of the corresponding acetal with N/10-sulphuric acid and subsequent treatment with baryta, under the influence of 0·1% excess of baryta at the ordinary temperature, a solution was obtained which yielded a crystalline mixture of two hexoses; this could be separated by recrystallisation from hot methyl alcohol; the less soluble constituent, needles, m. p. 129—130°, D^{16} 1·665, osazone n. p. 216—217°, was *dl*-fructose, whilst the more soluble, rhombic leaflets, m. p. 162—163°, D^{17} 1·634, osazone m. p. 169—170° (decomp.), was *dl*-sorbose, the identity being confirmed by comparison with an artificial mixture of the enantiomorphous forms. The *dl*-fructose, here obtained crystalline for the first time, of course represents α-acrose, whilst the *dl*-sorbose in spite of the somewhat higher m. p. doubtless represents the β-acrose which had previously not been obtained in a quite pure condition. The formation of a racemic sorbose would be expected on theoretical grounds from the condensation of dihydroxyacetone with *dl*-glyceraldehyde.   D. F. T.

Cyanohydrins of Certain Monosaccharides. CYRILL KRAUZ and JAN KLOUD (*Eighth Inter. Cong. App. Chem.*, 1912, **25**, 397—401).—On the addition of hydrogen cyanide to a monosaccharide, two epimeric cyanohydrins are produced :

$$\cdot -CH(OH)\cdot CHO + HCN = CN\cdot CH(OH)\cdot CH(OH)-$$
(compare Votoček, A., 1911, i, 179). A study has now been made of

the products obtained by the action of hydrogen cyanide on certain monosaccharides.

When arabinose is treated with solution of hydrogen cyanide, a mixture of the amides of l-gluconic and l-mannonic acids is obtained; the former has m. p. 181°, not 160° (decomp.) as stated by Kiliani (A., 1887, 230). In the case of xylose and rhamnose, liquid products were obtained which could not be separated. Rhodeose yields α- and β-rhodeohexonamides (Krauz, A., 1910, i, 224). Fucose furnishes α-fucohexonamide and β-*fucohexonamide*, m. p. 176°. With galactose, α-galactoheptonamide, m. p. 201°, was obtained; the mother liquor when treated with phenylhydrazine gave the phenylhydrazide of this amide, m. p. 226°, together with another phenylhydrazide, m. p. 186°. Mannose yields a mixture of α- and β-mannoheptonamides, the former melting at 214—215°, and not at 182—183° (Fischer and Hirschberger, A., 1889, 482).   E. G.

Hydrolysis of Cellulose. I. RICHARD WILLSTÄTTER and LÁSZLÓ ZECHMEISTER (*Ber.*, 1913, **46**, 2401—2412). —Whereas ordinary concentrated hydrochloric acid (37·6% of hydrogen chloride) decomposes and gelatinises cellulose after about a day's action, a more concentrated acid (40—41% of hydrogen chloride) dissolves cellulose completely within a few seconds. At first the cellulose can be precipitated again, but it is rapidly hydrolysed, and finally only dextrose remains in solution. It is possible to follow the course of the change both polarimetrically and gravimetrically, whereby 96% of the theoretical quantity of dextrose is obtained. The 1% solution of cellulose in the concentrated acid is at first optically inactive; it becomes active after about an hour, and increases until hydrolysis is complete in twenty-four to forty-eight hours at the ordinary temperature. The change in rotatory power gives indication of the intermediate formation of higher carbohydrates. An acid, D^{15} 1·212 (41·4% of hydrogen chloride), dissolves 15% of cellulose; the solution is at first colourless and clear; in time it becomes yellow, and later dark yellow as the dextrose is decomposed. On dilution of the solution during the first half-hour, unchanged cellulose is precipitated.

Cellulose dissolves similarly in 66% (D 1·78) hydrogen bromide, but not in concentrated hydriodic acid; hydrofluoric acid (70—75% of hydrogen fluoride) gelatinises, and quickly dissolves cellulose.

Pine-wood dissolves quickly in fuming hydrochloric acid, leaving 30% of its weight undissolved as lignin substance.

The rotatory power of dextrose ($[\alpha]_D$) increases from $+54·5°$ in hydrochloric acid D 1·018 to $+97·5°$ in an acid D 1·204, $+106°$ in an acid D 1·212, and $+164·6°$ in a 44·5% acid.   E. F. A.

Certain Substances containing the Cetyl Radicle. ALBERT REYCHLER (*Bull. Soc. chim. Belg.*, 1913, **27**, 217—225).—Triethylcetylammonium iodide, $C_{16}H_{33}\cdot NEt_3I$, is obtained when a mixture of triethylamine and cetyl iodide is heated for two hours at 130°. It dissolves in water, yielding soapy solutions, which develop an abundant

lather when shaken. These solutions only give an opalescence with silver nitrate, and thus appear to be colloidal, this observation being confirmed by a study of their b. p.'s and electrical conductivities. The solid iodide has m. p. 179—181° without decomposition (contrast Krafft and Moye, A., 1889, 689).

An attempt has been made to prepare triethylcetylammonium hydroxide by the action of freshly prepared silver oxide on a boiling alcoholic solution of the corresponding iodide. Under these conditions, however, the base, if formed, is decomposed into diethylcetylamine.

Aqueous solutions of diethylcetylamine hydrochloride behave similarly to those of the above iodide. Determinations of the conductivity at different temperatures show that a period of rapid crystallisation occurs in the region of 0°. The values obtained for the molecular conductivity are greater than those observed for triethylcetylammonium iodide at similar dilutions.

Triethylcetylammonium cetylsulphonate, $C_{16}H_{33} \cdot SO_3 \cdot NEt_3 \cdot C_{16}H_{33}$, is readily prepared by heating a boiling alcoholic solution of *silver cetylsulphonate* with triethylcetylammonium iodide. It is molten at 172—179° without showing any distinct m. p. It yields soapy solutions in hot water, which, on cooling, separate into a clear liquid and a jelly-like mass. It is soluble in alcohol and in ethyl acetate. From the latter it separates in crystals, m. p. about 53°, which contain solvent of crystallisation. Determinations of the conductivity of aqueous solutions lead to the conclusion that the substance is probably present in the form of multi-molecular aggregates.

In chemical constitution and in the behaviour of their aqueous solutions or pseudo-solutions, these substances are somewhat analogous to soaps. This is confirmed by the fact that solutions of triethylcetylammonium iodide or, better, of diethylcetylamine hydrochloride in water yield excellent results in the cleansing of samples of wool.

<div align="right">H. W.</div>

The Homologue of Muscarine in the C_3 Series   V. Brabant (*Zeitsch. physiol. Chem.*, 1913, **86**, 206—214).—To prepare β homo-muscarine acraldehyde is converted into ethyl αγ-dichloropropyl ether, $CH_2Cl \cdot CH_2 \cdot CHCl \cdot OEt$, and this into the ethylacetal of β-chloropropaldehyde, $CH_2Cl \cdot CH_2 \cdot CH(OEt)_2$. When this is heated with trimethylamine in a sealed tube on the water-bath, the *hydrochloride* of β homo-*muscarineacetal*, $NMe_3Cl \cdot CH_2 \cdot CH_2 \cdot CH(OEt)_2$, is obtained.

This is hydrolysed by concentrated hydrochloric acid to β-homo-*muscarine hydrochloride*, $NMe_3Cl \cdot CH_2 \cdot CH_2 \cdot CHO$, which shows all the typical reactions of both aldehyde and amino-groups.

β-Homomuscarineacetal hydrochloride forms stellate aggregates of small needles which are very hygroscopic; the *platinichloride* forms large, prismatic-rhombic, orange-red crystals which blacken at 160°, m. p. 190—195° (decomp.); the *aurichloride* separates in broad, lustrous, straw-yellow needles, m. p. 93—95° (decomp.).

β-Homomuscarine hydrochloride forms hygroscopic crystals; the free base could not be isolated. The *platinichloride* separates in microscopic, orange-yellow rods, decomp. 156—160°. The *auri-*

chloride is straw-yellow, m. p. 150—155° (decomp.). The *semicarbazone* crystallises in small, colourless, regular octahedra, m. p. 247 5° (corr.).

E. F. A.

Compounds of Hydrated Salts with Organic Bases (Dithionates, Sulphates, Thiosulphates). FILIPPO CALZOLARI (*Atti R. Accad. Lincei*, 1913, [v], 22, i, 787—792. Compare A , 1912, i, 812).— The dithionate, $MgS_2O_6,8H_2O,2C_8H_{10}O_2N_4$, prepared from magnesium dithionate and a large excess of caffeine, forms colourless, prismatic crystals. The *manganese* derivative, $MnS_2O_6,8H_2O,2C_8H_{10}O_2N_4$, crystallises in colourless needles. The *ferrous* salt,

$$FeS_2O_6,8H_2O,2C_8H_{10}O_2N_4,$$
forms prismatic crystals. The *cobalt* salt, $CoS_2O_6,8H_2O,2C_8H_{10}O_2N_4$, crystallises in pale rose-coloured needles. The *nickel* salt,

$$NiS_2O_6,8H_2O,2C_8H_{10}O_2N_4,$$
forms green crystals isomorphous with those of the cobalt compound.

The compound of magnesium dithionate with hexamethylenetetramine, $MgS_2O_6,6H_2O,2C_6H_{12}N_4$, forms large crystals. The *manganese* compound, $MnS_2O_6,6H_2O,2C_6H_{12}N_4$, is a white, crystalline powder. The *ferrous* salt, $FeS_2O_6,6H_2O,2C_6H_{12}N_4$, is a greenish-white, crystalline powder. The *cobalt* salt, $CoS_2O_6,6H_2O,2C_6H_{12}N_4$, forms rose-red, regular crystals. The *nickel* salt, $NiS_2O_6,6H_2O,2C_6H_{12}N_4$, forms green crystals similar to those of the cobalt compound.

The *compound* of magnesium sulphate and hexamethylenetetramine, $MgSO_4,9H_2O,C_6H_{12}N_4$, forms colourless crystals. The *manganese* compound, $MnSO_4,9H_2O,C_6H_{12}N_4$, forms colourless crystals, and mixed crystals of this compound with that of nickel were also obtained. The *ferrous* compound, $FeSO_4,9H_2O,C_6H_{12}N_4$, must be prepared in the absence of air. The *cobalt* compound, $CoSO_4,9H_2O,C_6H_{12}N_4$, forms rose-red crystals, and mixed crystals of it with the magnesium compound can be obtained. The *nickel* compound, $NiSO_4,9H_2O,C_6H_{12}N_4$, forms large, emerald-green crystals isomorphous with those of the cobalt salt.

The compound of magnesium thiosulphate with hexamethylenetetramine, $MgS_2O_3,8H_2O,C_6H_{12}N_4$, forms colourless, rhombohedral crystals. The *manganese* compound, $MnS_2O_3,8H_2O,C_6H_{12}N_4$, forms very pale rose-coloured crystals. The *ferrous* compound,

$$FeS_2O_3,8H_2O,C_6H_{12}N_4,$$
must be prepared out of contact with the air; it forms greenish-white crystals. The *cobalt* salt, $CoS_2O_3,8H_2O,C_6H_{12}N_4$, forms rose-coloured crystals. The *nickel* compound, $NiS_2O_3,8H_2O,C_6H_{12}N_4$, forms emerald-green crystals.

R. V. S.

Condensation of Amino-acids with Formaldehyde. GINO GALEOTTI (*Biochem. Zeitsch*, 1913, 53, 474—492).—On heating aminoacids with formaldehyde, products are obtained which differ both from the original acids and fresh mixtures of the reacting products. Reddish-yellow solutions are obtained, which do not deposit crystals, but yield an amorphous residue on evaporating off the water. The solutions are acid, and only the tyrosine derivative is precipitated on the addition of dilute acids. The glycine, alanine, aspartic acid

and tyrosine derivatives are insoluble in alcohol or acetone, but the leucine and phenylalanine derivatives are soluble. All are insoluble in ether. The aqueous solutions give voluminous precipitates with phosphotungstic, picric and tannic acids, and with the salts of heavy metals. They do not reduce copper salts in alkaline solution, give the diazo-reaction with a yellowish-red or cherry-red colour, and give precipitates on saturation with ammonium sulphate. They dissolve copper hydroxide, yielding malachite-green solutions which give a precipitate on addition of alcohol. They no longer contain the amino-group, as no nitrogen is evolved in the van Slyke reaction, which can be employed for tracing the course of the reaction of the aldehyde on the acids. The glycine derivative was studied in some detail. It has a molecular weight of 288, corresponding with the formula $C_{12}H_{21}O_5N_3$, and m. p. 164°. Attention is called to the similarity in the behaviour of the compounds obtained to the polypeptides, and it is suggested that formaldehyde may play some part in forming complex derivatives from amino-acids in living organisms, analogous to the supposed formation of carbohydrates by condensation with this substance.   S. B. S.

Synthesis of the Anhydrides of α-Aminoacyl Glucosamines. CHARLES WEIZMANN and ARTHUR HOPWOOD (*Proc. Roy. Soc.*, 1913, *A*, 88, 455—461. Compare P., 1912, 28, 261).—α-Bromoacyl haloids are condensed with glucosamine hydrochloride in the presence of sodium hydroxide (compare P., 1912, 28, 261), and cold aqueous ammonia is allowed to act on the α-bromoacylglucosamines formed. Anhydrides of the expected α-aminoacylglucosamines are obtained.

Alanylglucosamine anhydride separates in colourless, prismatic needles, which turn brown at 245—250°, and melt at 269—272° to a black liquid. It reduces Fehling's solution on prolonged boiling, but does not react with either phenylhydrazine or semicarbazide.

Leucylglucosamine anhydride forms similar colourless, prismatic needles, which sinters at 205°, m. p. 213—215° (decomp.).

α-Aminolaurylglucosamine anhydride was obtained in colourless crystals.   •   E. F. A.

Esters of Imino- and Oximino-carbonic Acid. JOSEPH HOUBEN and ERICH SCHMIDT (*Ber.*, 1913, 46, 2447—2460).—Sandmeyer (A., 1886, 611) claimed to have reduced esters of chloroiminocarbonic acid, and obtained ethyl iminocarbonate, $HN{:}C(OEt)_2$, which was dried over potassium hydroxide. It is shown that under these conditions urethane is formed, and that it was present in Sandmeyer's product.

When the reduction product is carefully dried over ignited sodium sulphate and fractionated in a vacuum, pure iminocarbonic esters are obtainable. Even the pure esters change on prolonged keeping into crystalline cyanuric acid derivatives.

The hydrochloride of the imino-ester is to be regarded as a chloroimino-ether, $NH_2 \cdot CCl(OR)_2$. In presence of water the chlorine is exchanged for hydroxyl, $NH_2 \cdot C(OR)_2 \cdot OH, HCl$, following which the hydrogen chloride conditions elimination of ammonium chloride and the formation of alkyl carbonate, $CO(OR)_2$.

Similarly, with hydroxylamine the compound

$$NH_2 \cdot C(OR)_2 \cdot NH \cdot OH, HCl$$
formed decomposes into the oximinocarbonic ester, $C(OR)_2:N \cdot OH$. Working in ethereal solution it was possible to prepare *diethyl* or *dimethyl oximinocarbonate* in this manner, and the method has been extended to the preparation of the true hydroximic esters of the aliphatic series, $OEt \cdot CR:N \cdot OH$.

The oximinocarbonic esters, which crystallise well, are obtained by a similar process from the chloroiminocarbonic esters.

Ethyl chloroiminocarbonate has m. p. 39°, agreeing with Sandmeyer's statement; during its preparation a product of unknown constitution crystallising in needles, m. p. 148—149°, is formed.

Methyl chloroiminocarbonate has m. p. 20°, b. p. 63—64°/13 mm., without decomposition.

Ethyl iminocarbonate is a transparent liquid of a strongly basic odour, D^{22} 0·9637.

Ethyl iodoiminocarbonate, $NI:C(OEt)_2$, forms yellow crystals and crusts. When shaken with mercury in ethereal or alcoholic solution, *aziethyl carbonate*, $C(OEt)_2:N \cdot N:C(OEt)_2$, is formed.

Ethyl carbanilinoiminocarbonate, $C_6H_5 \cdot NH \cdot CO \cdot N:C(OEt)_2$, forms crystals sintering at 100°, m. p. 101°.

Ethyl thiocarbanilinoiminocarbonate has m. p. 117—118°.

E. F. A.

The Organic Acid Amides and their Metallic Derivatives as Acids and Salts of the Ammonia System of Acids, Bases, and Salts. EDWARD C. FRANKLIN (*Eighth Inter. Cong. App. Chem.*, 1912, **6**, 119—130. Compare A., 1912, ii, 451).—A recapitulation of the author's classification of amides and their derivatives into "ammonoacids," "ammono-bases," "ammono salts," "ammono-esters," "mixed ammono-acids," and "acid anammonides." The ammono-acids vary in strength from acetamide, benzamide, and carbamide, which only form salts in liquid ammonia solution and have only a feeble conductivity in that solvent, to such compounds as phthalimide and "saccharin" which are not excelled in strength by the strongest carboxylic acids.

J. C. W.

Compounds of Ferricarbamide. GIUSEPPE A. BARBIERI (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 867—870).—These compounds exhibit complete chemical and crystallographic similarity to the salts of chromicarbamide already known. They are all greenish-blue in the solid state and in concentrated solution, but dilute solutions are yellow and are precipitated by ammonia even in the cold. Compounds analogous to the hydrate and carbonate of chromicarbamide cannot be prepared.

The *perchlorate*, $[Fe(CON_2H_4)_6](ClO_4)_3$, is obtained by adding a concentrated solution of carbamide to a solution of ferric perchlorate containing excess of perchloric acid, or from a perchlorate and another ferricarbamide compound. It forms mixed crystals with the corresponding *chromicarbamide perchlorate*, $[Cr(CON_2H_4)_6](ClO_4)_3$, which is a green, crystalline powder.

Ferricarbamide nitrate, $[Fe(CON_2H_4)_6](NO_3)_3$, the *permanganate,* $[Fe(CON_2H_4)_6](MnO_4)_3$, the *dichromate,* $[Fe(CON_2H_4)_6](Cr_2O_7)_3$, the *chloride,* $[Fe(CON_2H_4)_6]Cl_3,3H_2O$, the *bromide,*
$$[Fe(CON_2H_4)_6]Br_3,3H_2O,$$
and the *nitrate periodide,* $[Fe(CON_2H_4)_6](NO_3)_2I,I_2$, are similarly prepared. On treating the bromide with bromine an unstable perbromide is obtained.   R. V. S.

Preparation of Melamine and Ammeline from Dicyanodiamide ; Triaminomelamine and Diaminoammeline. ROBERT STOLLÉ and K. KRAUCH (*Ber.*, 1913, **46**, 2337—2339).—When powdered dicyanodiamide is treated with concentrated ammonia solution in a sealed tube at 120° for three hours, a crystalline deposit is obtained consisting of melamine in 35% yield and of ammeline in 20% yield, which can be separated by the sparing solubility of the latter in water ; a small quantity of carbamide and guanidine can be found in the liquid from which the crystalline mass has separated. It is suggested that possibly the dicyanodiamide is acted on concurrently by the ammonia and by water, with the production of guanidine and cyanamide and of guanidine and cyanic acid respectively ; unchanged dicyanodiamide then reacts with the cyanamide yielding melamine, and with the cyanic acid yielding ammeline.

Triaminomelamine (cyanuric hydrazide ; von Meyer and Näbe, A., 1911, i, 122 ; Finger, A., 1907, i, 298), microscopic needles, m. p. 287°, was obtained by heating melamine with a quinquemolecular proportion of hydrazine hydrate for five hours under pressure at 150° ; it quickly reduces warm ammoniacal silver nitrate, and when shaken in hydrochloric acid solution with benzaldehyde yields a *tribenzylidene* derivative.

When ammeline is heated with an equal quantity of hydrazine hydrate for five hours under pressure at 130°, diaminoammeline, prisms, m. p. above 340°, is obtained ; this in aqueous solution reacts with benzaldehyde, producing a *dibenzylidene* derivative, m. p. 315°.
                                        D. F. T.

Condensation of Melamine with Dextrose. LEOPOLD RADLBERGER (*Chem. Zentr.*, 1913, i, 2110 ; from *Öster-ung Zeitsch. Zuckerind.*, 1913, **42**, 236—239).—Melamine and dextrose were condensed by heating in 30% alcoholic solution on the water-bath. The product consisted of 2 mols. melamine to 1 mol. dextrose, namely, $[C_3N_3(NH_2)_2\cdot NH]_2CH\cdot[CH\cdot OH]_4\cdot CH_2\cdot OH$. It has m. p. 281°, forming colourless, lustrous crystals which do not reduce Fehling's solution.
                                        E. F. A.

Synthesis of Mercury Fulminate from Propyl Alcohol. A. L. KIBLER (*Eighth Inter. Cong. App. Chem.*, 1912, **25**, 239—243). —Experiments are described in which propyl alcohol, *iso*butyl alcohol, amyl alcohol, acetone, and propaldehyde were substituted for ethyl alcohol in the usual process for the preparation of mercury fulminate. A small quantity of mercury fulminate was obtained from the propyl alcohol, but not from any of the other substances. In the experi-

ments with propyl alcohol, an intermediate compound was isolated, which forms large, white, lustrous plates, and decomposes either spontaneously or when treated with water, leaving traces of a grey powder, probably composed of mercury.　　　　　　　　　　E. G.

Azides of Carbamic Acid from Ketens. VII. E. OLIVERI-MANDALÀ and E CALDERARO (*Gazzetta*, 1913, **43**, i, 538—543. Compare this vol., i, 716).—Azoimide reacts with ketens giving azides of carbamic acid. The stages in the reaction are probably indicated by the scheme: $CR_2 \text{:} CO \longrightarrow CHR_2 \cdot CO \cdot N_3 \longrightarrow [CHR_2 \cdot CO \cdot N] \longrightarrow CHR_2 \cdot N \text{:} CO$, and from this carbimide the azide, $CHR_2 \cdot NH \cdot CO \cdot N_3$, is produced by the addition of a further molecule of azoimide.

Keten reacts with an ethereal solution of azoimide at the temperature of a mixture of ice and salt, yielding *methylcarbamazide*, $N_3 \cdot CO \cdot NHMe$, which forms lustrous laminæ or tablets, m. p. 46—47°. The formation of the azide shows that keten has reacted as though it had the ketonic formula of Staudinger, and not the hydroxylic formula of Wilsmore. With aniline, the azide yields *s*-phenylmethylcarbamide and aniline azoimide. Alcoholic ammonia reacts with the azide, yielding methylcarbamide and ammonium azoimide. Boiling water decomposes the azide, carbon dioxide, azoimide and methylamine being formed; by keeping an aqueous solution of the azide in a desiccator, *methylammonium azoimide*, CH_5N_4, can be obtained; it is a deliquescent substance, which is completely fused at 115°.

Diphenylketen and azoimide yield *diphenylmethylcarbamazide*,
$$N_3 \cdot CO \cdot NH \cdot CHPh_2,$$
which crystallises in colourless, silky needles, m. p. 121—123°. When heated for four hours at 100—110° in a sealed tube with alcoholic ammonia, the azoimide yields *as*-diphenylmethylcarbamide. When heated with aniline in a sealed tube for two hours at 90°, the azide is converted into *diphenylmethylphenylcarbamide*,
$$NHPh \cdot CO \cdot NH \cdot CHPh_2,$$
which forms silky crystals, m. p. 208—209°. This substance dissolves in concentrated sulphuric acid, giving an orange-red coloration.　　　　R. V. S.

Action of Magnesium Methyl Iodide on Silicon Hexachloride. GEOFFREY MARTIN (*Ber.*, 1913, **46**, 2442—2447. Compare P., 1913, **29**, 190).—The yellow substance formed by the action of magnesium methyl iodide on silicon hexachloride has the composition $Si_6H_9O_{13}Me$. When heated, hydrogen and methane are evolved, and a silicon compound is obtained practically without carbon, but which still contains coupled silicon groups, since on dissolution in potassium hydroxide hydrogen is evolved. On the addition of excess of acid, silicic acid is precipitated.　　　　　　　　　　E. F. A.

Researches on the Direct Introduction of Substituents into the Benzene Nucleus During the Years 1910, 1911, and 1912. ARNOLD F. HOLLEMAN (*Chem. Weekblad*, 1913, **10**, 604—620). —A summary of papers on this subject published since the issue of

the author's work, "Die direkte Einfuhrung von Substituenten in den Benzolkern," in the year 1910. A. J. W.

A Simple Method of Preparing Hexamethylbenzene. HANS RECKLEBEN and JOHANNES SCHEIBER [with K. SCHNABEL] (*Ber.*, 1913, 46, 2363—2365).—When the vapour from a molecular mixture of acetone and methyl alcohol is passed over aluminium oxide, heated at about 400°, clean crystals of hexamethylbenzene are obtained in about 10% of the theoretical quantity. The oily residue represents a complicated mixture. Replacement of aluminium oxide by other oxides led to unfavourable results.

On bromination of hexamethylbenzene, a mixture of bromides, m. p. 231—269°, and containing from 64% to 80% of bromine, is obtained. E F. A.

Nitro-derivatives of High-boiling Mineral Oils. KONSTANTIN CHARITSCHKOFF (*Chem. Zeit.*, 1913, 37, 869).—When Caucasian lubricating oils are warmed with fuming nitric acid, they form syrupy, very viscous nitro-derivatives, which are soluble in most organic solvents with the exception of light petroleum. They are weak acids, dissolve in alkalis, and form insoluble salts with the alkaline earths and heavy metals which are similar to the salts of polynaphthenic acids (A., 1910, i, 110). Moreover, their composition and properties agree with those of the nitro-derivatives of polynaphthenic acids.

J. C. W.

The Reaction Between Selenic Acid and Toluene. HOWARD WATERS DOUGHTY and FRANK ROSE ELDER (*Eighth Inter. Cong. App. Chem.*, 1912, 6, 93—101).—Toluene and concentrated selenic acid were left together for some months during which time carbon dioxide was evolved. The lower, dark red, viscous layer was then poured into water and separated into an acid solution and a small amount of a red oil with a solid admixture.

The acid solution was exactly neutralised with barium hydroxide, filtered from barium selenate, evaporated to dryness, and extracted during several days with chloroform, which removed traces of the above red oil. The residue gave a mixture of *o*- and *p*-tolueneselenonic acids which could not be separated, but on reduction of a concentrated solution with hydrogen chloride, p(?)-*tolueneseleninic acid*, $C_6H_4Me \cdot SeO_2H, H_2O$, was precipitated in long, silky, white needles, m. p. 160°, whilst the mother liquor yielded o(?) *tolueneseleninic acid*, with $\frac{1}{2}H_2O$, in nodules of short, white needles, m. p. 99—101°.

The red oil was washed with ether in which the solid substance is insoluble, and then distilled. It had b. p. 201—202°/18—20 mm., and solidified to a light yellow, crystalline mass, m. p. 69·5—70·5°, which was identified with *p*-ditolyl selenide (Zeiser, A., 1895, i, 512). On oxidation with hot permanganate, it yielded *diphenylselenone*-4 : 4'-*dicarboxylic acid*, $SeO_2(C_6H_4 \cdot CO_2H)_2$, as a heavy, white solid, m. p. 283°, which is sparingly soluble in hot alcohol, and insoluble in all other common solvents.

The crystalline substance, insoluble in ether or water, was recrystal-

lised from alcohol in colourless, stout, hexagonal prisms, m. p. 183°. It was not affected by boiling alkalis or permanganate, but yielded salicylic acid on fusion with potassium hydroxide. It is, therefore, *benzophenoneselenone* (III), and its formation is explained by assuming that *o*-ditolyl selenide (I) is formed as an intermediate product, and is then oxidised to diphenylselenone-2 : 2'-dicarboxylic acid (II), which condenses with loss of carbon dioxide and water.
<div style="text-align:right">J. C. W.</div>

Action of Sodium in Liquid Ammonia on Phenylacetylene and Styrene. PAUL LEBEAU and MARIUS PICON (*Compt. rend.*, 1913, 157, 223—224. Compare this vol., i, 950).—Sodium in liquid ammonia reacts with phenylacetylene, giving the corresponding sodium derivative (2 mols.) and ethylbenzene (1 mol), with the formation of sodamide. Unlike the true acetylenes of the fatty series, the hydrogenation does not stop at the ethylenic hydrocarbon, but the fully saturated hydrocarbon is produced :

$$3CPh\ddot{:}CH + 4NH_3Na = 2CPh\ddot{:}ONa + C_6H_5 \cdot Et + 2NaNH_2 + 2NH_3.$$

Styrene itself reacts slowly with sodium in liquid ammonia, the products being ethylbenzene and sodamide. W. G.

A Yellow Hydrocarbon of the Fluorene Series. RUDOLF PUMMERER and GUSTAV DORFMÜLLER (*Ber.*, 1913, 46, 2386—2389).— When fluorene is heated with lead dioxide and sodium ethoxide in pyridine solution, small quantities of a yellow hydrocarbon are formed, owing to the formation of acetaldehyde, and coupling of this with two molecules of fluorene. The final product is *dehydroethylidenebisfluorene* (I), but *ethylidenebisfluorene* (II) is formed first, and may also be obtained by reducing the dehydro-compound with zinc dust and acetic acid. It is very readily oxidised by lead dioxide and even by atmospheric oxygen. The double bond only very slowly absorbs bromine, and does not react with permanganate in pyridine solution.
Dehydroethylidenebisfluorene crystallises in oblique-ended, yellow prisms ; it darkens at 280°, but has not melted at 350°. In small quantities it apparently distils unchanged.

Ethylidenebisfluorene is colourless, m. p. 262—263°, to a yellowish-brown liquid. E. F. A.

Orthohalogenated *p*-Nitroanilines and their Derivatives. WILHELM KÖRNER and ANGELO CONTARDI (*Atti R. Accad. Lincei*, 1913, [v], 22, i, 823—836).—2-Chloro-4-nitroaniline forms pale yellow

needles, m. p. 104·5°. Its acetyl derivative crystallises in straw-coloured prisms, m. p. 139°.

3-*Chloro-4-bromo-1-nitrobenzene* (obtained from the perbromide of the diazonium compound of the preceding substance) forms colourless needles or prisms, m. p. 62°.

3-*Chloro-4-iodo-1-nitrobenzene* (similarly prepared) crystallises in almost colourless needles, m. p. 103°.

2-Bromo-4-nitroaniline crystallises in pale yellow needles, m. p. 104·5°. Its monoacetyl derivative forms flat prisms, m. p. 114°; the *diacetyl* derivative in stout prisms, m. p. 132°.

From the amino-derivative by diazotisation, 4-chloro-3-bromo-1-nitrobenzene can be obtained; it crystallises in almost colourless prisms, m. p. 61°. and is identical with the compound obtained from 6-chloro-3-nitroaniline. The corresponding 3-bromo-4-iodo-1-nitrobenzene crystallises in needles or prisms, m. p. 106°. 2-Iodo-4-nitroaniline, m. p. 109°, occurs in yellowish-red prisms and also in golden-yellow laminæ; the former is the more stable form. The substance yields a *monoacetyl* and a *diacetyl* derivative.

2-Iodo-4-nitroaniline can be diazotised, and by the subsequent introduction of chlorine, 4-chloro-3-iodo-1-nitrobenzene can be prepared; it crystallises in colourless needles, m. p. 78°, and is identical with the compound obtained from 6-chloro-3-nitroaniline in a similar way.

2 : 6-Dichloro-4-nitroaniline crystallises in lemon-yellow needles, m. p. 195°. It is best diazotised in nitric acid (D 1·38) at 0°. It yields a monoacetyl derivative (almost colourless, flat needles, m. p. 215°) and a diacetyl derivative, m. p. 142·5°, which crystallises in prisms of the monoclinic system

[E. Artini: $a : b : c = 1·1361 : 1 : 0·8753$; $\beta = 70·4°$, D 1·565].

When an alcoholic solution of the preceding amino-compound containing a little concentrated sulphuric acid is treated with ethyl nitrite, 3 : 5-dichloro-1-nitrobenzene is produced; it crystallises in colourless plates, m. p. 65·4°. On reduction with tin and hydrochloric acid it yields the corresponding dichloroaniline, which forms needles or prisms, m. p. 51·5°. From this substance, 1 : 3 : 5-trichlorobenzene is obtainable; it crystallises in colourless needles, m. p. 63·5°, and is identical with that obtained from 2 : 4 : 6-trichloroaniline, m. p. 77·5°. 3 : 5-Dichloro-1-bromobenzene crystallises in colourless needles, m. p. 75·8°. 3 : 5-*Dichloro-1-iodobenzene* has m. p. 54°; it is identical with that obtained from 2 : 4-dichloro-6-iodoaniline, m. p. 84°.

3 : 4 : 5-Trichloro-1-nitrobenzene (from 2 : 6-dichloro-4-nitroaniline) forms pale yellow prisms, m. p. 72·5°. On reduction and elimination of the amino-groups it yields 1 : 2 : 3-trichlorobenzene, m. p. 50·8°, identical with that obtained from 2 : 6-dichloroaniline (Körner and Contardi, A., 1909, i, 220).

3 : 5-Dichloro-4-bromo-1-nitrobenzene (from the dichloronitro-derivative) crystallises in pale yellow prisms, m. p. 88°.

3 : 5-*Dichloro-4-iodo-1-nitrobenzene* forms yellow prisms, m. p. 154·8°. On reduction with ferrous sulphate and ammonia, and subsequent elimination of the amino-group, it yields 1 : 3-*dichloro-2-iodobenzene*, which crystallises in thin, colourless plates, m. p. 68°. The same

substance can be prepared from the 2 : 6-dichloroaniline already mentioned.

2 : 6-Dibromo-4-nitroaniline (by the action of bromine on *p*-nitroaniline) crystallises in golden-yellow laminæ, m. p. 202·5°. Its monoacetyl derivative forms almost colourless needles, m. p. 232°. The diacetyl derivative, m. p. 136°, crystallises in the pinaconic class of the triclinic system [*a* : *b* : *c* = 1·0901 : 1 : 0·8325, α 88°43′4″, β 70°49′34″, γ 93°25′39″, D 1·939].

3 : 5-Dibromo-1-nitrobenzene is obtained by diazotising (in alcoholic solution containing sulphuric acid) either 2 : 6-dibromo-4-nitroaniline or 4 : 6-dibromo-2-nitroaniline ; it crystallises in thin, almost colourless laminæ, m. p. 104·5°. From it *s*-chlorodibromobenzene (m. p. 119°) and *s-dibromoiodobenzene* (m. p. 124·8°) can be readily prepared. These substances can also be obtained from the following corresponding halogenated anilines : 4-chloro-2 : 6-dibromoaniline (m. p. 102°) ; 2 : 6-*dibromo-4-iodoaniline* (colourless needles, m. p. 147°) ; 2 : 4-*dibromo-6-iodoaniline* (colourless needles, m. p. 123·5°).

3 : 4 : 5-Tribromo-1-nitrobenzene (from the perbromide of the diazocompound of the dibromonitroaniline already mentioned) crystallises in yellow prisms, m. p. 111·9°. On diazotisation and elimination of the amino-group it yields 1 : 2 : 3-tribromobenzene, m. p. 87·8°.

4-*Chloro*-3 : 5-*dibromo-1-nitrobenzene* (obtained in an analogous manner to the nitrotribromo-derivative) crystallises in yellow, tabular prisms, m. p. 92·7°. On reduction and elimination of the amino-group it yields 1-chloro-2 : 6-dibromobenzene, which forms colourless plates, m. p. 71°, and is identical with the product obtained from the corresponding dibromoaniline.

3 : 5-*Dibromo-4-iodo-1-nitrobenzene* crystallises in prisms, m. p. 135·5°. It is not possible to reduce this compound without altering it. The corresponding 1 : 3-dibromo-2-iodobenzene (colourless, tabular prisms, m. p. 72°) is prepared from *o*-dibromoaniline.

2 : 6-Di-iodo-4-nitroaniline (from iodine chloride and an acetic acid solution of *p*-nitroaniline) forms golden-yellow scales or flat needles, m. p. 245°. Its *monoacetyl* derivative forms slightly yellow needles, m. p. 249° ; the *diacetyl* derivative forms stout prisms, m. p. 171°, of the pinacoidal class of the triclinic system [*a* : *b* : *c* = 0·9682 : 0 : 0·7260, α 83°6′43″, β 76°8′29″, γ 99°42′44″, D 2·290].

3 : 5-Di-iodo-1-nitrobenzene (from the di-iodonitroaniline above described by diazotisation in alcoholic solution in presence of sulphuric acid) forms slightly yellow prisms, m. p. 104·5°. When reduced with ferrous sulphate and ammonia it gives 3 : 5-di-iodoaniline (colourless needles, m. p. 110°).

5-*Chloro*-1 : 3-*di-iodobenzene* is obtained from 4-chloro-2 : 6-di-iodoaniline, and forms lustrous, colourless needles, m. p. 101°.

5-*Bromo*-1 : 3-*di-iodobenzene* (similarly obtained) crystallises in long needles, m. p. 140°.

1 : 3 : 5-Tri-iodobenzene (from 2 : 4 : 6-tri-iodoaniline, m. p. 185·6°, or from *s*-di-iodoaniline, m. p. 110°) forms opaque, colourless needles, m. p. 184·2°.

4-*Chloro*-3:5-*di-iodo-1-nitrobenzene* (prepared by the action of cuprous chloride on the nitrate of the diazo-compound from 4 : 6-di-iodo-2-nitro-

aniline) crystallises in almost colourless needles, m. p. 110°. Reduction of this compound is best effected with an alcoholic solution of ammonium sulphide; a small quantity of a sulphur *compound* is formed at the same time. 2-*Chloro*-1 : 3-*di-iodobenzene* is obtained by decomposing the diazo-salt of this amino-compound with absolute alcohol; it forms thin, rhombic plates, m. p. 82°.

4-*Bromo*-3 : 5-*di-iodo*-1-*nitrobenzene* (from the nitrate of the diazo-compound of the di-iodonitroaniline and cuprous bromide) forms almost colourless needles, m. p. 125·4°, and crystallises from benzene with $1C_6H_6$ in prisms.

3 : 4 : 5-Tri-iodo-1-nitrobenzene (from di-iodonitroaniline by way of the diazo-compound) crystallises in shining yellow prisms. It is reduced (with difficulty) to the corresponding aniline by ferrous sulphate and ammonia, and when this is treated with an alcoholic solution of ethyl nitrite, 1 : 2 : 3-tri-iodobenzene (m. p. 116°) is obtained, identical with that from 2 : 6-di-iodoaniline (m. p. 122°; Körner and Bellasio, A., 1908, i, 778).

2-Chloro-6-bromo-4-nitroaniline is obtained by treating 2-chloro-4-nitroaniline with the calculated quantity of bromine; it forms yellow needles, m. p. 177·4°. The monoacetyl derivative crystallises in pale straw-coloured needles, m. p. 224°, and the diacetyl derivative, tabular prisms, m. p. 139° [prismatic class of the monoclinic system, $a : b : c = 1·1127 : 1 : 0·8509$, β 70·36°, D 1·749].

3-Chloro-5-bromo-1-nitrobenzene (from 2-chloro-6-bromo-4-nitroaniline by means of ethyl nitrite) crystallises in thin plates, m. p. 81·2°. On reduction with tin and hydrochloric acid it yields 3-*chloro*-5-*bromoaniline* (colourless needles or prisms), from which 1-*chloro*-5-*bromo*-3-*iodobenzene* can be prepared by way of the diazo-compound; it forms lustrous needles, m. p. 85·8°, and can also be obtained from 4-*chloro*-2-*bromo*-6-*iodoaniline*, which crystallises in needles, m. p. 110·5°.

3 : 4-*Dichloro*-5-*bromo*-1-*nitrobenzene* (from the corresponding chlorobromonitroaniline already described) forms yellow prisms, m. p. 82·4°.

5-*Chloro*-3 : 4-*dibromo*-1-*nitrobenzene* (similarly prepared) crystallises in yellow prisms, m. p. 99·5°. The corresponding 3-chloro-1 : 2-dibromobenzene (prepared by replacing $-NH_2$ by $-Br$ in 2-chloro-3-bromoaniline) forms rhombic plates, m. p. 72·6°.

3-*Chloro*-5-*bromo*-4-*iodo*-1-*nitrobenzene* (prepared in a similar way to its analogues above described) crystallises in lustrous needles, m. p. 159°.

2-Chloro-6-iodo-4-nitroaniline (from 2-chloro-4-nitroaniline and iodine chloride) forms pale yellow needles, m. p. 195°. Its *monoacetyl* derivative forms needles or prisms, m. p. 207°, and the *diacetyl* derivative, m. p. 113°, prisms of the monoclinic system [$a : b : c = 1·038 : 1 : 0·799$, $\beta = 71·44°$, D 1·913].

By elimination of the amino-group the preceding aniline yields 3-*chloro*-5-*iodo*-1-*nitrobenzene*, which forms bundles of prisms, m. p. 70·4°.

3 : 4-*Dichloro*-5-*iodo*-1-*nitrobenzene* (from the above-described aniline) crystallises in pale yellow prisms, m. p. 59°. It is not possible to obtain the corresponding aniline by reduction. Ammonia and ferrous sulphate reduce it very slowly, tin and hydrochloric acid yield

3-*chloro*-5-*iodoaniline* (colourless plates, m. p. 69·8°), whilst ammonium sulphide in alcoholic solution gives 3 : 4-dichloroaniline.

3-*Chloro*-4-*bromo*-5-*iodo*-1-*nitrobenzene* (prepared like the analogous compound above described) crystallises in almost colourless needles, m. p. 95°.

5-*Chloro*-3 : 4-*di*-*iodo*-1-*nitrobenzene* (from 2-chloro-6-iodo-4-nitroaniline) forms almost colourless needles, m. p. 146·5°.

2-*Bromo*-6-*iodo*-4-*nitroaniline* (from 2 - bromo - 4 - nitroaniline and iodine chloride) crystallises in pale yellow needles, m. p. 221°. The *monoacetyl* derivative forms yellow prisms, m. p. 226°, and the *diacetyl* derivative, m. p. 134°, stout prisms of the pinacoidal class of the triclinic system [$a : b : c = 0\ 9470 : 1 : 0·7288$, a 83°59′54″, β 77°30′18″, γ 99°6′14″, D 2·112].

3-*Bromo* 5-*iodo*-1-*nitrobenzene* (from the preceding aniline) forms thin, flat needles, m. p. 97·5°.

4-*Chloro* 3-*bromo*-5-*iodo*-1-*nitrobenzene* (from the above-described bromoiodonitroaniline) crystallises in yellow prisms, or in colourless needles, m. p. 84°.   R. V. S.

Preparation of Benzylamine. MARTIN O. FORSTER and HILDA M. JUDD (*Eighth Inter. Cong. App. Chem.*, 1912, **6**, 118).—A cheap laboratory process for the preparation of benzylamine hydrochloride is described. Benzyl chloride is occasionally shaken during three days with sodium azoimide in spirit, the benzylazoimide is extracted with ether, and, without purification, reduced by means of zinc dust and 50% acetic acid.   J. C. W.

Salts of Dibasic Organic Acids with *o*-, *m*-, **and** *p*-**Toluidine, and with** *m*-4-**Xylidine.** F. GRÜNWALD (*J. pr. Chem.*, 1913, [ii], **88**, 168—179).—The three toluidines and *m*-4-xylidine combine with malonic, succinic, malic, tartaric, and fumaric acids in aqueous solution to form acid salts. Attempts to prepare the normal salts were unsuccessful.

o-*Toluidine hydrogen malonate* crystallises in short prisms (decomp. 108°); the m-*toluidine* salt in colourless prisms (decomp. 93°). The corresponding *hydrogen succinates* also crystallise in prisms (decomp. 60° and 121° respectively).

o-*Toluidine hydrogen malate* forms leaflets (decomp. 120°); the isomeric m- and p-*toluidine* salts, colourless needles (decomp. 103° and 153°). *o*-*Toluidine hydrogen fumarate* crystallises in hexagonal leaflets (decomp. 150°); the m- and p-*toluidine* salts in colourless prisms (decomp. 165° and 175°).

Of the salts of *m*-4-xylidine, the *hydrogen malonate* forms thin needles (decomp. 93°), the *hydrogen succinate*, large prisms (decomp. 89°), the *hydrogen tartrate*, prisms (decomp. 170°), and the *hydrogen fumarate*, leaflets (decomp. 175°).

When heated with cupric oxide, an aqueous solution of *m*-toluidine hydrogen oxalate yields *cupric* m-*toluidine oxalate*, $Cu(C_9H_{10}O_4)_2$, which separates with $3H_2O$ in crystals resembling copper sulphate ; the acid oxalates of *o*- and *p*-toluidine do not form similar copper salts.

Cupric o-*toluidine malonate*, $Cu(C_{10}H_{12}O_4)_2, 5H_2O$, forms bluish-green

crystals, which become anhydrous and green at 100°. *Cupric* m-*tolui-dine malonate* separates with $3H_2O$ in steel-blue crystals; the anhydrous salt is green. *Cupric* p-*toluidine malonate* crystallises with $1H_2O$. *Cupric* m-4-*xylidine malonate*, $Cu(C_{11}H_{14}O_4)_2,3H_2O$, forms blue leaflets.

The acid toluidine succinates do not yield normal cupric salts.

When boiled with nickel hydroxide in aqueous solution, *o*-toluidine hydrogen malonate yields a *nickel* salt, which forms green crystals containing $6H_2O$; *nickel* m-*toluidine malonate*, $Ni(C_{10}H_{12}O_4)_2$, crystallises with $4H_2O$ in reddish-violet leaflets; *nickel* p-*toluidine malonate* forms green, rhombic leaflets containing $2H_2O$.

Nickel m-4-*xylidine malonate* separates in dove-grey crystals containing $4H_2O$.   F. B.

Interactions with Succinylglycyl Chloride and Hippuryl Chloride. JOHANNES SCHEIBER and HANS RECKLEBEN (*Ber.*, 1913, 46, 2412—2420).—*Succinylglycine*, $C_2H_4{<}{}^{CO}_{CO}{>}N \cdot CH_2 \cdot CO_2H$, is prepared by heating molecular proportions of succinic anhydride and glycine at 170—180°; the colourless crystals have m. p. 113°.

With phosphorus pentachloride, colourless needles, m. p. 76°, of *succinylglycyl chloride* are obtained.

The chloride reacts with aniline, forming *succinylglycylanilide*, which crystallises in colourless needles, m. p. 151°.

With benzene and aluminium chloride, *succinyliminoacetophenone*, $C_2H_4 \cdot (CO)_2 \cdot N \cdot CH_2 \cdot COPh$, is formed; it separates in colourless needles, m. p. 143—144°, and yields a colourless *phenylhydrazone*, m. p. 201°.

Condensation of succinylglycyl chloride with ethyl sodiomalonate in boiling ether gives *ethyl di(succinylglycyl)malonate*,

$$O[CO \cdot CH_2 \cdot N:(CO)_2 \cdot C_2H_4]_2(CO_2Et)_2;$$

it separates in colourless platelets, m. p. 107°, and gives no coloration with ferric chloride.

Phenylhydrazine converts it into *ethyl 1-phenyl-3-succinylimido-methyl-5-pyrazolone-4-carboxylate*,

$$C_2H_4:(CO)_2:N \cdot CH_2 \cdot C{<}{}^{CH(CO_2Et)}_{N\text{-----}NPh}{>}CO.$$
This crystallises in matted needles, m. p. 157°, giving a bluish-red coloration with ferric chloride.

Succinylglycylphenylhydrazide,

$$C_2H_4:(CO)_2:N \cdot CH_2 \cdot CO \cdot NH \cdot NHPh,$$

forms colourless needles, m. p. 213°.

A second product of the condensation is *ethyl succinylglycylmalonate*, $C_2H_4:(CO)_2:N \cdot CH_2 \cdot CO \cdot CH(CO_2Et)_2$, which forms colourless needles, m. p. 55°.

Succinylglycyl chloride and ethyl sodioacetoacetate condense to *ethyl succinylglycylacetoacetate*, of which the colourless needles have m. p. 102°.

Condensation with sodium acetylacetone leads to two products. *Succinylglycylacetylacetone*, $C_2H_4:(CO)_2:N \cdot CH_2 \cdot CO \cdot CH(COMe)_2$, forms

needles, m. p. 122°. *Di(succinylglycyl)acetylacetone* also yields needles, m. p. 150°.

Ethyl cyanosuccinylglycylacetate,

$$C_2H_4{:}(CO)_2{\cdot}N{\cdot}CH_2{\cdot}CO{\cdot}CH(CN){\cdot}CO_2Et,$$
forms colourless needles, m. p. 73°.

Hippuryl chloride and ethyl sodiomalonate condense to a derivative of 2 : 5-*diketo*-1 : 4-*dibenzoylpiperazine* and *ethyl hippurylmalonate*, $C_6H_5{\cdot}CO{\cdot}NH{\cdot}CH_2{\cdot}CO{\cdot}CH(CO_2Et)_2$. The latter has m. p. 85°, and shows a positive ferric chloride reaction. With phenylhydrazine, *ethyl* 1-*phenyl*-3-*benzamidomethyl*-5-*pyrazolone*-4-*carboxylate,*

$$NHBz{\cdot}CH_2{\cdot}C{<}^{CH(CO_2Et)}_{N{-}\!\!-\!\!-NPh}{>}CO,$$

is obtained, m. p. 122—123°. It forms a well characterised, crystalline *sodium* salt. The above derivative of 2 : 5-diketo-1 : 4-dibenzoylpiperazine has m. p. 116°; it dissolves in sodium carbonate, and on precipitation with acid, a substance, m. p. 137°, is obtained containing $\frac{1}{2}H_2O$ less, and likewise giving a bluish-violet ferric chloride reaction ; on crystallising the compound m. p. 137° from ethyl alcohol, the substance of m. p. 116° is obtained. The latter is regarded as a condensation of two molecules of the piperazine with a molecule of water.

O-Hippurylacetylacetone, $NHBz{\cdot}CH_2{\cdot}CO{\cdot}O{\cdot}CMe{:}CH{\cdot}COMe$, crystallises in platelets, m. p. 109°.

Ethyl cyanohippurylacetate, $NHBz{\cdot}CH_2{\cdot}CO{\cdot}CH(CN){\cdot}CO_2Et$, forms colourless needles, m. p. 139°. The additive product with phenylhydrazine has m. p. 107°. E. F. A.

Cholesterol. XVII. a-Cholestanol. ADOLF WINDAUS and C. UIBRIG (*Ber.*, 1913, 46, 2487—2491).—a-Cholestanol yields on oxidation a ketonic acid, $C_{32}H_{56}O_3$. This is not in agreement with the usual formula $C_{27}H_{48}O$ for cholestanol, and it is proved that the analytical data, particularly of cholestyl chloride and bromide, agree with the formula $C_{32}H_{56}O$ or $C_{32}H_{58}O$. Apparently on treatment of cholesterol with sodium and amyl alcohol, condensation and ring closure to a saturated compound takes place. Accordingly, cholestanol is not a dihydrocholesterol, but an *isoamyl* derivative of cholesterol,

$$C_{25}H_{44}{<}^{CH{\cdot}OH}_{CH{\cdot}C_5H_{11}}.$$
Cholestyl bromide crystallises in hexagonal platelets, m. p. 118°.

Ketocholestanolcarboxylic acid, $C_{25}H_{44}{<}^{CO_2H}_{CO{\cdot}C_5H_{11}}$, separates in long, slender needles which sinter at 110°, m. p. 125°. The *semicarbazone* crystallises in long needles, m. p. 207°. E. F. A.

Isomeric Naphthenic Acids. FRANK W. BUSHONG and I. W. HUMPHREY (*Eighth Inter. Cong. App. Chem.*, 1912, 6, 57—67).—A quantity of commercial naphthenic acid from Baku, which contained about 50% of water and 5% of illuminating oils, was fractionally esterified. Several portions of 2 litres were heated with 200 c.c. of alcohol and 400 c.c. of sulphuric acid until the temperature rose to 140°, when a further 200 c.c. of alcohol was slowly run in. The distillate

was saponified, the hydrocarbons were removed by steam distillation, and, finally, the naphthenic acids were liberated and converted into methyl esters. These were fractionated and the constants of twenty-six fractions are given. The fraction 165—170° contained methyl hexanaphthenecarboxylate; fraction 189—192°, methyl heptanaphthene-carboxylate; fraction 210—212°, methyl octanaphthenecarboxylate, and fraction 220—224°, methyl nonanaphthenecarboxylate. The densities of the fractions rise continuously with the exception of fraction 200—204°, which agrees with the formula $C_8H_{15} \cdot CO_2Me$, and thus contains a methyl *iso*octanaphthenecarboxylate.

The residual, partly esterified naphthenic acids were then distilled in a current of natural gas from a copper still, when 40% passed over below 285° and 10% between 285—295°. The lower-boiling ethyl esters were redistilled and the fractions boiling below 236° were saponified, freed from hydrocarbons, and the naphthenic acids were finally separated into eighteen fractions. By means of diagrams it is shown that the optical-rotation curve for the acids is parallel to the curve for the methyl esters. The cause of the activity of petroleum is thus due to the naphthenic acids and not to impurities. The maximum lævorotation is exhibited by the hexanaphthenecarboxylic acid and its ester. J. C. W.

The Condensation of Aromatic Aldehydes with Pyruvic Acid. Eva Lubrzynska and Ida Smedley (*Biochem. J.*, 1913, 7, 375—379).—A full account of work of which an abstract has already appeared (P., 1913, 29, 174). W. D. H.

Camphenecarboxylic Acids and the Constitution of Camphene. Josef Houben and Ernst Willfroth (*Ber.*, 1913, 46, 2283—2299).—If Wagner's views with respect to the formation of camphene by the loss of hydrogen chloride from bornyl chloride are correct, the intermediate compound (II), formed by a similar removal of hydrogen chloride from α-chloro*allo*camphanecarboxylic acid (I), should give rise to two isomeric camphanecarboxylic acids (III and IV):

$$I. \quad \begin{array}{c} CH_2 \cdot CH - CH_2 \\ | \quad CMe_2 \quad | \\ CH_2 \quad | \quad CCl \cdot CO_2H \\ \diagdown CMe \diagup \end{array} \qquad II. \quad \begin{array}{c} CH_2 \cdot CH - CH_2 \\ | \quad CMe_2 \quad | \\ CH - \!\!\!-\!\!\!- C \cdot CO_2H \\ \diagdown CMe \diagup \end{array}$$

$$III. \quad \begin{array}{c} CH_2 \cdot CH - CH_2 \\ | \quad CMe_2 \quad | \\ CH_2 - \!\!\!\!\mid\!\!\!\!- C \cdot CO_2H \\ CH_2 : C \end{array} \qquad IV. \quad \begin{array}{c} CH_2 \cdot CH_2 - CH_2 \\ | \quad CMe_2 \quad | \\ CH - \!\!\!-\!\!\!- CH \cdot CO_2H \\ \diagdown C : CH_2 \end{array}$$
The authors find that two isomeric unsaturated acids of this composition are formed when the methyl ester of α-chloro*allo*camphane-carboxylic acid is heated with methyl-alcoholic potassium hydroxide, although only one of them could be isolated in a state of purity.

On oxidation, the camphanecarboxylic acids should be transformed into α- and β-camphenilonecarboxylic acids (V and VI).

$$\text{V.} \quad \begin{array}{c} \text{CH}_2\cdot\text{CH}\text{------}\text{CMe}_2 \\ | \qquad\qquad | \\ \text{CH}_2 \\ | \\ \text{CH}_2\cdot\text{C(CO}_2\text{H)}\cdot\text{CO} \end{array} \qquad \text{VI.} \quad \begin{array}{c} \text{CH}_2\cdot\text{CH}\text{---}\text{CMe}_2 \\ | \qquad\qquad | \\ \text{CH}_2 \\ | \\ \text{CO}_2\text{H}\cdot\text{CH}\text{-}\text{CH}\text{---}\text{CO} \end{array}$$
Oxidation of the acids formed by the removal of hydrogen chloride from chloro*allo*camphanecarboxylic acid resulted in the formation of two isomeric ketonic acids having the composition of the camphenilonecarboxylic acids. The investigation of these acids is not yet complete; both are very stable and can be distilled without decomposition, whereas α-camphenilonecarboxylic acid, being a β-ketonic acid, should be readily transformed by loss of carbon dioxide into camphenilone. In addition to the above ketonic acids, considerable quantities of hydropinenecarboxylic (*allo*camphanecarboxylic) acid were found amongst the oxidation products. It is probable that this acid was originally present in the mixture of unsaturated acids submitted to oxidation, and was formed by the reducing action of the methyl-alcoholic potassium hydroxide on the methyl ester of α-chloro*allo*camphanecarboxylic acid.

Hydropinenecarboxylic acid, prepared from pinene hydrochloride by Houber's method (A., 1906, i, 21), has m. p. 78°, $[\alpha]_D^{20} - 18\cdot26°$ in alcohol, and is converted by phosphorus pentachloride or thionyl chloride into the *chloride*, $C_{10}H_7\cdot COCl$, which forms a colourless liquid, b. p. 110°/10 mm., and yields a *methyl* ester, b. p. 119°/18 mm., and *phenyl* ester, b. p. 187°/14 mm.

When heated for one hour with phosphorus pentachloride, hydropinenecarboxyl chloride yields α-*chloro*allocamphanecarboxyl (*chlorohydropinenecarboxyl*) *chloride*, $C_{10}H_{15}Cl\cdot COCl$, which sublimes with partial decomposition into hydrogen chloride and an unsaturated chloride. The chloro-chloride is obtained as a white, camphor-like mass, m. p. 118—119°, by evaporation of its ethereal solution after shaking with aqueous sodium carbonate. It probably consists of a mixture of two stereoisomerides related to one another as the *endo-* and *exo-*modifications of bornyl chloride. This view is supported by the behaviour of the *methyl* ester, which is obtained by boiling the chloro-chloride with methyl alcohol for fifteen hours, and apparently consists of two stereoisomerides of different stability, one of the isomerides readily losing hydrogen chloride on distillation, whilst the other is stable. The stable (presumably *exo-*) chloro-ester can be isolated from the mixture by repeated distillation under diminished pressure and has b. p. 131°/13 mm.

α-*Chloro*allocamphanecarboxyl*amide*, prepared from the chloro-chloride and ammonia in ethereal solution, has m. p. 122°, and when boiled with water loses hydrogen chloride, yielding an unsaturated *amide*, $C_{10}H_{15}\cdot CO\cdot NH_2$, which crystallises in lustrous leaflets, m. p. 210°, and when kept in contact with fuming hydrochloric acid overnight, is transformed into the original chloro-amide.

When boiled with methyl-alcoholic potassium hydroxide, methyl α-chloro*allo*camphanecarboxylate yields an oil which consists of a

mixture of hydropinenecarboxylic acid and two isomeric *camphene-carboxylic acids*. One of the latter acids has been isolated, and crystallises in needles, m. p. 105°, b. p. 149—151°/11 mm.

From the product of oxidation of the above acid mixture with potassium permanganate in alkaline solution, two isomeric *ketonic (camphenilonecarboxylic?) acids*, $C_{10}H_{14}O_3$, of m. p. 106° and 131°, together with a hydropinenecarboxylic acid of m. p. 71°, were isolated. The last-mentioned acid gave the same copper, lead, ferrous, ferric, mercuric and silver salts, and the same *anhydride* (microscopic, regular octahedra, m. p. 210°, b. p. 228°/16 mm.) as the original hydropinenecarboxylic acid of m. p. 78°, but differed from it in the magnitude and sign of its rotation ($[a]_D^{21}$ 11·29° in alcohol).

The ketonic acid of m. p. 106° forms a *semicarbazone* (decomp. 203°), and when boiled with acetic anhydride yields an *unhydride*, $C_{20}H_{26}O_5$, crystallising in leaflets, m. p. 114°.   F. B.

Ethyl p-Bromobenzoylacetate. WILLIAM J. HALE and LAMBERT THORP (*Eighth Inter. Cong. App. Chem.*, 1912, 6, 132—137).—The preparation of dehydro-p-bromobenzoylacetic acid by the method employed by Perkin in the case of the unsubstituted acid (A., 1885, 277) is described.

p-Bromotoluene was oxidised by boiling permanganate to p-bromobenzoic acid; this was converted into the chloride, which was then condensed with ethyl sodioacetoacetate, and, finally, the sodium compound of ethyl p-bromobenzoylacetoacetate was gently warmed with aqueous ammonia. The resulting *ethyl p-bromobenzoylacetate*, $C_6H_4Br \cdot CO \cdot CH_2 \cdot CO_2Et$, was obtained as a heavy oil, which, in extremely small quantities, gives a deep red colour with ferric chloride. It could not be distilled, and, when boiled in an open tube, it gave a quantitative yield of *dehydro-p-bromobenzoylacetic acid*, $C_6H_4Br \cdot CO \cdot CH < ^{CO——O}_{CO \cdot CH} > O \cdot C_6H_4Br$, in the form of small, yellow needles from glacial acetic acid, m. p. 261°. *p-Bromobenzoylacetic acid*, $C_9H_7O_3Br$, was obtained by hydrolysing the ester with cold 3% potassium hydroxide in the form of needle-like plates which decompose at 106—107° into p-bromoacetophenone, and give a violet colour with ferric chloride.   J. C. W.

Spirans. III. Attempts to Prepare Optically Active Spirans and Asymmetric Rearrangement. HERMANN LEUCHS and JOHANNES WUTKE (*Ber.*, 1913, 46, 2420—2435. Compare Leuchs and Gieseler, A., 1912, i, 714).—In the preparation of bis-1-hydrindone-2:2-spiran from dibenzylmalonyl chloride, when aluminium chloride serves to eliminate hydrogen chloride, two by-products are obtained. The one, $C_{16}H_{13}Cl$, 1-chloro-2-benzylidene, m. p. 65°, amounts to 19% of the theoretical. The other is a yellow oil identified by means of its phenylhydrazone as 2-benzylhydrindone. Although only 10% have been separated, it amounts to 50% of the theoretical quantity.

When ferric chloride is substituted for aluminium chloride, a much better yield of the bishydrindonespiran is obtained. Its properties

are in accord with the formula $C_6H_4{<}^{CH_2}_{CO}{>}C{<}^{CH_2}_{CO}{>}C_6H_4$. It forms a diphenylhydrazone and a mono-oxime, and also reacts with two molecules of hydroxylamine, forming a dioxime dihydrate from which the excess of hydroxylamine oxidises away two atoms of hydrogen.

The mono-oxime (m. p. 215°) is converted by phosphorus pentachloride in ethereal suspension into an amide, either 1-hydrindone-dihydrocarbostyril-2 : 3-spiran or *iso*carbostyrilspiran. The mono-oxime shows no tendency to form an *iso*oxazole.

The 2-position of the carbonyl group in the spiran makes it possible to convert it into an acid, $C_{17}H_{14}O_3$,

$$CO_2H \cdot C_6H_4 \cdot CH_2 \cdot CH{<}^{CH_2}_{CO}{>}C_6H_4,$$
which when heated regenerates the spiran.

Semicarbazide acetate in cold alcoholic solution converts the spiran into an insoluble mixed hydrazide of the carbamic acid and the acid $C_{17}H_{14}O_3$, namely, $C_6H_4{<}^{\overline{\quad\quad\quad CH_2 \cdot CH \cdot CH_2}}_{CON_2H_2 \cdot CO \cdot NH_2 \quad CO-C_6H_4}$, from which the free acid is recovered.

Hydroxylamine yields an oximic acid,

$$CO_2H \cdot C_6H_4 \cdot CH_2 \cdot CH{<}^{\overline{CH_2\quad}}_{C(N \cdot OH)}{>}C_6H_4,$$
which can be easily reduced with sodium amalgam. Two hydrogen atoms are taken up, and a new asymmetric carbon atom formed, the hydroxy-acid having the formula

$$CO_2H \cdot C_6H_4 \cdot CH_2 \cdot CH{<}^{\overline{CH_2\quad}}_{CH(OH)}{>}C_6H_4,$$
and being a mixture of two racemic forms. It does not tend to form an anhydride. The keto-acid is converted into the corresponding acid chloride by means of phosphorus pentachloride; this as low as 60° loses hydrogen chloride, and forms bishydrindonespiran.

Ammonia acts on the spiran to form two compounds—the one, $C_{17}H_{15}O_2N$, representing the amide of the ketonic acid, and the other, $C_{17}H_{13}ON$, being the corresponding nitrile,

$$CN \cdot C_6H_4 \cdot CH_2 \cdot CH{<}^{CH_2}_{CO}{>}C_6H_4.$$
This constitution is confirmed by the fact that the action of ammonia on the keto-chloride gives rise to the same amide.

The amide is not hydrolysed by cold concentrated hydrochloric acid, but converted into an anhydride, which is hydrolysed by heating with 70% sulphuric acid at 170° to a spiran-anhydride.

Crystallisation of the brucine salt of the ketonic acid yields a theoretical yield of the optically active *dextro* salt, both the crystals and the mother liquor being dextrorotatory. It is assumed that the *laevo*-acid salt is enolised and the enol re-converted into the ketonic *d*-salt, since the equilibrium is determined entirely in this direction owing to the crystallisation of the *d*-salt as fast as it is formed.

The transformation is an instance of asymmetric rearrangement

rather than of autoracemisation, since the optically inactive enol gives rise exclusively to an optically active acid.

The *d*-ketonic acid slowly but completely loses its activity on keeping in chloroform solution, and still more quickly in neutral or alkaline aqueous solution, owing to conversion into the enol.

An optically active bishydrindonespiran could not be obtained by eliminating hydrogen chloride from the active keto-chloride.

Bishydrindonespirandioxime dihydrate forms colourless, slender needles, m. p. 175° (decomp.).

The Beckmann rearrangement product, $C_{17}H_{18}O_2N$, of the mono-oxime separates in long, colourless needles, m. p. 255° (decomp.); it gives no ferric chloride reaction.

The mixed *hydrazide* from the spiran and carbamic acid, $C_{18}H_{17}O_4N$, crystallises in short needles, m. p. 245° (decomp.).

The *oxime* of 1-hydrindone-2-benzyl-*o*-carboxylic acid forms dome-like prisms, m. p. 188° (decomp.).

The *amide*, prepared from the keto-chloride by the action of ammonia, has m. p. 138—140°, crystallising in massive, four-sided platelets.

The *brucine* salt of the *dextro*-ketonic acid forms transparent, massive crystals, m. p. 180—183°. The acid derived from it has $[\alpha]_D^{20} + 64°$ in chloroform. The pure active acid could not be obtained —a product evaporated at 20° had m. p. 128—141°, $[\alpha]_D^{20} + 56°$. In benzene the pure acid had $[\alpha]_D^{20} + 79°$; it racemises here more quickly than in chloroform.   E. F. A.

Spirans. IV. Stereochemical Treatment of the Keto-Enol Question. HERMANN LEUCHS (*Ber.*, 1913, **46**, 2435—2442. Compare Lapworth, T, 1904, **85**, 30; K. H. Meyer, A., 1911, i, 350, 940).—1-Hydrindone-2-benzyl-*o*-carboxylic acid when treated with bromine in chloroform solution readily forms a brominated ketonic acid, $CO_2H \cdot C_6H_4 \cdot CH_2 \cdot CBr {<}_{CO}^{CH_2}{>} C_6H_4$. Proof of this structure is afforded by the fact that on heating with ammonium hydroxide, the bromine is displaced and a lactone formed, namely, *dihydro*isocoumarin-1-*hydrindone*-3 : 2-*spiran*, $C_6H_4 {<}_{CO \cdot O}^{CH_2}{>} C {<}_{CO}^{CH_2}{>} C_6H_4$.

If in the process of bromination the first stage is the formation of an enol, $CO_2H \cdot C_6H_4 \cdot CH_2 \cdot C {<}_{C(OH)}^{CH_2}{>} C_6H_4$, which contains no asymmetric carbon atom, then on bromination of the optically active 1-hydrindone-2-benzyl-*o*-carboxylic acid, an optically inactive product should result.

Actually an optically active ($[\alpha]_D + 6\cdot5°$) product is obtained containing much inactive brominated keto-acid. Heating with sodium carbonate changes the sign of the rotation, and it was possible to isolate the pure 1-*dihydro*isocoumarin-1-*hydrindone*-3 : 2-*spiran*, which crystallises in lustrous needles, m. p. 175—176°, $[\alpha]_D^{20} - 65\cdot3°$.

This is the first optically active substance in which the spiran carbon atom is the asymmetric centre.

Bromination of ketones does not in consequence necessarily involve the intermediate formation of enol; in this case about 5—10% of

the brominated product is optically active. It is considered that even in this instance the greater part of the bromination involves the intermediate formation of the enol, and that this will be still more the case with substances which are more easily enolised.

2-*Bromo-α-hydrindone-2-benzyl-o-carboxylic acid* forms colourless crystals pointed at one end, m. p. 154° ; they are converted into the lactone on fusion.

Dihydroisocoumarin-1-hydrindone-3 : 2-*spiran* crystallises in needles or prisms, m. p. 153—154°. E. F. A.

Studies in Esterification. V. Esterification of Amides and Thioamides and the Formation of Dithio-esters. E. EMMET REID (*Eighth Inter. Cong. App. Chem.*, 1912, 25, 423—430. Compare A., 1909, ii, 650 ; 1910, i, 481 ; 1911, i, 199 ; ii, 477).—In earlier papers it has been shown with reference to esterification that benzamide is the analogue of benzoic acid, and that mercaptan is the analogue of alcohol. It is now shown that benzamide can be esterified by mercaptan, and thiobenzamide by alcohol or mercaptan.

Ethyl thiolbenzoate is readily decomposed into mercaptan and benzamide by the action of ammonia at 20°, whereas ethyl benzoate reacts but slowly with ammonia even at 200°. Benzamide is readily esterified in presence of hydrochloric acid, which not only catalyses the reaction, but also combines with the ammonia so that the action proceeds to completion, and it was therefore expected that hydrogen chloride would similarly accelerate the esterification of benzamide by mercaptan. On heating benzamide in a sealed tube at 100° with mercaptan, saturated with hydrogen chloride at $-20°$, ethyl thiolbenzoate and ammonium chloride were produced. Thiobenzamide unites with about 1·5 mols. of hydrogen chloride to form an amber-coloured liquid, whilst other thioamides combine with about 1 mol.

Ethyl dithiobenzoate can be prepared by treating thiobenzamide, saturated with dry hydrogen chloride at 0°, with rather more than the calculated amount of mercaptan, and leaving the mixture in a sealed tube for about five weeks ; the ester has b. p. 180°/28 mm., D_{25}^{25} 1·1477, D_4^{25} 1·1439, apparent coefficient of expansion 0—25°, 0·000699, molecular volume, 159·28, viscosity at 25°, 0·03117, and fluidity at 25°, 32·09. Those constants are compared with those of ethyl benzoate and ethyl thiolbenzoate. Ethyl dithiobenzoate is readily transformed into thionbenzamide by alcoholic ammonia at the ordinary temperature. The reaction : $Ph \cdot CS \cdot NH_2 + C_2H_5 \cdot SH \rightleftharpoons Ph \cdot CS \cdot SEt + NH_3$ is therefore reversible. E. G.

Action of Potassium Xanthate on Halogen-malonic Acids. EINAR BIILMANN and ERIK HOST MADSEN (*Eighth Inter. Cong. App. Chem.*, 1912, 25, 339—342).—It has been shown in earlier papers (A., 1905, i, 625 ; 1906, i, 625, 626) that by the action of potassium xanthate on the halogen derivatives of certain organic acids, xanthyl derivatives are produced which, on treatment with ammonia, are converted into thiol acids. The action of potassium xanthate on bromomalonic, bromoisopropylmalonic, bromoethylmalonic, and bromobenzylmalonic acids has now been studied. These acids yield xanthyl derivatives which are very unstable, and from which pure xanthylmalonic acids

cannot be obtained. On heating the acidified solutions, the corresponding monobasic acids are produced, and in this way xanthylacetic, α-xanthylbutyric, and β-phenyl-α-xanthylpropionic acids have been isolated.

If the solutions of potassium xanthate and alkali halogenmalonates are acidified immediately after they have been mixed, an entirely different reaction takes place and dixanthyl is produced, thus: $2OEt \cdot CS \cdot SK + R \cdot CBr(CO_2K)_2 + 3HCl = OEt \cdot CS_2 \cdot CS_2 \cdot OEt + R \cdot CH(CO_2H)_2 + KBr + 3KCl$.

β-Phenyl-α-xanthylpropionic acid, $CH_2Ph \cdot CH(CO_2H) \cdot S \cdot CS \cdot OEt$, m. p. 89—90°, prepared by the action of potassium xanthate on sodium α-bromophenylpropionate, forms colourless crystals, and when treated with a mixture of aqueous ammonia and alcohol, is converted into *α-thiol-β-phenylpropionic acid*, $CH_2Ph \cdot CH(SH) \cdot CO_2H$, b. p. 184—187°/11—12 mm., m. p. 46°, which forms colourless crystals. By the action of copper sulphate on the alkali salts of this thiol acid, the latter is oxidised to *α-disulphido-β-phenylpropionic acid*,

$$[CH_2Ph \cdot CH(CO_2H)]_2S_2,$$
and the cuprous salt of the thiol acid is precipitated. The disulphido-acid can be obtained as a crystalline solid by oxidising the thiol acid with iodine.   E. G.

as-Phthalyl Chloride. JOHANNES SCHEIBER (*Ber.*, 1913, **46**, 2366—2370).—The author (A., 1912, i, 542, 559) has shown that the unsymmetrical formula, $C_6H_4{<}{}^{COl_2}_{CO}{>}O$, proposed for phthalyl chloride is untenable on both chemical and physical grounds, and Ott (A., 1912, i, 828) has obtained the isomeric asymmetric form of phthalyl chloride. The behaviour of the new chloride towards compounds of the type of ethyl sodioacetoacetate and towards ammonia has been now studied as well as the ultra-violet absorption spectra.

Both chlorides behave similarly with ethyl acetoacetate, since in each case reaction involves the formation of a compound

$$COCl \cdot C_6H_4 \cdot CO \cdot CHAc_2.$$
Hence the behaviour of such chlorides with sodium acetoacetate as also with ammonia gives no clue as to their structure.

Both chlorides give exclusively o-cyanobenzoic acid with ammonia, but the new asymmetric chloride reacts more slowly. There is thus a considerable difference in the stability of the complexes $C_6H_4{<}{}^{COl_2}_{SO_2}{>}O$ and $C_6H_4{<}{}^{COl_2}_{CO}{>}O$. The asymmetric chloride absorbs less strongly than phthalic acid or its esters in the ultra-violet.   E. F. A.

Methylcarbonato-derivatives of Phenolcarboxylic Acids and Their Use for Synthetical Operations. IX. EMIL FISCHER and MAX RAPAPORT (*Ber.*, 1913, **46**, 2389—2401).—In part already abstracted (this vol., i, 731).

[With H. STRAUSS.]—*Trimethylcarbonatophloroglucinolcarboxylic acid*, obtained on treating phloroglucinolcarboxylic acid with methyl chloroformate in presence of dimethylaniline, forms small, colourless prisms,

m. p. 122° (decomp.), and no longer shows a bluish-violet coloration with ferric chloride. It is converted into the corresponding chloride by phosphorus pentachloride. E. F. A.

Pyrimidines. LV. The Catalytic Action of Esters in the Claisen Condensation. TREAT B. JOHNSON and ARTHUR J. HILL (*Eighth Inter. Cong. App. Chem.*, 1912, **6**, 147—156 *).—Ethyl phenoxy-acetate undergoes a Claisen condensation in ethereal solution in presence of sodium to form the sodium compound of ethyl $\alpha\gamma$-di-phenoxyacetoacetate, $OPh \cdot CH_2 \cdot CO \cdot CH(OPh) \cdot CO_2Et$. The same substance was produced in presence of ethyl acetate, and no evidence of the formation of the condensation product of the two esters, namely, ethyl γ-phenoxyacetoacetate, could be obtained. As has since been described (A., 1912, i, 912), the crude sodium salt condenses with thiocarbamide to form 2-thio-5-phenoxy-4-phenoxymethyltetrahydro-6-pyrimidone, and the yield of this insoluble product has been taken as an indication of the extent of the above Claisen condensation under different conditions. It is found that ethyl acetate acts as a catalyst, the addition of 0·5 mol. more than doubling the yield. J. C. W.

Some Derivatives of 4-Hydroxy*iso*phthalic Acid. FRANCIS D. DODGE (*Eighth Inter. Cong. App. Chem.*, 1912, **6**, 81—85).—During the steam-distillation of large quantities of methyl salicylate, the author has sometimes obtained, towards the end of the operation, crystals of dimethyl 4-hydroxy*iso*phthalate (Jacobsen, A., 1878, 583). Its presence is ascribed to irregularities in the manufacture of salicylic acid, since 4-hydroxy*iso*phthalic acid may be prepared by the action of carbon dioxide on sodium salicylate at 370° (Ost, A., 1876, 521).

Partial esterification of the acid and also partial hydrolysis of the dimethyl ester lead to the same *mono* ester, which crystallises in transparent plates with $1H_2O$ from diluted alcohol, has m. p. 187° when anhydrous, and gives a reddish-purple coloration with ferric chloride. From the fact that it yields methyl anisate on heating, and according to V. Meyer's ester law, it is the para-ester (annexed formula). J. C. W.
Carminic Acid. OTTO DIMROTH (*Annalen*, 1913, **399**, 1—35)—Investigations of the three "insect" dyes, carminic acid, kermesic acid, and laccaic acid, have been carried out concurrently in the expectation, which has been justified, that the results would mutually confirm one another. The structure of kermesic acid, which is the simplest of the three, has been determined (Dimroth and Scheurer, this vol., i, 980). The present paper, however, deals mainly with carminic acid. The remarkable and unexpected result has been established that this acid and kermesic acid are derivatives of an anthraquinone.

[With G. WEURINGH and L. HOLCH.]—Carminic acid, isolated from cochineal by Schunck and Marchlewski's process (it is advantageous, however, to decompose the lead lake by sulphuric acid and methyl, not

ethyl, alcohol), is oxidised by hydrogen peroxide and aqueous sodium hydroxide in the presence of a little cobalt sulphate as catalyst, whereby carminoquinone is formed as a labile intermediate product, the final product, after acidification with 80% acetic acid, being a sparingly soluble *sodium hydrogen* salt, $C_{26}H_{12}O_{16}Na_3,5H_2O$, yellow crystals. By trituration with dilute hydrochloric acid at 0° and crystallisation of the product from cold ethyl acetate, this salt yields 2 : 6-*dihydroxy-8-methyl-α-naphthaquinone*-3 : 5-*dicarboxylic acid*,

$$CO_2H \cdot C_6HMe(OH) \begin{smallmatrix} CO \cdot C \cdot OH \\ CO \cdot C \cdot CO_2H \end{smallmatrix},$$
a pale yellow, extremely hygroscopic, crystalline powder, which forms a *sodium* salt, $C_{13}H_6O_8Na_3,4H_2O$, orange needles, and yields carminazarin by oxidation with potassium permanganate and sulphuric acid. The orientation of the substituents in the dicarboxylic acid is determined by its oxidation to carminazarin and by the colour reactions of the acid, which are identical with those of 2 : 6-dihydroxy-α-naphthaquinone (compare Dimroth and Kerkovius, following abstract). By gentle warming with water, the acid loses carbon dioxide and yields 2 : 6-*dihydroxy-8-methyl-α-naphthaquinone*-5-*carboxylic acid*,

$$C_{12}H_8O_6,$$
brownish-yellow needles (*potassium* salt, $C_{12}H_7O_6K$, citron-yellow needles ; *dipotassium* derivative, $C_{12}H_6O_6K_2$, orange-red crystals), which develops a red coloration with alkalis, brownish-yellow with concentrated sulphuric acid, and brownish-red with alcoholic ferric chloride. The monocarboxylic acid, which is obtained more conveniently by heating the sodium hydrogen derivative of the dicarboxylic acid with *N*-hydrochloric acid on the water-bath, reacts with bromine in glacial acetic acid at 40° to form 7-*bromo*-2 : 6-*dihydroxy-8-methyl-α-naphthaquinone*-5-*carboxylic acid*, $C_{12}H_7O_6Br$, m. p. 240—244°, yellow needles. The brominated acid forms α-bromocarmin by treatment with hydrobromic acid, and Will and Leymann's β-bromocarmin by treatment with bromine in cold methyl alcohol ; the latter is thus definitely proved to be 3 : 5 : 7-tribromo-2 : 6-dihydroxy-8-methyl-α-naphthaquinone.

The constitution, 2 : 3 : 6-trihydroxy-8-methyl-α-naphthaquinone-5-carboxylic acid, previously ascribed by the author to carminazarin, is supported by the fact that its oxidation product, carminazarinquinone, reacts with alcoholic *o*-phenylenediamine to form a *diphenazine*,

$$C_{24}H_{14}O_3N_4,$$
yellow needles, the *acetyl* derivative, $C_{26}H_{16}O_4N_4$, of which still forms a sparingly soluble *sodium* salt.

[With B. KERKOVIUS.]—The largest, well characterised fission product of carminic acid is coccinin, obtained by Hlasiwetz and Grabowski in 1867 by fusing the acid with potassium hydroxide. Prepared at 170—200° by a modification of these authors' process, coccinin, $C_{17}H_{14}O_6$, has been obtained as a crystalline substance which forms a *tetra-acetyl* derivative, $C_{25}H_{22}O_{10}$, m. p. 242—244°, faintly yellow crystals. By oxidation in 6% sodium hydroxide with air or oxygen until the colour of the solution has changed from yellow through green to a pure violet, and then acidifying with hydrochloric acid, coccinin

yields *coccinone*, $C_{17}H_{12}O_7$, dark brown, metallic crystals, which begins to decompose at 250°, and forms a *triacetyl* derivative, $C_{23}H_{18}O_{10}$, m. p. 210°, orange-red crystals, and three *barium* salts, one of which crystallises in glistening leaflets, and has a composition,

$$2C_{17}H_{10}O_7Ba,(C_{17}H_{11}O_7)_2Ba,$$
analogous to that of the sodium hydrogen salt of 2 : 6-dihydroxy-8-methyl-α-naphthaquinone 3 : 5-dicarboxylic acid. In concentrated sulphuric acid, coccinone develops a violet colour which changes to blue on the addition of boric acid—a reaction similar to those exhibited by most hydroxyanthraquinones.

Coccinone is reduced to coccinin by zinc dust and ammonia, and is oxidised by hydrogen peroxide and aqueous sodium hydroxide below 20°, yielding cochenillic acid and a second, unexamined acid. The author is of opinion that coccinin and coccinone are derivatives of anthranol and of anthraquinone respectively. The formation of cochenillic acid determines the orientation of a hydroxyl, methyl, and carboxyl group in coccinone which, therefore, receives the constitution

$$C_6HMe(OH)_2 {<}^{CO \cdot C \cdot CMe \Equals CH}_{CO \cdot C \cdot C(CO_2H):C \cdot OH},$$ whilst coccinin is regarded as

$$C_6HMe(OH)_2 {<}^{CH \text{—} C \cdot CMe \Equals CH}_{C(OH) \cdot C \cdot C(CO_2H):C \cdot OH} \text{ or}$$

$$C_6HMe(OH)_2 {<}^{C(OH) \cdot C \cdot CMe \Equals CH}_{CH \text{—} C \cdot C(CO_2H):C \cdot OH}.$$
By heating with water at 200° or with dilute sulphuric acid at 170°, coccinone loses carbon dioxide and yields *decarboxycoccinone*,
$$C_6HMe(OH)_2 {<}^{CO \cdot C \cdot CMe:CH}_{CO \cdot C \cdot CH=C \cdot OH},$$ reddish-brown crystals, which forms a purplish-red solution in alkalis, and dissolves in concentrated sulphuric acid with a blue colour changing to violet after the addition of boric acid.

[With L. HOLCH.]—The question remains to be discussed whether carminic acid is a derivative of anthraquinone, or whether the anthracene nucleus in coccinin is produced during the fusion of carminic acid with potassium hydroxide. By distillation with zinc dust in a current of hydrogen, carminic acid yields about 5% of a mixture of hydrocarbons which apparently contains anthracene and α-methylanthracene, since in the mixture, after oxidation, anthraquinone has been certainly identified, whilst a substance, m. p. 165°, has also been obtained which has the very characteristic crystalline form of α-methylanthraquinone.

When boiled with dilute sulphuric acid, carminic acid yields about 10% of a *trihydroxymethylanthraquinonecarboxylic acid*, $C_{16}H_{10}O_7$, m. p. above 305° which crystallises in needles, and is converted by water at 230—240° into a *trihydroxymethylanthraquinone*, $C_{15}H_{10}O_5$, brick-red needles. C. S.

2 : 6- and 2 : 7-Dihydroxy-α-naphthaquinones. OTTO DIMROTH and BERTHOLD KERKOVIUS (*Annalen*, 1913, 399, 36—43).—By treatment with acetic anhydride containing a few drops of concentrated sulphuric acid, 6-hydroxy-β-naphthaquinone yields 1 : 3 : 4 : 6-*tetra-*

acetoxynaphthalene, $C_{18}H_{18}O_8$, m. p. 181—182°, colourless leaflets. By hydrolysis with methyl-alcoholic potassium hydroxide, the passage of oxygen through the resulting solution, and acidification, 2 : 6-*dihydroxy-a-naphthaquinone*, $C_{10}H_6O_4$, yellow crystals, is obtained. It forms a *diacetyl* derivative, yellow leaflets, and dissolves in sodium carbonate and sodium hydroxide with a blood-red colour, and in concentrated sulphuric acid with a brownish-yellow colour. By bromination in glacial acetic acid, 2 : 6-dihydroxy-a-naphthaquinone forms a *dibromo*-derivative, $C_{10}H_4O_4Br_2$, m. p. 283—286°, yellowish-brown crystals, which is converted by bromine in methyl alcohol into 3 : 5 : 7-*tribromo*-2 : 6- *dihydroxy - a - naphthaquinone*, $C_{10}H_3O_4Br_3$, m. p. 242°, yellow crystals ; the latter dissolves in sodium carbonate or hydroxide, or in concentrated sulphuric acid, with a reddish-brown colour.

By reactions similar to the preceding, 7-hydroxy-β-naphthaquinone has been converted into 1 : 2 : 4 : 7-*tetra-acetoxynaphthalene*, m. p. 140—141°, colourless crystals, from which 2 : 7-*dihydroxy-a-naphthaquinone*, decomp. above 200°, orange-yellow needles, has been obtained. The latter dissolves in aqueous sodium hydroxide and in concentrated sulphuric acid with a crimson-red colour, and by bromination in glacial acetic acid yields 3 : 6 : 8-*tribromo*-2 : 7-*dihydroxy-a-naphthaquinone*, m. p. 228—229°, pale yellow prisms, the solution of which in sodium carbonate or hydroxide is much more blue than that of the preceding isomeride.

Mention has been made (Dimroth, preceding abstract) of the importance of the preceding colour reactions in connexion with the constitutions of β-bromocarmin and of 2 : 6-dihydroxy-8-methyl-*a*-naphthaquinone-5-carboxylic acid.

C. S.

Kermes Dye. OTTO DIMROTH and WILHELM SCHEURER (*Annalen*, 1913, **399**, 43—61).—In addition to kermesic acid, kermes dye contains about 0·06% of a second acid, $C_{18}H_8O_8$, which is called *flavo-kermesic acid*. It crystallises in needles or prisms. In the optical properties of its solutions and as a dye, it shows very little resemblance to kermesic acid, and, therefore, has not been studied thoroughly. The separation of flavokermesic acid from kermesic acid is effected best by utilising the facts that the disodium salt of the latter is almost insoluble in hot 2*N*-sodium acetate, whilst sodium flavokermesate dissolves fairly easily. The presence of flavokermesic acid in kermesic acid is easily detected by the colour of the solution in concentrated sulphuric acid containing boric acid ; the solution of the pure acid is a clear blue, that of the impure acid is dull, or a dirty bluish-violet.

When heated with water at 150°, kermesic acid loses carbon dioxide, and is converted into *decarboxykermesic acid*, $C_{17}H_{12}O_7$, red needles, which begins to sublime above 150°, carbonises without melting, is almost insoluble in sodium hydrogen carbonate, and dissolves in aqueous sodium hydroxide and in concentrated sulphuric acid containing boric acid, forming solutions which have the same colours as the corresponding solutions of kermesic acid. Kermesic acid yields a-bromocarmin by bromination in boiling 50% acetic acid. When brominated in boiling glacial acetic acid, however, it is converted into

bromococcin, $C_{16}H_9O_8Br$, m. p. 259—260° (decomp.), red needles, which forms a *potassium hydrogen* salt, $C_{16}H_8O_8BrK, C_{16}H_9O_8Br$, and a *tetra-acetyl* derivative, $C_{16}H_5O_8BrAc_4$, yellow crystals, and yields cochenillic acid by oxidation with warm alkaline hydrogen peroxide in the presence of a trace of a manganous salt. These results indicate that bromococcin must have the constitution

$$C_6Br(OH)_3 \diagdown \genfrac{}{}{0pt}{}{CO \cdot C \cdot CMe \!=\!\!=\! CH}{CO \cdot C \cdot C(CO_2H) : C \cdot OH}$$
The three homonuclear hydroxyl groups cannot be in the vicinal position because bromococcin resembles purpurin, not anthragallol, in its dyeing function.

When kermesic acid or bromococcin is brominated in methyl alcohol and the product is treated with concentrated hydrobromic acid, *tribromococcin*, $OH \cdot C_6MeBr_2 \diagup \!\!\!\diagdown \genfrac{}{}{0pt}{}{CO}{CO} \diagdown \!\!\!\diagup C_6Br(OH)_3$, m. p. 245—248° (decomp.), is obtained, which crystallises from acetic acid in long, red needles. It dissolves in concentrated sulphuric acid with a reddish-violet colour, which changes to deep blue by the addition of boric acid. It forms a *tetra-acetyl* derivative, $C_{15}H_8O_6Br_3Ac_4$, m. p. 223°, greenish-yellow needles, and is converted into nitrococcusic acid by fuming nitric acid. A *substance*, $C_{16}H_6O_5Br_4$, yellow needles, is obtained as a by-product in the preparation of tribromococcin.

Kermesic acid, $C_{18}H_{12}O_9$, and bromococcin, $C_{16}H_9O_8Br$, are nearly related substances. Hence from the constitution of the latter, it is very probable that kermesic acid, which does not exhibit the properties of an aldehyde, has the constitution

$$C_6Ac(OH)_3 \diagdown \genfrac{}{}{0pt}{}{CO \cdot C \cdot CMe \!=\!\!=\! CH}{CO \cdot C \cdot C(CO_2H) : C \cdot OH}$$
This deduction is supported, not only by the formation of tribromococcin by bromination, but also by the result of the distillation of kermesic acid with zinc dust. The mixture of hydrocarbons thus obtained contains α-methylanthracene (isolated as the styphnic acid compound, and identified in the form of α-methylanthraquinone) and, probably, anthracene.

[With A. E. Sherndal.]—The wax which is obtained in working up the kermes dye is *ceryl cerotate*, $C_{52}H_{104}O_2$, m. p. 81°, colourless leaflets, since it yields ceryl alcohol and cerotic acid by hydrolysis.

C. S.

Stick-lac Dye. Otto Dimroth and Stephan Goldschmidt (*Annalen*, 1913, **399**, 62—90).—Stick-lac or gum-lac contains, embedded in resin, wax, and other substances, a small quantity of a red dye similar to cochineal. The dye has been called laccaic acid. It is not, as supposed formerly, identical with carminic acid, but the two are closely related, giving solutions in alkalis of the same colour and exhibiting the same spectrum ; the characteristic absorption bands shown by the two acids in concentrated sulphuric acid, however, are differently situated in the two spectra.

Laccaic acid is isolated as follows : Stick-lac is digested with water at 50°, the clear red solution when cold, is acidified with acetic acid,

decanted from the precipitated resin, evaporated to a small bulk, and acidified with hydrochloric acid ; the crude laccaic acid thus obtained is crystallised from hot 85% formic acid, washed, dried at 60—70°, and finally crystallised from hot dilute hydrochloric acid. It has the formula $C_{20}H_{14}O_{10}$, not $C_{16}H_{12}O_8$ as stated in the literature, crystallises in dark red, microscopic rhombohedra, decomposes and yields a trace of a red sublimate when heated, and does not form crystalline salts except a *sodium hydrogen* salt, $C_{20}H_{12}O_{10}Na_2, C_{20}H_{13}O_{10}Na$. Its dyeing properties are similar to those of carminic acid. Laccaic acid neutralises five equivalents of barium hydroxide, and when treated with acetic anhydride and a few drops of concentrated sulphuric acid yields a *triacetyl* derivative, $C_{20}H_{20}O_{13}, C_2H_4O_2$, m. p. 176°, reddening at about 160°, yellow, microscopic needles (from acetic acid).

By reduction with tin and hydrochloric acid or with zinc dust and boiling aqueous ammonia, laccaic acid is converted into a *substance*, $C_{20}H_{16}O_9$, brownish-yellow rhombohedra, which is oxidised by hydrochloric acid and cupric chloride to a *substance*, $C_{20}H_{14}O_9$, which differs from laccaic acid in its colour reactions ; the substances $C_{20}H_{16}O_9$ and $C_{20}H_{14}O_9$ are probably related as quinol and quinone.

An alkaline solution of laccaic acid is readily oxidised by hydrogen peroxide in the presence of a trace of a cobalt, manganese, cerous, or ferrous salt. When one molecular proportion of hydrogen peroxide is used, the solution contains an unstable intermediate oxidation product, since by acidifying the solution and adding sulphurous acid, laccaic acid is recovered. The complete oxidation requires 2·5 to 3 molecular proportions of hydrogen peroxide, manganous chloride being the best catalyst. The oxidation product thus obtained is *calaic acid*, $C_{18}H_{14}O_{11}$, which crystallises from ether in small, yellow prisms containing ether of crystallisation and from water in needles containing $2\frac{1}{2}H_2O$. Calaic acid contains three carboxyl groups and one carbonyl group, does not possess dyeing properties, and forms a crystalline *barium* salt (by means of which it is best purified) and a *silver* salt, $C_{18}H_{12}O_{11}Ag_2$.

By bromination in glacial acetic acid, calaic acid yields two products. One of these is an *a-ketonic acid*, $C_{12}H_{10}O_6Br_2$, m. p. 208—209°, brownish-yellow crystals, which forms a *phenylhydrazone* and *semicarbazone*, develops a dirty reddish-violet coloration with ferric chloride, and by treatment with methyl-alcoholic hydrogen bromide yields an additive *compound* of the *methyl* ester, $C_{13}H_{12}O_6Br_2, HBr$, m. p. 133—134° (decomp.), colourless needles. When heated with concentrated sulphuric acid at 80—90°, the ketonic acid loses carbon monoxide and yields an *acid*, $C_{11}H_{10}O_5Br_2$, m. p. 245—246° (decomp.), which is monobasic and develops an intense violet coloration with ferric chloride.

The second and more important product of the bromination of calaic acid is *β-bromolaccain*, $C_{12}H_5O_8Br$, which is separated from the other product by means of its solubility in cold acetone. β-Bromolaccain has m. p. 234—235° (decomp.), separates from aqueous solution in stout crystals containing $2H_2O$, and forms a *potassium* salt,

$$C_{12}HO_8BrK_4, H_2O,$$

hexagonal plates. It develops a deep red coloration with ferric

chloride, dyes wool reddish-yellow in an acid-bath, and by treatment with acetic anhydride and concentrated sulphuric acid forms *diacetyl-β-bromolaccain anhydride*, $C_{16}H_7O_9Br$; the last reaction proves that β bromolaccain contains two carbonyl groups in the ortho-position and two hydroxyl groups.

Since β-bromolaccain presents in its behaviour a close analogy to β-bromocarmin and resembles 2 : 6-dihydroxy-α-naphthaquinone in its colour reactions (Dimroth and Kerkovius, preceding abstract), there can be little doubt that its constitution is

$$CO_2H \cdot C \vdots C(CO_2H) \cdot C \cdot CO \cdot C \cdot OH$$
$$OH \cdot C = CH \cdot C \cdot CO \cdot CBr$$
This is supported by the following evidence. Just as β-bromocarmin yields the indone derivative, α-bromocarmin, so β-bromolaccain in boiling aqueous solution yields with bromine, *a-bromolaccain*,

$$CBr_2 {<}^{CO \cdot C \cdot C(CO_2H) \vdots CBr}_{CO \cdot C \cdot CBr = C \cdot OH}$$
colourless needles, which decomposes when heated and yields bromoform and 2 : 6-*dibromophenol* 3 : 4 : 5-*tricarboxylic acid*, m. p. 257—258°, by treatment with sodium hypobromite; the tricarboxylic acid develops only a faint coloration with ferric chloride (therefore, the hydroxyl group is not in the ortho-position to a carboxyl group) and as a phthalic acid derivative yields a yellow dye by fusion with resorcinol and zinc chloride.

The constitution of β-bromolaccain is also supported by the fact that oxidation by hydrogen peroxide in glacial acetic acid on the water-bath produces *hydroxytricarboxyphenylglyoxylic acid*,

$$OH \cdot C_6H(CO_2H)_3 \cdot CO \cdot CO_2H,$$
m. p. 229·5—230° (decomp.), flattened plates, which develops a brownish-red coloration with ferric chloride and is converted into a *phenol-tetracarboxylic acid*, m. p. 212—214° (decomp.), quadratic crystals, by concentrated sulphuric acid at 130—140°.

A by-product of the oxidation of β-bromolaccain is a *substance*, $C_{12}H_6O_9Br_2$, m. p. 188—190° (decomp.), which readily loses bromine and probably has the constitution

$$CBr_2 {<}^{C(OH)(CO_2H) \cdot C \cdot C(CO_2H) \vdots C \cdot CO_2H}_{CO = C \cdot CH = C \cdot OH}$$ C. S.
[Angeli-Rimini Reaction of the Aldehydes] ANGELO ANGELI (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 851—854).—A reply to Balbiano (this vol , i, 733).   R. V. S.

The New Decomposition of the Oximes. ANGELO ANGELI and LUIGI ALESSANDRI (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 735—744. Compare Angeli, A., 1912, i, 269).—Benzophenoneoxime decomposes rapidly at about 180°, yielding benzophenone, nitrogen and ammonia. The decomposition occurs at a lower temperature (140°) in presence of copper oxide, whilst with cuprous chloride it begins a little above 100°. It was not possible to isolate a copper salt, but the *silver* salt was prepared. It is stable when dry, but if kept in a moist state in

the absence of air it evolves pure nitrogen, and benzophenone is formed at the same time.

The *silver* salt of piperonaldehydeoxime behaves similarly.

Fluorenoneoxime also decomposes at its m. p. ($194°$); the gas evolved contains nitric oxide as well as nitrogen, even when the decomposition is effected in the absence of air.

The mixture of stereoisomeric oximes prepared from phenyl *p*-tolyl ketone (m. p. about $120°$) decomposes above $200°$ in a like manner, nitric oxide being also formed.

In the case of deoxybenzoinoxime and acetophenoneoxime decomposition is slight when the pure substance is heated, but becomes considerable in presence of cuprous chloride or of cupric oxide.

Benzophenoneoxime, phenyl *p*-tolyl ketoneoxime, and acetophenoneoxime are apt to decompose spontaneously on keeping.   R. V. S.

Phototropy. FERDINANDO GRAZIANI and F. BOVINI (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 793—797).—The authors have prepared a number of diphenylhydrazones and *p*-ditolylhydrazones, none of which is phototropic. In some cases in which the compounds had been previously prepared, the m. p.'s were found somewhat different from those given in the literature. Benzaldehydediphenylhydrazone has m. p. $125°$.

Anisaldehydediphenylhydrazone, $NPh_2 \cdot N{:}CH \cdot C_6H_4 \cdot OMe$, forms colourless crystals, m. p. $76°$.

Cuminaldehydediphenylhydrazone has m. p. $80—81°$.

Salicylaldehydediphenylhydrazone has m. p. $139—140°$.

Benzaldehyde-p-ditolylhydrazone, $N(C_7H_7)_2 \cdot N{:}CHPh$, crystallises in small, yellow prisms, m. p. $99°$.

Anisaldehyde-p-ditolylhydrazone, $N(C_7H_7)_2 \cdot N{:}CH \cdot C_6H_4 \cdot OMe$, forms large, flat needles, m. p. $128°$.

Cuminaldehyde-p-ditolylhydrazone, $N(C_7H_7)_2 \cdot N{:}CH \cdot C_6H_4 \cdot CHMe_2$, crystallises in long, silky needles, m. p. $104°$.

Cinnamaldehyde-p-ditolylhydrazone, $N(C_7H_7)_2 \cdot N{:}CH \cdot CH{:}CHPh$, forms flat, deep yellow needles, m. p. $143°$.

Salicylaldehyde-p-ditolylhydrazone, $N(C_7H_7)_2 \cdot N{:}CH \cdot C_6H_4 \cdot OH$, is a greenish-yellow, crystalline powder, m. p. $126°$.

Piperonaldehyde-p-ditolylhydrazone, $N(C_7H_7)_2 \cdot N{:}CH \cdot C_6H_3 \cdot O_2{:}CH_2$, forms colourless leaflets, m. p. $134°$.   R. V. S.

Tetra-alkylation of 1-Methyl*cyclo*hexanone. ALBIN HALLER (*Compt. rend.*, 1913, **157**, 179—185. Compare this vol., i, 629).—Whilst the alkylation of *cyclo*hexanone by means of sodamide proceeds but difficultly, methyl*cyclo*hexanone readily undergoes progressive alkylation. Thus 1-methyl*cyclo*hexan-6-one dissolved in ether, treated with sodamide, followed by the addition of methyl iodide, readily yields 1 : 5-dimethyl*cyclo*hexan-6-one, b. p. $170—171°$ (corr.), D_4^{18} $0·9146$, n_D^{18} $1·4508$ (compare Wallach, this vol., i, 482), together with a very small amount of the 1 : 1-isomeride. Further alkylation of the 1 : 5-compound yields 1 : 1 : 5-*trimethylcyclohexan-6-one*, b. p. $178—179°/755$ mm. (corr.), D_4^{18} $0·9043$, n_D^{18} $1·4493$, yielding in its turn 1 : 1 : 5 : 5-*tetra*methyl*cyclo*hexan-6-one (*loc. cit.*). The corresponding alcohols are

obtained by reduction with sodium in absolute alcohol. 1 : 5-*Dimethyl-cyclohexan-6-ol*, a viscous liquid with an odour like eugenol, has b. p. 174·5—175·5°/748 mm. (corr.), D_1^{20} 0·9235, n_D^{20} 1·4628. 1 : 1 : 5-*Trimethylcyclohexan-6-ol* has a similar odour, b. p. 186—187°/753 mm. (corr.), D_1^{20} 0·9128, n_D^{20} 1·4600.

Ethyl derivatives have been similarly prepared from 1-methyl*cyclo*hexan-6-one, the first stage giving 1-*methyl-5-ethylcyclohexan-6-one*, b. p. 194—196°/745 mm. (corr.), D_4^{20} 0·9162, n_D^{20} 1·4555. This then yields 1-*methyl-1 : 5-diethylcyclohexan-6-one*, b. p. 222—224°/757 mm. (corr.), D_4^{20} 0 9054, n_D^{20} 1·4572, and finally 1-*methyl-1 : 5 : 5-triethylcyclohexan-6-one*, b. p. 249—252°/765 mm. (corr.), b. p. 123—126°/16 mm. (corr.), D_4^{20} 0·9132, n_D^{20} 1·4634.

The corresponding alcohols have been prepared by reduction.

1-*Methyl-5-ethylcyclohexan* 6-*ol*, b. p. 202—204°/761 mm. (corr.), D_4^{20} 0 9268, n_D^{20} 1·4689.

1-*Methyl-1 : 5-diethylcyclohexan-6-ol*, b. p. 232—235°/749 mm. (corr), D_4^{20} 0 9206, n_D^{20} 1·473.

1-*Methyl-1 : 5 : 5-triethylcyclohexan-6-ol*, b. p. 258—260°/759 mm. (corr.), D_4^{20} 0·9255, n_D^{20} 1·4769.

The successive introduction of methyl groups into *cyclo*hexanone elevates the boiling point progressively, whilst causing a diminution in the density and the index of refraction, the same holding good for the corresponding alcohols.

The introduction of ethyl groups into methyl*cyclo*hexan-6-one produces a steady rise in the boiling point, whilst the density diminishes for the first two stages and increases at the third, the refractive index showing steady rise throughout. The same remarks apply to the corresponding alcohols. W. G.

Interaction of Diketones and Acid Amides. L. H. FRIEDBURG (*Eighth Inter. Cong. App. Chem.*, 1912, **6**, 131).—When molecular quantities of pure benzil and benzamide are distilled, a quantitative yield of benzonitrile, together with benzaldehyde and benzoic acid, is obtained. J. C. W.

Oxidation of Hydroxy*peri***naphthindenone. III.** GIORGIO ERRERA (*Gazzetta*, 1913, **43**, i, 583—594. Compare Errera and Cuffaro, A., 1912, i, 273).—The paper deals with some derivatives of hydroxy*peri*naphthindenone obtained from a substance mentioned in a former paper (A., 1911, i, 465) as having been prepared by the action of phenylhydrazine on hydroxy*peri*naphthindenone. The constitution of this substance is still being investigated. It

dissolves in bromine water, yielding the *hydrate* of *peri*naphthindantrione (annexed formula) (compare Ruhemann, T., 1911, **99**, 1146), which forms golden-yellow, prismatic crystals. These begin to decompose at about 110°, yielding the anhydrous *peri*naphthindantrione, which forms red crystals, m. p. about 273° (decomp.). The hydrate dissolves in cold concentrated sodium carbonate, yielding a white, crystalline *substance* from which acids regenerate the triketone. The hydrate yields a *sodium bisulphite*
compound; hydroxylamine and phenylhydrazine do not give oxime or hydrazone, but reduce the substance. Both the hydrate and the anhydrous ketone readily yield an *alcoholate*, $C_{15}H_{12}O_4$, which crystallises in yellow, triclinic plates. The triketone reacts with *o*-phenylenediamine with production of the *phenazine*, $C_{19}H_{10}ON_2$, which crystallises in golden-yellow needles, m. p. 255—256°. The phenazine yields a *hydrazone*, $C_{25}H_{16}N_4$, crystallising in violet laminæ, m. p. about 299° (decomp.).
Reduction of the triketone (best with phenyl-hydrazine) leads to the formation of *dihydroxy*peri-naphthindenone (annexed formula), which can also be prepared by boiling the substance from phenylhydrazine and hydroxy*peri*naphthindenone with alcohol and sulphuric acid for six hours. Dihydroxy*peri*naphthindenone crystallises in silky, red needles, m. p. 258—259° (sintering previously). The *potassium* salt,

$$C_{13}H_7O_3K,H_2O,$$
resembles permanganate in appearance. The salts of the substance are stable in the solid state, but are readily oxidised by air when in solution, yielding eventually naphthalic anhydride. Oxidation with bromine water regenerates the triketone. Conversely, the latter substance is partly reduced to dihydroxy*peri*naphthindenone when boiled with water. The author suggests that the blue coloration observed by Ruhemann (T., 1910, **97**, 2027) when triketohydrindene is treated with potassium hydroxide is probably due to the transitory appearance of hydroxydiketohydrindene in its tautomeric form.

On esterification with methyl sulphate, dihydroxy*peri*naphthindenone yields a *monomethyl ether*, $C_{14}H_{10}O_3,H_2O$, crystallising in golden-yellow leaflets or needles, which on heating melt and lose water below 100°, giving the anhydrous substance, m. p. 115—135°. The *dimethyl ether*, $C_{15}H_{12}O_3$, is obtained by the same method, and forms golden-yellow needles, m. p. 84—85°. The *dibenzoyl* derivative, $C_{27}H_{16}O_5$, crystallises in greenish-yellow prisms, m. p. 217—218°.   R. V. S.

Improved Method for the Production of β-Aminoanthra-quinone. M. L. Crossley (*Eighth Inter. Cong. App. Chem.*, 1912, **25**, 351—352).—β-Aminoanthraquinone has been obtained by Bourcart and also by Perger by heating sodium anthraquinone-β-sulphonate with solution of ammonia (25%) in a sealed glass tube. This method has now been found unsuitable for the preparation of the compound, as it is dangerous and gives only a small yield. A modified method has therefore been devised in which the reagents are heated at 190° in an iron tube, and the yield increased from 14% to 45%. When the ammoniacal filtrate from the β-aminoanthraquinone is acidified with hydrochloric acid, a brown precipitate is obtained which shows strong tinctorial properties with animal fibres.   E. G.

Syntheses in the Terpene Group. William H. Perkin, jun. (*Eighth Inter. Cong. App. Chem.*, 1912, **6**, 224—264).—A review of the chemistry of the known and possible menthenols and menthadienes with special reference to the syntheses accomplished by Perkin and his collaborators.   J. C. W

Terpenes. Polymerisation of Pinene. GEORGE B. FRANKFORTER and F. W. POPPE (*Eighth Inter. Cong. App. Chem.*, 1912, **25**, 363—369). —By the action of iodine on pinene in presence of aluminium iodide, a pinene *hydriodide*, b. p. 107°/7 mm., D 1·447, and n_D 1·6245, is produced, together with a *di-iodide*, $C_{10}H_{16}I_2$, b. p 119—125°/7 mm., D 1·69. Both the hydriodide and di-iodide are decomposed by light with formation of dipinene and colophonene.

Dipinene, $(C_{10}H_{16})_2$, b. p. 172°/7 mm., D_{20} 0·947, n_D^{20} 1·52517, is optically inactive, and has a viscosity 101 at 25° as compared with water. *Colophonene*, $(C_{10}H_{16})_4$, m. p. 102—103°, is a pale yellow, crystalline substance; it yields two *tetrachloro*-derivatives, $(C_{10}H_{15}Cl)_4$, one, m. p. 119—121°, obtained by treating it with potassium permanganate and hydrochloric acid, and the other, m. p. 99—102°, obtained by the action of sulphuryl chloride. Both dipinene and colophonene are remarkably stable. E. G.

Constituents of Essential Oils. Reductions in the Sesquiterpene Group. FRIEDRICH W. SEMMLER and FELIX RISSE (*Ber.*, 1913, **46**, 2303—2308). — Eudesmone, b. p. 122—124°/7 mm., D^{20} 0·91964, n_D 1·50874, $[\alpha]_D$ +54·6°, obtained by the action of alcoholic potassium hydroxide on eudesmene dihydrochloride (which is produced when eudesmol is treated with hydrogen chloride in acetic acid solution; compare Semmler and Tobias, this vol., i, 885), can be reduced in acetic acid by free hydrogen under the catalytic influence of platinum black, producing *tetrahydroeudesmene*, $C_{15}H_{28}$, b. p. 122—122·5°/7·5 mm., D^{20} 0·8893, n_D 1·48278, $[\alpha]_D$ +10·2°.

Similar reduction of purified eudesmol, needles, m. p. 84°, not only removed the ethylenic linkings, but also affected the hydroxyl group, for the product is a *hydrocarbon*, $C_{15}H_{28}$, b. p. 117°/5·5 mm., D^{20} 0·8896, n_D 1·48425, $[\alpha]_D$ +11·8°; this is strikingly different from the result of reduction in ethereal solution (*loc. cit.*), the product of which is dihydroeudesmol, $C_{15}H_{28}O$.

The action of ozone on eudesmene in acetic acid solution gave decided indications of the distinct natures of eudesmene and selinene; one of the products was a *substance*, b. p. 180—200°/7 mm., D^{20} 1 081, n_D 1·49429, $[\alpha]_D$ +13°, which yields a *semicarbazone*.

Catalytic reduction of guajol, m. p. 91°, in acetic acid solution by free hydrogen resulted in the simultaneous elimination of the ethylenic linkings and the hydroxyl group with the formation of *tetrahydroguajene*, $C_{15}H_{28}$, b. p. 118—119°/7 mm., D^{20} 0·8806, n_D 1·47840, $[\alpha]_D$ +10·6°.

Reduction of tricyclic α-santalol, b. p. 147—148°/4·5 mm., D^{20} 0·9745, n_D 1·50552, $[\alpha]_D$ +0·6°, in a similar manner yielded almost quantitatively a bicyclic *tetrahydrosantalene*, $C_{15}H_{28}$, b. p. 115—116°/9 mm., D^{20} 0·8655, n_D 1·46908, $[\alpha]_D$ +5·6°, not only the ethylenic linkings and the hydroxyl group, but also one of the rings having been eliminated. Reduction of bicyclic β-santalol, b. p. 158—158·5°/5 mm., D^{20} 0·97174, n_D 1·51357, $[\alpha]_D$ −41·8°, yielded a product, b. p. 119°/10 mm., D^{20} 0·8550, n_D 1·46612, $[\alpha]_D$ +2·8°, which is mainly a *tetrahydrosantalene*, $C_{15}H_{28}$, probably containing a small quantity of a hexahydrosantalene due to a little monocyclic santalol, $C_{15}H_{24}O$, in the starting

product; at the same time in the reduction a bicyclic saturated alcohol, $C_{15}H_{26}O$, was obtained, b. p. 155—160°/10 mm., D^{20} 0·9380, n_D 1·48471, $[a]_D +4·4°$.   D. F. T.

The Essential Oil of Jamaica Ginger.

FRANCIS D. DODGE (*Eighth Inter. Cong. App. Chem.*, 1912, **6**, 77—80).—The lowest-boiling fractions of oil of ginger contain an aldehyde, which may be removed as the bisulphite compound, and has now been identified with decaldehyde (compare von Soden, A., 1900, i, 605). The aldehyde has D^{15} 0·828, is optically inactive, is unstable towards alkalis, and changes spontaneously with the lapse of some years into an oil which smells like geraniol, and does not form a bisulphite compound or a semicarbazone.   J. C. W.

Essential Oil of Witch Hazel.

H. A. DICKINSON JOWETT and F. LEE PYMAN (*Pharm. J.*, 1913, **91**, 129—130).—This oil had D 0·9001, an optical rotation of +4·29° in a 100 mm. tube, was slightly soluble in 90% alcohol, and gave a small quantity of colourless precipitate when mixed with absolute alcohol. It was found to consist chiefly of a sesquiterpene having $D^{15·5}_{15·5}$ 0·8970, $a_D +14·88°$, and n_D 1·4916. A trace of a phenolic substance, a mixture of fatty acids in the free and combined state, and a mixture of solid saturated hydrocarbons were also isolated, whilst indications of the presence of other compounds, including oxygenated substances, were obtained. The oil contained 0·6% of acids (expressed as acetic acid) and 7·3% of esters (expressed as $C_{10}H_{17}·C_2H_3O_2$).   W. P. S.

Chemistry of Wood. The Resins of the Douglas Fir.

GEORGE B. FRANKFORTER and HAROLD H. BROWN (*Eighth Inter. Cong. App. Chem.*, 1912, **25**, 359).—The resin extracted from the wood of the Douglas fir yields a crystalline acid, $C_{17}H_{24}O_2$, m. p. 143·5—144·5°, which has been termed *betic acid*; its salts, and bromine and iodine compounds have been prepared.   E. G.

Oxidation of Caoutchouc.

FRANZ KIRCHHOF (*Kolloid. Zeitsch.*, 1913, **13**, 49—61).—The author has carried out experiments on the oxidation of raw and vulcanised caoutchouc by means of air at the ordinary temperature and at 100°. It is shown that on account of the unsaturated nature of the caoutchouc, an autoxidation occurs which gives rise to the formation of a relatively unstable peroxide, which then undergoes a secondary oxidation: (1) $C_{10}H_{16}+O_2 \rightarrow C_{10}H_{16}O_2$; (2) $C_{10}H_{16}+C_{10}H_{16}O_2 \rightarrow 2C_{10}H_{16}O$; (3) $C_{10}H_{16}O + O_2 \rightarrow C_{10}H_{16}O_3$. This process is accompanied, in the case of raw caoutchouc, by a softening of the material, which is quite sticky at first and later becomes hard and has a glassy nature. The latter condition is due to the presence of the higher oxidation products. The oxidation of vulcanised caoutchouc is in the same way to be regarded as a primary formation of a peroxide which then decomposes, producing the same soft and sticky substance. Further oxidation produces the hard substances and free sulphuric acid. The action of the acid appears also to consist in an oxidation of the rubber, since the acid

is reduced to sulphur dioxide. In the oxidation at 100°, a separation of water occurs; this appears to be a result of the formation of sulphuric acid, since under the same conditions raw caoutchouc does not give rise to water.

It is further shown that the combined sulphur-content after oxidation and extraction with alkali is reduced to two-thirds of the amount originally contained in the product. This and other observations lead to the conclusion that vulcanisation consists in the addition of S_8 or of a thiozone molecule to the hydrocarbon residue. Since the thiozone molecule is unstable, it is likely that vulcanised caoutchouc is a thiozonide, which probably is transformed into other products in the ageing process, and since the formation of the thiozone occurs most readily at 135—160°, the part played by the vulcanisation catalysts is to be explained by a local raising of the temperature. In the oxidation of caoutchouc by air, a notable increase in weight occurs with the formation of products soluble respectively in acetone and alkali which have an acidic character. It is also indicated that the bromide and nitrosite methods for the analysis of rubber consist of oxidation processes which are probably responsible for the untrustworthy nature of the results of these processes. J. F. S.

Synthesis of Glucosides by means of Ferments. ÉMILE BOURQUELOT (*Bull. Soc. chim.*, 1913, [iv], 13, i—xxviii).—A lecture delivered to the Chemical Society of France on May 9th, 1913.
J. F. S.

Synthetic β - Glucosides of Terpene Alcohols. III. JUHO HÄMÄLÄINEN (*Biochem. Zeitsch.*, 1913, 53, 423—428. Compare this vol., i, 497, 639, 888).—By condensation of a-santenol and camphene hydrate with bromoacetyldextrose in the presence of silver carbonate, and the subsequent hydrolysis of the acetyl derivatives, the glucosides were obtained. *a-Santenoltetra-acetyl-d-glucoside*, $C_{26}H_{34}O_{10}$, m. p. 135·5—137° (corr.), yields on hydrolysis *a-santenol-d-glucoside*, $C_{15}H_{26}O_6$, m. p. 122·5—125·5° (corr.), $[a]_D^{20} - 44·63°$. It is readily hydrolysed by emulsin.

Camphenehydratetetra-acetyl-d-glucoside, $C_{24}H_{36}O_{11}$, m. p. 115—117° (corr.), yields on hydrolysis *camphenehydrate-d-glucoside*, $C_{15}H_{28}O_6$, m. p. 96·5—102·5° (corr.), $[a]_D^{20} - 30·56°$, which is slowly hydrolysed by emulsin. S. B. S.

Eutannin. WILHELM RICHTER (*Chem. Zentr.*, 1913, i, 1820—1821; from *Arb. Pharm. Inst. Univ. Berlin*, 9, 85—112).—Eutannin has the composition $C_{28}H_{24}O_{10}, H_2O$, $[a]_D^{15} + 58·9°$, and forms a crystalline *sodium* salt. It contains a carboxyl group and a lactone or anhydride grouping. When heated in a stream of hydrogen at 240°, a molecule of carbon dioxide is eliminated and pyrogallol sublimes. Some diphenylmethane is formed on distillation with zinc dust. *Eutannin hydrate*, $C_{28}H_{26}O_{20}$, contains two carboxyl groups owing to the opening of the lactone or anhydride ring; the *disodium* salt forms a colourless precipitate. Eutannin is hydrolysed by emulsin to gallic acid and a substance which reduces Fehling's solution on boiling. Gallic acid is similarly formed on hydrolysing with 10% sulphuric acid.

Acetyleutannin, $C_{28}H_{18}O_9(CO\cdot CH_3)_{11}$, formed on boiling with acetic anhydride, is a colourless powder composed of tiny, crystalline splinters which sinter at 180—185°, decomp. 215°.

Methyl chloro-formate acts on eutannin to form a compound
$$C_{28}H_{19}O_{11}(O\cdot CO_2Me)_6,$$
a colourless, amorphous powder, which sinters at 150—153°, decomp. 180°. Diazomethane acting on this introduces four further methyl groups, yielding a product $C_{28}H_{15}O_{10}(O\cdot CO_2Me)_5(OMe)_4,H_2O$. This is composed of small, crystalline splinters, which sinter at 125°, m. p. 137°, decomp. 179°.
Diazomethane acting on eutannin produces at first the *methyl* derivative, $C_{28}H_{20}O_{11}(OMe)_4$, an amorphous powder, which sinters at 145°, decomp. 210—215°. On continued treatment the fully methylated compound, $C_{28}H_{13}O_{10}(OMe)_9$, is obtained, forming minute, crystalline splinters, m. p. 154—155°. On hydrolysis with sodium hydroxide, trimethylgallic acid is obtained.

The tannin obtained on hydrolysis of eutannin with sodium hydroxide has the composition $C_{14}H_{16}O_{11}$. Six hydroxyl groups in it are replaced by $-O\cdot CO_2Me$ on treatment with methyl chloro-formate. The formula $[(OH)_3(C_6H_2\cdot CO\cdot O]_2C_6H_2(CO_2H)\cdot O\cdot C_6H_4O(CO)(OH)_4$ is proposed for eutannin.   E. F. A.

Arsenites of Alkaloids. ALFRED C. MANGOLD (*Eighth Inter. Cong. App. Chem.*, 1912, **17**, 37—43).

—Analyses of compounds of arsenious acid with various alkaloids showed that the acid does not form true salts with quinine, cinchonidine, cinchonine, quinidine, brucine, and strychnine ; the compounds obtained under varying conditions of preparation were mixtures of arsenious acid with the alkaloids. Arsenic acid, however, forms well-crystallised, definite salts with these alkaloids.   W. P. S.

Occurrence of Histidine-betaine in Fungi. ERNST WINTER-STEIN and CAMILLE REUTER (*Zeitsch. physiol. Chem.*, 1913, **86**, 234—237).

—The base $C_9H_{15}O_2N_3$ obtained by Reuter (A., 1912, ii, 593) from fungi is shown to be histidine-betaine identical with that obtained by Barger and Ewins (this vol., i, 529) from ergothionin and the synthetic product made by Engeland and Kutscher (*ibid.*). The monopicrate, m. p. 201°, forms slender, soft needles. The dipicrate, $2H_2O$, loses this water at 105°, and forms flat, thin prisms, or long plates, m. p. 212—213°. The base has $[a]_D +41\cdot1°$.

E. F. A.

Some Derivatives of 8-Hydroxyquinoline. HANS SCHULLER (*J. pr. Chem.*, 1913, [ii], **88**, 180—188).

—8 : 8'-*Dihydroxy-5 : 5'-diquinolylmethane*, $CH_2(C_9H_5N\cdot OH)_2$, obtained in the form of its *sulphate* (stellar aggregates of yellow needles, m. p. 198—200°) by the addition of 40% aqueous formaldehyde to a well cooled solution of 8-hydroxyquinoline in sulphuric acid, is precipitated from its salts by aqueous ammonia as a white, amorphous precipitate (decomp. 247°), which separates from pyridine in hexagonal crystals and couples with diazotised *m*-toluidine and *α*-naphthylamine, yielding carmine-red and reddish-brown *azo-dyes*. The *hydrochloride*, B,2HCl, crystallises in

radiating clusters of lustrous, silky needles (decomp. 260°); the *zinci-chloride* forms yellowish-green, prismatic crystals; the *diacetyl* derivative has m p. 160°, and decomposes slowly on exposure to air; the *dibenzoyl* derivative, prepared by the pyridine method, separates from alcohol in small crystals, and has an odour resembling that of ethyl benzoate.

7 : 7'-*Dinitroso*-8 : 8'-*dihydroxy*-5 : 5'-*diquinolylmethane* (or 7 : 7'-*di-oximino*-8 : 8'-*diketo*-5 : 5'-*di*-7 : 8-*dihydroquinolylmethane*),

$$CH_2[C_9H_4N(NO)\cdot OH]_2,$$
or $CH_2(C_9H_4ON:N\cdot OH)_2$, prepared by the addition of sodium nitrite to an aqueous solution of the sulphate or hydrochloride, is a yellow crystalline substance, which explodes at about 130°, and is precipitated from its solution in sodium carbonate by acetic acid in a red, gelatinous condition. With salts of iron, nickel, copper, and many other metals, it yields coloured precipitates, which are more or less soluble in mineral acids, but insoluble in dilute acetic acid. Unsuccessful attempts to condense 8 hydroxyquinoline with oxalic acid, formic acid, and carbon tetrachloride are also recorded.   F. B.

The Desmotropy of *o*- and *p*-Quinonoid Salts in the Thiazine Group. RUDOLF PUMMERER and SEBASTIAN GASSNER (*Ber.*, 1913, **46**, 2310—2327).—In order to throw further light on the debated constitution of the thiazines, the authors have turned their attention to some of the simpler salts and have examined them chemically and optically; they find in certain cases an equilibrium between the ortho- and para-constitutions favoured by Kehrmann and Hantzsch respectively.

Their results with the phenazothionium salts differ in several respects from those of Kehrmann and Veselý (A., 1902, i, 186). The action of bromine on an alcoholic solution of thiodiphenylamine at even −15° yielded a *dibromide*, $NHBr\!<\!\!{}^{C_6H_4}_{C_6H_4}\!\!>\!SBr$, prisms, which readily decomposes with liberation of hydrogen bromide; it is reconverted by sulphurous acid into thiodiphenylamine. The *dichloride* is still less stable, but the more stable *di-iodide*, blackish-brown crystals, can be obtained by double decomposition of the dibromide and potassium iodide and also by the action of iodine on thiodiphenylamine in chloroform solution. Treatment of an acetone solution of the di-iodide with sodium acetate causes the production of a salt derived probably from a bimolecular colourless *base*.

The ferrochloride described earlier, from its quantitative reduction with stannous chloride, appears to be a *meri*-quinonoid compound which readily accounts for the deposition of thiodiphenylamine when its solution in hydrochloric acid is diluted. *Phenazothionium perchlorate,* obtained by the action of perchloric acid on diphenylaminesulphoxide (Barnett and Smiles, T., 1910, **97**, 186), is a stable, crystalline substance, which, like the phenazothionium salts generally, shows in dilute hydrochloric acid an absorption band in the green portion of the spectrum; a green *diperchlorate* was also obtained. In addition to the green picrate obtained by Kehrmann and Veselý, the authors have isolated the unstable brown intermediate product, which proves to

be of the same composition, the green picrate being regarded as a polymeride of the brown; a very dilute solution of the green picrate in nitrobenzene turns brown, the change in colour being favoured by warming and dilution, whilst stronger solutions of both forms at first have the characteristic colour of the respective solids, but shortly assume an intermediate tone.

Phenazothione (for which the authors prefer the term thiazone), obtained by a slight modification of Kehrmann's method, judging from its absorption spectrum and its reaction with magnesium phenyl bromide, can hardly have the suggested phenol-betaine structure :

$$N\!\!<^{C_6H_4}_{C_6H_3\!-\!O}\!\!>\!S.$$
This view is confirmed by the behaviour of its *hydrochloride*, which exists in two forms. On intimately mixing the base with hydrochloric acid a brown solution is obtained which changes to violet and subsequently deposits violet needles; the violet hydrochloride can be obtained directly by reaction in benzene-ether solution. The conversion of the brown form into the violet could be followed photometrically, and it was found that a unimolecular reaction occurs, yielding an equilibrium mixture, and that the velocity is independent of the concentration; from these facts the change must be an isomerisation, probably of the brown para-quinonoid salt, $N\!\!<^{C_6H_3O(HCl)}_{C_6H_4}\!\!>\!S$, into violet

ortho-quinonoid, $N\!\!<^{C_6H_3(OH)}_{C_6H_4}\!\!>\!SCl$; reduction of the brown salt (which was only obtained in solution) was usually accompanied by more or less isomerisation to the violet salt, which is less easily reduced. Only one *hydriodide* was obtainable, and from its brown colour it is probably of the para-quinonoid structure. Similar phenomena are met with 3-*methoxythiodiphenylamine*, leaflets, m. p. 163°, which on oxidation by p-benzoquinone in acetic acid containing a little sulphuric acid gives a mixture of ortho- and para-quinonoid salts; addition of perchloric acid causes precipitation of the o-quinonoid violet *perchlorate*, which in the absence of any excess of acid gives a brown solution in water, but on addition of a few drops of acid the violet form is obtained. With 3-*benzoyloxythiodiphenylamine*, leaflets, m. p. 202—203°, obtained like the corresponding methoxy-compound by acting on a reduced solution of phenazothione, only ortho-quinonoid salt formation could be observed.

The acetylated amino-compounds, such as diacetylthionine (free *base*, needles, decomp. above 250°), are only ortho-quinonoid, whilst from similar colour considerations aminophenazothionium hydrochloride is of para-quinonoid constitution, but shows desmotropy analogous to that of phenazothione hydrochloride, and is transformed by concentrated acid into a brown ortho-quinonoid salt. Indications of such structural change could also be detected with thionine, but not with methylene-blue.   D. F. T.

The Deepening of Colour by Auxochrome Groups and Colours of an Higher Order. FRITZ STRAUS and A. ZELME (*Ber.*, 1913, 46, 2267—2283).—From a study of the *meri*-quinonoid salts of

the *p*-phenylenediamine and benzidine series, Piccard (this vol., i, 895) has drawn the conclusion that Nietzki's rule, concerning the deepening of the colour from yellow to green by auxochrome groups, requires extension so as to include colours of a higher order. When the auxochromic effect has been gradually increased by substitution so that the colour has successively passed from yellow to red, blue and green, further increase in the auxochrome action is accompanied by a repetition of the colours in the same order; the colours of the second series are said to be of the second order.

The authors have arrived at the same conclusion from a consideration of the relationship of the yellow auramine to the blue and green dyes of the diaminodiphenyl and diaminotriphenyl series previously described by Straus and Bormann (A., 1910, i, 281). The latter dyes are derived from the reddish-blue salts of tetramethyldiaminobenzhydrol, $NMe_2 \cdot C_6H_4 \cdot CH:C_6H_4:NMe_2Cl$ (I), by replacement of the central methane hydrogen by chlorine, cyanogen, phenyl and other groups.

The yellow auramine and the orange-yellow salts of Michler's ketone differ from the above dyes in that the chromophoric groups are replaced by the auxochromic, hydroxyl and amino-groups, which thus cause a change in colour from blue to yellow; the yellow colour of the auramine is, therefore, considered to be of the second order.

This view is supported by the observation of Semper (A., 1911, i, 577), that the acetylated auramine base yields reddish-blue salts, $NMe_2 \cdot C_6H_4 \cdot C(NHAc):C_6H_4:NMe_2Cl$; the auxochromic effect of the amino-group almost completely disappears on acetylation, so that the yellow colour of the second order of the auramine passes back again into the blue colour of the first order shown by the parent substance (I).

The conception of colours of a higher order also throws light on the relationships existing between the dyes of the diamino- and triamino-triphenyl series. The dyes of the triamino-series are not so deep in colour as those of the diamino-series, although they are produced from the latter by the introduction of the auxochrome amino-group. Thus, the red magenta corresponds with Döbner's violet, and the reddish-violet tetramethylmagenta with malachite-green. On the other hand, if the effect of the third amino-group in the magenta series is caused to disappear by acetylation, or by the conversion of the nitrogen atom into the quinquevalent condition, the colour apparently deepens. These anomalies disappear if it is assumed that the colours of the triaminotriphenyl series are of the second order, and those of the malachite-green group of the first order.

The authors also point out that whilst nitrosobenzene in the unimolecular condition is bluish-green and *p*-nitrosodimethylaniline pure green, the colour of *p*-nitrosodiphenylamine is yellow, and that tetramethyldiaminothiobenzophenone is orange-red, whilst thiobenzo-phenone is blue; from this the conclusion is drawn that the colours of *p*-nitrosodiphenylamine and tetramethyldiaminothiobenzophenone are of the second order.

Attempts have been made to prepare dyes having colours of the second order by replacing the *p*-hydrogen atoms of the terminal phenyl groups in viridine, $C_6H_5 \cdot NH \cdot C_6H_4 \cdot CPh:C_6H_4:NHCl \cdot C_6H_5$, by chlorine,

bromine, methyl, methoxy- and ethoxy-groups. The attempts, however, were not successful, the various substituents producing very little change in the colour of the parent substance ; even replacement of the terminal phenyl groups by the naphthyl or diphenylyl groups failed to produce the desired effect.

The substituted viridines were all prepared by fusing di-*p*-methoxy-triphenylcarbinol with the necessary substituted aniline (3 to 4 mols.) and benzoic acid (3 mols.) at 120—160° and isolated in the form of their chlorides.

The corresponding imine bases,

$$X \cdot C_6H_4 \cdot NH \cdot C_6H_4 \cdot CPh : C_6H_4 : N \cdot C_6H_4 X,$$
crystallise with benzene in dark reddish-brown needles having a green glance, and appear to polymerise when kept. The carbinols were prepared by dissolving the picrates or chlorides in pyridine and allowing the solution, after dilution with benzene or ether, to flow slowly into dilute aqueous alkali ; only in a few cases could the carbinols be obtained crystalline. Ethers of the carbinols were also prepared, and resemble the latter in being difficult to obtain in the crystalline condition.

The *chloride* of *di-p-methylviridine*, prepared from *p*-toluidine, separates from acetone in small, lustrous, bronze crystals of the composition $C_{33}H_{29}N_2Cl, C_3H_6O$ (decomp. 248—250°) ; it crystallises with alcohol in needles having a green metallic glance. The *picrate* forms dark green needles, m. p. 211°, with previous sintering at 205° ; the *imine base* has m. p. 182°.

The *chloride* of *di-p-chloroviridine*, prepared from *p*-chloroaniline, forms lustrous, metallic green needles, m. p. about 285°, the *picrate*, prismatic crystals, having a golden-yellow or green metallic lustre, m. p. 243°, with previous sintering at 236° ; the *imine base* crystallises in dark brown needles, m. p. 136°, when rapidly heated.

The *chloride* of *di-o-chloroviridine* has m. p. 191° ; the *picrate* crystallises in leaflets of a coppery-red, metallic lustre, m. p. 148° ; the *imine base* has m. p. 107°.

The *chloride* of *di-p-bromoviridine* forms a powder having a bronze lustre, m. p. indefinite (290—305°) ; the *picrate* crystallises from acetone in prismatic crystals of a golden-yellow, metallic glance, m. p. 253—257° ; the *imine base* has m. p. 186—187°.

The *chloride* of *di-p-methoxyviridine* forms green, metallic, lustrous needles ; the *picrate* forms green or golden-bronze, lustrous crystals, m. p. 205—208° ; the *imine base*, m. p. 167°, crystallises with benzene (1 mol.).

The *chloride* of *di-p-ethoxyviridine* has m. p. 243—245° ; the *picrate* separates from acetone in light green, metallic, lustrous crystals, which on drying pass into a lustrous coppery modification, m. p. 176° ; the *imine base* crystallises with benzene (1 mol.), m. p. 97°.

The following derivatives of *di-p-nitroviridine* were prepared : the *chloride* ; *picrate*, lustrous, bronze crystals ; *imine base*, dark brown needles, m. p. 176—178° ; the *carbinol*, which sinters and decomposes at 110—115°, and is completely fused at 140° ; the *ethyl ether*, which is light yellow, becomes brown at 200°, and has m. p. 204°.

The *chloride* of *di-p-phenylviridine*, prepared from *p*-aminodiphenyl,

forms a dark green, metallic,' lustrous powder, m. p. 300—305°; the *picrate*, dark red scales, m. p. 252°, with previous sintering at 247°; the *imine base* crystallises with benzene (1 mol.), and has m. p. 136°; the *carbinol*, a light pink powder, and *ethyl ether* were also prepared.

β-Naphthylaminofuchsone-β-naphthylimine,

$$C_{10}H_7\cdot NH\cdot C_6H_4\cdot CPh:C_6H_4:N\cdot C_{10}H_7,$$
prepared from β-naphthylamine, has m. p. 147°; the *chloride* crystallises from acetone in brown needles of a bronze lustre, m. p. 290—300° (decomp.); the *picrate* in cubical crystals, sintering at 215°, m. p. 224°; the *carbinol* and *leuco*-compound do not crystallise.

F. B.

Ring Closing Accompanied by the Elimination of a Nitrogroup from the Benzene Nucleus. SIEGMUND REICH and GEORGES GAIGAILIAN (*Ber.*, 1913, 46, 2380—2386).—When potassium hydroxide is added to 2 : 6-dinitrobenzaldehydephenylhydrazone, the red alcoholic solution becomes deep blue, but in a few minutes the colour lessens and changes to a pale yellow; pale yellow needles, m. p. 165°, crystallise out. The change is analogous to that observed by V. Meyer with the phenylhydrazone of methyl dinitrophenylglyoxylate (compare A., 1889, 516).

The blue colour is due to the formation of the potassium salt, $C_6H_3(NO_2)_2\cdot CH:N\cdot NPhK$, from which potassium nitrite is eliminated, and 7-nitro-1-phenylisoindazole is formed, $NO_2\cdot C_6H_3\overset{CH}{\underset{NPh}{>}}N$.

Corresponding *iso*indazole derivatives are formed by the substituted phenylhydrazones, or by the naphthyl- or benzyl-hydrazones. The semicarbazone does not react in this manner.

When the imide hydrogen atom is replaced there is no reaction; thus neither the phenylmethyl- nor the phenylbenzyl-hydrazones shows the reaction.

The *iso*indazole derivatives crystallise well, and are stable compounds. The presence of the phenyl and nitro-groups reduces the basic properties, so that the hydrochlorides are not precipitated on passing hydrogen chloride into the ethereal solution of the base. They are especially resistant towards reducing agents.

7-*Nitro*-1-*phenyl*isoindazole crystallises in yellow needles, m. p. 165°.

2 : 6-*Dinitrobenzaldehyde*-p-*bromophenylhydrazone* forms red crystals, m. p. 176° (blackening). The corresponding 7-*nitro*-1-p-*bromophenyl*-isoindazole separates in yellow crystals, m. p. 185° (blackening).

2 : 6-*Dinitrobenzaldehyde* - p - *nitrophenylhydrazone* forms reddishbrown crystals, m. p. 207—208°. The isomeric o-*nitrophenylhydrazone* gives similar-coloured crystals, m. p. 220—221°.

7-*Nitro*-1-p-*nitrophenyl*isoindazole yields yellow, microscopic crystals, m. p. 261°.

7-*Nitro*-1-o-*nitrophenyl*isoindazole forms yellow needles, m. p. 162—163°.

2 : 6-*Dinitrobenzaldehyde*-a-*naphthylhydrazone* forms red crystals, m. p. 205—206°.

7-*Nitro*-1-a-*naphthyl*isoindazole gives yellow crystals, m. p. 113—114°.

The isomeric *β naphthylhydrazone* crystallises in tiny red needles, m. p. 183—184°, whilst the 7-*nitro*-1-*β naphthyl*isoindazole separates in yellow crystals, m. p. 152—153°.

2 : 6-*Dinitrobenzaldehydebenzylhydrazone* crystallises in citron-yellow needles, m. p. 86°.

7-*Nitro*-1-*benzyl*isoindazole forms tiny, pale yellow, lustrous needles, m. p. 97—98°.

2 : 6-*Dinitrobenzaldehydephenylmethylhydrazone* separates in reddish-yellow crystals, m. p. 127°.

2 : 6-*Dinitrobenzaldehydephenylbenzylhydrazone* crystallises in yellow needles, m. p. 110°.

2 : 6-*Dinitrobenzaldehydesemicarbazone* forms a yellow, crystalline powder, m. p. 207—208°.

2 : 6 : 2′ : 6′-*Tetranitrobenzylideneazine*,

$$C_6H_3(NO_2)_2 \cdot CH{:}N \cdot N{:}CH \cdot C_6H_3(NO_2)_2,$$
prepared by the interaction of hydrazine hydrochloride with the aldehyde, forms pale yellow-coloured needles, m. p. 246—247°.

E. F. A.

Bisdiphenyleneacetylhydrazide Chloride and its Reaction Products. ROBERT STOLLÉ, H. MUNZEL, and F. WOLF (*Ber.*, 1913, 46, 2339—2352).—The elimination of halogen or of halogen hydracid at the 1 : 6-position occurs with bisdiphenyleneacetylhydrazide chloride just as with bisdiphenylacetylhydrazide chloride (Stollé and Laux, A., 1911, i, 508; Stollé and Schmidt, A., 1912, i, 980, 1035). Corresponding with the greater mobility of the *α*-hydrogen atom of diphenyleneacetic acid it is found that derivatives such as bisdiphenyleneacetylhydrazide chloride readily undergo oxidation to azo-compounds, whilst others can be further oxidised to tetrazine derivatives (compare Wislicenus and Russ, A., 1910, i, 840).

Diphenyleneacetylhydrazide, $CH(C_6H_4)_2 \cdot CH \cdot CO \cdot NH \cdot NH_2$, needles, m. p. above 360° (decomp.), was obtained by heating ethyl diphenyleneacetate with a sesquimolecular proportion of hydrazine hydrate at 120° for three hours; its *hydrochloride,* lustrous scales, is precipitated from solution by concentrated hydrochloric acid; *benzylidene* derivative, needles which sinter near 250°; *acetone* condensation product, lustrous needles, m. p. near 200° if rapidly heated.

If diphenyleneacetylhydrazide is heated for two hours with ethyl diphenyleneacetate in molecular proportion at 250°, symmetrical *bisdiphenyleneacetylhydrazide,* $CH(C_6H_4)_2 \cdot CO \cdot NH \cdot NH \cdot CO \cdot CH(C_6H_4)_2$, needles, m. p. 340°, from nitrobenzene, is obtained, and it can also be produced by the interaction of equimolecular proportions of diphenyleneacetyl chloride and hydrazine hydrate in cooled ethereal solution. When treated in suspension in benzene or carbon tetrachloride with phosphorus pentachloride at water-bath temperature, this symmetrical hydrazide is converted into *bisdiphenyleneacetylhydrazide chloride,* $CH(C_6H_4)_2 \cdot CCl{:}N \cdot N{:}CCl \cdot CH(C_6H_4)_2$, colourless crystals, which at its m. p. (approximately 192°) or in solution in boiling xylene or nitrobenzene assumes a deep red colour, due doubtless to elimination of hydrogen atoms at the 1 : 6-positions by oxidation with formation of the *azo*-compound, $C(C_6H_4)_2{:}CCl \cdot N{:}N \cdot CCl{:}C(C_6H_4)_2$. The hydrazide

chloride, when treated in benzene solution with an alcoholic solution of sodium ethoxide or with ammonia, or such bases as mercuric oxide and lead oxide, loses a molecule of hydrogen chloride, producing *bisdiphenylenesuccinonitrile*, a colourless, crystalline powder, m. p. 242°. If in the reaction with sodium ethoxide the solution of the latter is a concentrated one and the reaction mixture is heated, the nitrile undergoes further hydrolysis with scission of carbon dioxide, yielding bisdiphenylene-ethane. By boiling with acetic acid and zinc dust the nitrile undergoes successive reduction and hydrolysis to diphenyleneacetamide, m. p. 251°.

If an intimate mixture of bisdiphenyleneacetylhydrazide chloride and phosphorus pentachloride is heated for an hour at 180—200°, *bischlorodiphenyleneacetylhydrazide chloride*,

$$CCl(C_6H_4)_2 \cdot CCl \colon N \cdot N \colon CCl \cdot CCl(C_6H_4)_2,$$
pale red crystals, m. p. 240°, with reddening, is obtained. When heated in high-boiling solvents, a deep red colour develops, due to elimination of chlorine and formation of *bischlorodiphenylenevinyldi-imide*,

$$C(C_6H_4)_2 \colon CCl \cdot N \colon N \cdot CCl \colon C(C_6H_4)_2,$$
almost black, lustrous needles, m. p 295°, which is best produced by the action of mercury on the bischlorodiphenyleneacetylhydrazide chloride in benzene solution; the di-imide can unite with chlorine regenerating its parent substance, and is further reduced in benzene solution by hydrazine hydrate, yielding 3 : 6-difluorenyldihydrotetrazine,

$$CH(C_6H_4)_2 \cdot C \underset{NH \cdot NH}{\overset{N——N}{<} {>}} C \cdot CH(C_6H_4)_2,$$ m. p. 290°, and by acetic acid

and zinc dust to iminomethylfluorene, m. p. 148—149° (compare Wislicenus and Russ, *loc. cit.*). The addition of bromine to bischlorodiphenylenevinyldi-imide, effected in benzene solution, yields *bisbromodiphenyleneacetylhydrazide chloride*,

$$CBr(C_6H_4)_2 \cdot CCl \colon N \cdot N \colon CCl \cdot CBr(C_6H_4)_2,$$
colourless crystals, m. p. 245°, which like the corresponding chloro-compound readily passes into the red azo-compound at its m. p. or when heated in high-boiling solvents. On treatment of the di-imide compound in benzene solution with amyl nitrite and acetic acid, the colour disappears and *a-nitroso-a'-hydroxy-aa'-bisdiphenyleneacetylhydrazide chloride*, $OH \cdot C(C_6H_4)_2 \cdot CCl \colon N \cdot N \colon CCl \cdot C(C_6H_4)_2 \cdot NO$, colourless, microscopic needles, m. p. near 145°, with reddening, is formed.

When bisdiphenyleneacetylhydrazide chloride is heated for several days in benzene solution with phosphoryl chloride and phosphoric oxide, *bisfluorenyl-1 : 3 : 4-oxadiazole*,

$$CH(C_6H_4)_2 \cdot C \underset{-O}{\overset{N \cdot N}{<} {>}} C \cdot CH(C_6H_4)_2,$$
colourless needles, m. p. 223°, is obtained ; this assumes a blue coloration at its m. p. or when heated in high-boiling solvents ; by heating in benzene solution with phosphorus pentachloride for several hours it is converted into 2 : 5-*bischlorodiphenylenemethyl-1 : 3 : 4-oxadiazole*,

$$C(C_6H_4)_2Cl \cdot C \underset{-O}{\overset{N \cdot N}{<} {>}} CCl(C_6H_4)_2,$$ colourless prisms, m. p. 227°, which

can also be obtained by the action of thionyl chloride on s-diphenyleneacetylhydrazide. This product when heated in high-boiling solvents, or

preferably when shaken in benzene solution with mercury, loses chlorine with formation of blue 2 : 5-*bisdiphenylenemethylenedihydro*-1 : 3 : 4-*oxadiazole*, $C(C_6H_4)_2 \cdot C <^{N:N}_{O}> C:C(C_6H_4)_2$, m. p. above 360°, and when boiled in alcoholic solution for several days undergoes conversion into 2 : 5-*bisethoxydiphenylenemethyl*-1 : 3 : 4-*oxadiazole*,

$$OEt \cdot C(C_6H_4)_2 \cdot C <^{N \cdot N}_{O} > C \cdot C(C_6H_4)_2 \cdot OEt,$$
a colourless, crystalline powder, m. p. 290° (decomp.).

Bisdiphenyleneacetylhydrazide chloride, when heated under reflux for five hours with an equal quantity of hydrazine hydrate, condenses with the latter, producing 3 : 6-*difluorenyldihydrotetrazine*,

$$CH(C_6H_4)_2 \cdot C <^{N-----N}_{NH \cdot NH} > CH(C_6H_4)_2,$$
a colourless powder, m. p. 290°, together with 1-*amino*-2 : 5-*difluorenyl*-1 : 3 : 4-*triazole*, $CH(C_6H_4)_2 \cdot C <^{N-----N}_{N(NH_2)} > C \cdot CH(C_6H_4)_2$, microscopic tablets, m. p. 285°, which is also obtained by the action of hot alcoholic hydrogen chloride on the former product. The latter substance when treated in cold alcoholic solution with hydrogen chloride and sodium nitrite undergoes conversion into 2 : 5-*difluorenyl*-1 : 3 : 4-*triazole*, $CH(C_6H_4)_2 \cdot C <^{N \cdot N}_{NH} > C \cdot CH(C_6H_4)_2$, needles, m. p. 217°. The interaction of bisdiphenylacetylhydrazide chloride and aniline at 150° gives rise to 1-*phenyl*-2 : 5-*difluorenyl*-1 : 3 : 4-*triazole*,

$$CH(C_6H_4)_2 \cdot C <^{N \cdot N}_{NPh} > C \cdot CH(C_6H_4)_2,$$
a pale yellow, crystalline powder, m. p. 270°, the course of the reaction being strikingly different from that with ammonia (see above). The last product, in suspension in carbon tetrachloride and exposed to the rays from a quartz lamp, is converted by chlorine into 1-*dichlorophenyl*-2 : 5-*bisdiphenylenechloromethyl*-1 : 3 : 4-*triazole*,

$$CCl(C_6H_4)_2 \cdot C <^{N-----N}_{N(C_6H_3Cl_2)} > C \cdot Cl(C_6H_4)_2,$$
a colourless powder, m. p. above 360°, the solution of which in molten naphthalene becomes blue on shaking with mercury, probably due to the formation of unstable 1-*dichlorophenyl*-2 : 5-*bisdiphenylenemethylene*-2 : 5-*dihydro*-1 : 3 : 4-*triazole*, $C(C_6H_4)_2 : C <^{N=====N}_{N(C_6H_3Cl_2)} > C:C(C_6H_4)_2$.

When shaken in benzene suspension with amyl nitrite, 3 : 6-difluorenyldihydrotetrazine becomes oxidised to 3 : 6-*difluorenyltetrazine*, $CH(C_6H_4)_2 \cdot C <^{N-N}_{N=N} > C \cdot CH(C_6H_4)_2$, red needles, m. p. 225° (decomp.), the reverse change being possible by reduction with zinc dust and acetic acid. 3 : 6-Difluorenyltetrazine when subjected to the action of chlorine in boiling carbon tetrachloride under the influence of rays from a quartz lamp gives 3 : 6-*bischlorodiphenylenemethyltetrazine*, $CCl(C_6H_4)_2 \cdot C <^{N-N}_{N=N} > C(C_6H_4)_2Cl$, violet-black needles, m. p. 206° (decomp.), as a substitution product. Although already formed 3 : 6-

difluorenyltetrazine is not further oxidisable by amyl nitrite, if 3 : 6-difluorenyldihydrotetrazine is heated in benzene solution with amyl nitrite, the oxidation passes this stage, yielding 3 : 6-*bisdiphenylene-methylenedihydrotetrazine*, $C(C_6H_4)_2{:}C{<}^{N=N}_{N=N}{>}C{:}C(C_6H_4)_2$, green prisms, m. p. 240° (decomp.), which is also obtainable by the action of mercury on a benzene solution of 3 : 6-bischlorodiphenylene-methyltetrazine or 3 : 6-bisbromodiphenylenemethyltetrazine, into which substances it can be reconverted by the action of the respective halogens. When heated alone to 240°, 3 : 6-bisdiphenylenemethylene-dihydrotetrazine loses half its total nitrogen, and passes into bis-diphenylenesuccinonitrile ; by the action of bromine in benzene solution it is quantitatively converted into 3 : 6-*bisbromodiphenylenemethyl-tetrazine*, $CBr(C_6H_4)_2{\cdot}C{<}^{N=N}_{N=N}{>}C{\cdot}CBr(C_6H_4)_2$, a reddish-violet powder, decomp. near 260°, from which the bromine is removable by the action of mercury on its benzene solution. The action of sodium ethoxide on the bromine compound failed to yield any corresponding ethoxy-derivative, the only product being bisdiphenylene-ethane.

D. F. T.

Preparation and Reactions of 2 : 4-Dichlorophenylhydrazono-pyruvyl Chloride. CARL BÜLOW and PETER NEBER (*Ber.*, 1913, **46**, 2370—2379. Compare Bülow and Neber, this vol., i, 207).—On hydrolysing ethyl anilinoacetoacetate to the free carboxylic acid and allowing chlorine to act on this in alcoholic solution, 2 : 4-*dichloro-phenylhydrazonopyruvyl chloride* is obtained,

$$CH_3{\cdot}CO{\cdot}CCl{:}N{\cdot}NH{\cdot}C_6H_3Cl_2,$$
whereas carbon dioxide and hydrogen chloride are liberated. The chloride is very reactive ; on treatment with ammonia or hydrazine, action can be controlled, so that only the chlorine and not the keto-group is replaced by the amino- or hydrazino-group with the formation of the basic compounds, (A) 2 :4-*dichlorophenylhydrazonopyruvamide*, $CH_3{\cdot}CO{\cdot}C(NH_2){:}N{\cdot}NH{\cdot}C_6H_3Cl_2$, and (B) 2 : 4-*dichlorophenylhydrazono-pyruvylhydrazide*, $CH_3{\cdot}CO{\cdot}C{<}^{NH\cdot NH_2}_{N\cdot NH\cdot C_6H_3Cl_2}$.

When phenylhydrazine acts on the aminohydrazone (A), the colour-less basic osazone having the constitution

$$NHPh{\cdot}N{:}CMe{\cdot}C(NH_2){:}N{\cdot}NH{\cdot}C_6H_3Cl_2,$$
which is sensitive to light, is formed. The Bordeaux-red solution in concentrated sulphuric acid is turned blue both by oxidising agents and by atmospheric oxygen with the formation of osotetrazone.

The same osazone is obtainable from 2 : 4-dichlorophenylhydrazono-pyruvyl chloride and phenylhydrazine, which condense to the *phenylhydrazone* of the chloride, $\begin{array}{l}\alpha \quad CCl{:}N{\cdot}NH{\cdot}C_6H_3Cl_2\\ \beta \quad CH_3{\cdot}C{:}N{\cdot}NHPh\end{array}$. This is converted by alcoholic acid into the corresponding α-amino-osazone, The *hydrazone* of 2 : 4-dichlorophenylhydrazonopyruvamide,

$$NH_2{\cdot}C({:}N{\cdot}NH{\cdot}C_6H_3Cl_2){\cdot}CMe{:}N{\cdot}NH_2,$$

3 x 2
is typical of another class of compounds belonging to the basic osazonoid series; it no longer dissolves with a characteristic coloration in concentrated sulphuric acid, and cannot be oxidised to osotetrazone. The corresponding *hydrazide* behaves similarly.

2 : 4-*Dichlorophenylhydrazonopyruvyl chloride* crystallises in snowwhite needles, m. p. 125°, dissolving in concentrated sulphuric acid with a pure yellow coloration. With pyridine on boiling or on prolonged contact in the cold it forms a *compound* crystallising in red needles, m. p. 168°. The corresponding *amide* crystallises in centimetre-long, faintly yellow needles, m. p. 193°, and dissolves in concentrated sulphuric acid with a faint yellow coloration.

The *phenylhydrazone* of 2 : 4-*dichlorophenylhydrazonopyruvamide* separates in bunches of snow-white needles, m. p. 149° (decomp.).

The *phenylhydrazone* of the corresponding *chloride* is deposited in large, straw-yellow needles from chloroform or fine matted needles from acetic acid, m. p. 208° (decomp.), giving a brownish-yellow solution in concentrated sulphuric acid.

The *hydrazone* of 2 : 4-*dichlorophenylhydrazonopyruvamide* crystallises in large, colourless needles becoming yellow on exposure; it sinters at 120°, m. p. 130°. The corresponding *acetylhydrazone* forms colourless crystals, m. p. 217°.

2 : 4-*Dichlorophenylhydrazonopyruvylhydrazide* forms pale yellow needles, m. p. 131°. It is remarkably electric. It dissolves in concentrated sulphuric acid with a yellowish-brown coloration which deepens on keeping. The corresponding *acetylhydrazide* crystallises in colourless needles which sinter at 150°, m. p. 199°; they become yellow on exposure.   E. F. A.

Purines. XI. 2 : 8 - Dioxy-6-methyl - 9 - ethylpurine. CARL O. JOHNS and EMIL J. BAUMANN (*J. Biol. Chem.*, 1913, 15, 119—125).—The preparation of a derivative of 9-ethylpurine is described. 6-Chloro-2-ethylthiol-4-methylpyrimidine,

$$SEt \cdot C \underset{N \cdot CMe}{\overset{N=CCl}{<}} CH,$$
was heated with aqueous ethylamine, and gave an excellent yield of 6-*ethylamino-2-ethylthiol-4-methylpyrimidine*,

$$SEt \cdot C \underset{N----CMe}{\overset{N:C(NHEt)}{<}} CH,$$
colourless, pointed prisms, m. p. 70°. Boiling with hydrochloric acid converted this into 6-*ethylamino-4-methyl-2 : 3-dihydro-2-pyrimidone*,

$$CO \underset{NH----CMe}{\overset{N:C(NHEt)}{<}} CH,$$ acicular prisms, m. p. 245—250° (decomp.)
(*hydrochloride*, colourless, diamond-shaped plates, m. p. 214—215°); this gave 5-*nitro-6-ethylamino-4-methyl - 2 : 3 - dihydro - 2 - pyrimidone*, colourless needles, decomp. 238°, charring at 260—265°, which was very readily reduced by means of freshly precipitated ferrous hydroxide to 5-*amino-6-ethylamino 4-methyl-2 : 3-dihydro-2-pyrimidone*,

$$CO \underset{NH----CMe}{\overset{N:C(NHEt)}{<}} C \cdot NH_2,$$ clusters of needles. Heating with carbamide converted this into the desired 2 : 8-*dioxy-6-methyl-9-ethylpurine*,

$$CO\diagdown^{N:CMe}_{NH-C}\diagup^{C-NH}_{NEt\cdot CO}$$, which crystallises in sheaves of needles like

tyrosine; it has a pearly lustre, and does not melt at 310°.

<div align="right">E. F. A.</div>

Etherification of o-Hydroxyazo-compounds. III. G CHARRIER and G. FERRERI (*Atti R. Accad. Sci. Torino*, 1913, **48**, 854—872. Compare A., 1912, i, 812; this vol., i, 535).—In the present paper are described nitrates of azo-2-naphthyl ethers. They are obtained by adding an ethereal solution of nitric acid to ethereal solutions of the ethers. They are more stable than the corresponding hydrochlorides (*loc. cit.*), and have a definite m. p., but on cooling after fusion an equimolecular mixture of the corresponding 1-nitro-2-naphthyl ether and the diazonium nitrate is found to have been formed. The constitution of these nitrates is probably that represented by the

formula: $C_{10}H_6\diagdown^{N:NHAr(ONO_2)}_{OHR(ONO_2)}$.

The nitrate of 1-benzeneazo-2-naphthyl methyl ether, m. p. 67°, has already been described (*loc. cit.*), as has also the corresponding ethyl ether derivative, m. p. 80—81°.

1 o-*Tolueneazo-2-naphthyl methyl ether hydrochloride*,

<div align="center">$C_{18}H_{16}ON_2,2HCl$,</div>

forms metallic green needles; the *nitrate*, $C_{18}H_{16}ON_2,2HNO_3$, forms large, green, acicular crystals, m. p. 71° (decomp.). The *nitrate* of the ethyl ether, $C_{19}H_{18}ON_2,2HNO_3$, crystallises in cantharides-green laminæ, m. p. 62—63° (decomp.).

The *nitrate* of 1-m-*tolueneazo-2-naphthyl methyl ether*,

<div align="center">$C_{18}H_{16}ON_2,2HNO_3$,</div>

forms cantharides-green leaflets, m. p. 72° (decomp). The *nitrate* of the ethyl ether, $C_{19}H_{18}ON_2,2HNO_3$, m. p. 84° (decomp), crystallises similarly.

1-p-*Tolueneazo-2-naphthyl methyl ether hydrochloride*,
<div align="center">$C_{18}H_{16}ON_2,2HCl$,</div>

crystallises in red needles having a golden lustre. The *hydrobromide*, $C_{18}H_{16}ON_2,2HBr$, forms metallic green needles. The *nitrate*,

<div align="center">$C_{18}H_{16}ON_2,2HNO_3$,</div>

m. p. 77° (decomp.), forms dark red needles with a green metallic lustre. The *nitrate* of the ethyl ether, $C_{19}H_{18}ON_2,2HNO_3$, m. p. 94° (decomp.), crystallises in garnet-red leaflets, which have a golden lustre.

1-o-4-*Xyleneazo-2-naphthol*, $C_{14}H_{16}ON_2$, crystallises in cherry-red needles with a golden lustre, and has m. p. 146°; it dissolves in concentrated sulphuric acid, giving an intense red coloration. The *methyl ether*, $C_{19}H_{18}ON_2$, forms red, prismatic leaflets, m. p. 106°. The *hydrochloride* of the methyl ether, $C_{19}H_{18}ON_2,2HCl$, forms red needles having a golden lustre. The *hydrobromide*, $C_{19}H_{18}ON_2,2HBr$, crystallises in garnet red needles. The *nitrate*, $C_{19}H_{18}ON_2,2HNO_3$, m. p. 87—88° (decomp.), crystallises in coffee-coloured scales, which have a golden lustre. The *ethyl ether*, $C_{20}H_{20}ON_2$, m. p. 94—95°, forms

red needles which have a golden lustre. The *hydrochloride* of the ethyl ether, $C_{20}H_{20}ON_2,2HCl$, crystallises in metallic, coffee-coloured needles. The *hydrobromide*, $C_{20}H_{20}ON_2,2HBr$, forms red needles.

1-m 4-*Xyleneazo-2-naphthyl methyl ether*, $C_{19}H_{18}ON_2$, m. p. 72—73°, crystallises in garnet-red, prismatic leaflets, which have a violet lustre. The *hydrochloride*, $C_{19}H_{18}ON_2,2HCl$, and the *hydrobromide*,
$$C_{19}H_{18}ON_2,2HBr,$$

crystallise in microscopic, red needles. The *nitrate*, $C_{19}H_{18}ON_2,2HNO_3$, forms cantharides-green needles, m. p. 83° (decomp.). 1-m-4-*Xyleneazo-2-naphthylamine*, $C_{18}H_{17}N_3$, crystallises in orange-red leaflets, m. p. 128°; it dissolves in concentrated sulphuric acid, giving a reddish-violet coloration. 1-m-4-*Xyleneazo-2-naphthyl ethyl ether*, $C_{20}H_{20}ON_2$ forms garnet-coloured needles, m. p. 47°. The *hydrochloride*,

$$C_{20}H_{20}ON_2,2HCl,$$

forms coffee-coloured needles, and the *hydrobromide*, $C_{20}H_{20}ON_2,2HBr$, crystallises in garnet-red needles. The *nitrate*, $C_{20}H_{20}ON_2,2HNO_3$, forms cantharides-green needles, m. p. 82°.

1-p-*Xyleneazo-2-naphthyl methyl ether*, $C_{19}H_{18}ON_2$, crystallises in garnet-red, prismatic tablets, m. p. 91—92°. The *hydrochloride*, $C_{19}H_{18}ON_2,2HCl$, forms garnet-red needles, and the *hydrobromide*, $C_{19}H_{18}ON_2,2HBr$, forms coffee-coloured needles. The *nitrate*,
$$C_{19}H_{18}ON_2,2HNO_3,$$

crystallises in cantharides-green laminæ, m. p. 75° (decomp.). The *ethyl ether*, $C_{20}H_{20}ON_2$, crystallises in aggregates of red laminæ, or in needles, m. p. 61—62°. The *hydrochloride*, $C_{20}H_{20}ON_2,2HCl$, forms copper-coloured needles, as does also the *hydrobromide*,
$$C_{20}H_{20}ON_2,2HBr.$$

The *nitrate*, $C_{20}H_{20}ON_2,2HNO_3$, forms dark red, prismatic laminæ, m. p. 71° (decomp.).

The *hydrochloride* of 1-α-naphthaleneazo-2-naphthyl methyl ether, $C_{21}H_{16}ON_2,2HCl$, crystallises in bluish-violet needles, and the hydro-bromide, $C_{21}H_{16}ON_2,2HBr$, forms iridescent, greenish-brown needles.

R. V. S.

Formation of the Azo- and Bisazo-phenols. GIACOMO PONZIO (*Gazzetta*, 1913, **43**, i, 559—562).—Azo- and bisazo-phenols can be prepared very conveniently by keeping benzenediazonium acetate for a short time. If the solution prepared by diazotising 9·3 grams of aniline in the presence of 20 c.c. of hydrochloric acid (D 1·19) is treated with 25 grams of sodium acetate and diluted to a volume of 5 litres, *p*-benzeneazophenol is deposited after keeping for twenty-four hours at the ordinary temperature. The substance forms yellow leaflets, m. p. 154°, although in the literature the m. p. 148° is usually given. Both its acetate and its benzoate exhibit chromoisomerism, for they exist in red and in yellow forms. If phenol is added to the above solution an immediate precipitate of the azo-compound occurs, so that its spontaneous production when the solution is kept is due to inter-action of the diazo-compound with phenol which is slowly formed from it.

If the above-mentioned solution is diluted to a volume of only

500 c.c., 2:4-bisbenzeneazophenol is rapidly deposited by it. In the same way, the corresponding bisazocresol, as well as the azocresol, can be obtained from o-toluidine. R. V. S.

Polyazoxy-compounds. II. ANGELO ANGELI (*Atti R. Accad. Lincei*, 1913, [v], **22**, i, 844—850. Compare this vol., i, 658).—The present paper deals with bisazoxybenzene, previously described (*loc. cit.*). On reduction with aluminium amalgam it yields bisazobenzene (Mills, T., 1895, **67**, 929). By the action of concentrated sulphuric acid at 100°, bisazoxybenzene yields benzeneazobenzeneazophenol (*loc. cit.*), which is identical with that obtained by diazotising aminoazobenzene and treating the product with phenol. This derivative yields an *ethyl ether*, $C_{20}H_{18}ON_4$, which crystallises in red laminæ, melting to a turbid liquid at 138°, becoming then viscous and subsequently limpid again at about 210°. When bisazoxybenzene is treated with concentrated sulphuric acid for some hours at 0°, three substances are formed: (1) a substance, $C_{18}H_{14}O_2N_4$, which forms ruby-red crystals, m. p. 203°; (2) a substance, $C_{18}H_{14}O_2N_4$, which crystallises in shining, orange-yellow laminæ, m. p. 168°; and (3) a substance,

$$C_{18}H_{14}O_2N_4,$$
crystallising in deep orange-yellow laminæ, m. p. 148°. The first-mentioned compound (m. p. 203°) is soluble in alkalis and yields a *benzoyl* derivative, $C_{25}H_{18}O_3N_4$ (yellow crystals, m. p. 178°) and an *ethyl* derivative, $C_{20}H_{18}O_2N_4$ (orange-coloured prisms, m. p. 142°, forming a turbid liquid which becomes clear about 180°). The compound of m. p. 168° yields bisazobenzene on reduction, and gives a small quantity of a polybromo-derivative when heated with bromine; it is an isomeride of the bisazoxybenzene of m. p. 155°

$$[Ph \cdot N{:}NO \cdot C_6H_4 \cdot NO{:}NPh,$$
termed the β-form], and is assigned the formula

$$Ph \cdot NO{:}N \cdot C_6H_4 \cdot N{:}NOPh$$

(α-form). The compound of m. p. 148° is probably a third isomeride (γ-form), to which the constitution $Ph \cdot NO{:}N \cdot C_6H_4 \cdot NO{:}NPh$ is ascribed. R. V. S.

Colloidal Chemical Studies on the Proteins. HUGO ROHONYI (*Biochem. Zeitsch.*, 1913, **53**, 179—209).—Solutions of proteoclastic ferments possess the property of precipitating proteins and albumoses from their solutions under certain conditions. The latter are as follows: (1) The solutions should contain at the most only traces of neutral salts, as the precipitates are soluble in salt solutions; (2) as the precipitates are soluble in acids and alkalis, precipitation only takes place within narrow limits of the hydrogen-ion concentration; (3) the reacting substances must be present in certain definite proportions, as the precipitates are often soluble in excess of either reagent. The reactions can take place even after activation of the ferment, and the precipitates are probably complexes of the protein and ferment. If acid is added to protein solutions, and the conductivity curve is plotted, the formation of precipitates causes no discontinuity in the curve. The combination of acids with proteins depends there-

fore on the absolute amount of protein present, and is independent of the surface of the latter. Paranuclein is not a product of hydrolysis, but a caseinogen-caseose complex. The paranuclein of Brailsford Robertson is a complex compound of caseose and a protein contained in Grübler's pepsin preparation. It is not formed when certain other preparations of pepsin are employed. Reasons are given for supposing that the so-called plasteins are complex albumose enzyme compounds.

S. B. S.

The Precipitation of Egg-Albumin by Ammonium Sulphate. The Theory of the "Salting Out" of Proteins. HARRIETTE CHICK and CHARLES J. MARTIN (*Biochem. J.*, 1913, 7, 380—398).— The precipitation of egg-albumin by ammonium sulphate is, as Spiro showed for sodium sulphate and caseinogen and gelatin, due to the separation of the system into a protein-rich phase and a watery phase, and is to a certain extent analogous to the salting out of alcohol. The first effect of concentrated salt is to withdraw water from the protein aggregates; a surface tension is in consequence developed at the interfaces, which causes the protein particles to aggregate, thus dividing the system into two distinct phases (precipitate and filtrate). The various factors which influence the precipitation are discussed at length; a dominating influence is the concentration of hydrogen ions.   W. D. H.

The Molecular Weight of Hæmin. HANS FISCHER and AMANDUS HAHN (*Ber.*, 1913, 46, 2308—2309).—Ebullioscopic measurements in pyridine solution indicate for hæmin a molecular weight of 651, and therefore a molecular formula $C_{34}H_{32}O_4N_4FeCl$; the trustworthiness of the method is confirmed by numbers indicating the molecular weight 655 for the complex iron salt of mesoporphyrin,

$$C_{34}H_{36}O_4N_4FeCl.$$

The solution of free haematoporphyrin in pyridine appears to be colloidal, for the elevation in the b. p. of the solvent is so slight as to indicate a molecular weight over 3000 (compare Piloty and Dormann, A., 1912, i, 519).   D. F. T.

Hæmatin. III. Chemistry of the Formation of Hæmatoporphyrin. WILLIAM KÜSTER and PAUL DEITLE (*Zeitsch. physiol. Chem.*, 1913, 86, 51—76. Compare A., 1912, i, 670).—The age of hæmin preparations makes a considerable difference in their behaviour towards hydrogen bromide. Whereas freshly prepared hæmin yields almost exclusively hæmatoporphyrin and ferric iron, old hæmin preparations give both ferrous and ferric iron and much by-product. The changes in hæmin on keeping obviously take place at the centres which play a part in the formation of hæmatoporphyrin; these are considered to be the vinyl groups.

Hæmatoporphyrin is very readily esterified with methyl alcohol and hydrogen chloride. The product is a dimethyl derivative, insoluble in sodium carbonate, m. p. 142°, proving that the two carboxyl groups were present in hæmin, whereas the hydroxyl groups were formed

during the formation of hæmatoporphyrin. The ester is readily hydrolysed by sodium hydroxide.

A tetramethyl hæmatoporphyrin is obtained on prolonged heating with methyl alcohol and hydrogen chloride; the non-crystalline product has m. p. 81°.

A tetramethyl derivative is also obtained when the intermediate product formed by the action of hydrogen bromide in acetic acid on hæmin is warmed with anhydrous methyl alcohol. This substance, *methyl dimethoxydihydrohaematerindicarboxylate*, forms large crystals, m. p. 128°.

On hydrolysis the tetramethyl derivative forms *haematoporphyrin dimethyl ether*, a bright scarlet, amorphous powder, m. p. 105°, soluble in alkali; the *hydrochloride* is crystalline, forming needles; the *zinc* salt is bright red, and blackens at 100°. When esterified, it yields the original tetramethyl compound again.

A further argument against the assumption that hæmin contains, as supposed by Piloty, lactam junctions is afforded by the discovery of a dimethoxydihydrohæmin amongst the products of the action of methyl alcohol on the above intermediate product.

Hæmatoporphyrin forms a silver salt containing two atoms of metal; its dimethyl ether forms one with three atoms of metal; both compounds fix three molecules of ammonia. Hæmatoporphyrin forms a stable dihydrochloride, whereas the hydrochloride of the dimethyl ether is very unstable, and that of the dimethyl ester could not be prepared. This behaviour indicates betaine formation between the nitrogen and the methyl group of the ester, and to a less extent the methyl group of the dimethyl ether. Prolonged action of concentrated hydrochloric acid displaces one of the methyl groups, forming a mono-methyl ether, which, however, has a stable monohydrochloride.

The *dimethyl* ester of *anhydrohaematoporphyrin* forms an intense scarlet, bulky powder, m. p. 140—141°.   E F. A.

Hæmatin. V. Methylation of Hæmin and the Addition of Bromine to Chlorodimethylhæmin and Bromodimethyl-hæmin. WILLIAM KÜSTER and ALFRED GREINER (*Zeitsch. physiol. Chem*, 1913, 86, 185—205).—Dimethylhæmin is the dimethyl ester of the dibasic acid hæmin. Reasons are discussed for attributing a different degree of acidity to the two carboxyl groups, particularly the behaviour of hæmin to methyl sulphate In strongly alkaline solution there is no action, in weak alkali a monomethyl derivative is formed, whereas in acid solution dimethylhæmin is formed without difficulty, it is identical with the product produced by means of methyl alcohol and hydrogen chloride. The monomethyl derivatives from hæmatin and dehydrochlorohæmin did not crystallise.

When bromine in chloroform solution acts on dimethylhæmin, bromine is absorbed without the liberation of hydrogen bromide; more or less of the chlorine of the hæmin is replaced by bromine, so that a complex mixture results. In acetic acid solution, however, a chlorodimethylhæmin dibromide is obtained. Very little of a tetra-bromo-product is formed. In a similar manner, bromodimethylhæmin dibromide is formed. It can be crystallised from acetic acid.

No methyl is eliminated by the action of aniline on dimethylhæmin. The dimethyl dehydrochlorohæmin so obtained is partly soluble in ether; the two portions differ in the amount of chlorine they contain. When converted into the corresponding bromodimethylhæmins, compounds which differ in their crystalline habit are obtained. Aniline reconverts both of these into dehydrobromo-products which are soluble and insoluble in ether respectively.

Bromine may be eliminated from hæmin dibromide by means of aqueous alkali, sodium methoxide, or by zinc and acetic acid. On oxidation one molecule of the dibromide yields two molecules of hæmatic acid. The conclusion is drawn that the addition of bromine takes place at the vinyl residues.

The complex $C_{32}H_{34}N_4$ is termed *hæmaterin*, and its dicarboxylic acid, $C_{34}H_{34}O_4N_4$, *hæmaterindicarboxylic acid*. Hæmin, bromohæmin, and hæmatin are thus complex chloro-, bromo- and hydroxy-ferric salts, of this acid.   E. F. A.

Tetrachloromesoporphyrin.   HANS FISCHER and HEINRICH RÖSE (*Ber.*, 1913, 46, 2460—2466).—On the cautious addition of fuming hydrochloric acid and hydrogen peroxide to mesoporphyrin dissolved in glacial acetic acid, the hydrochloride of a dye crystallising in green needles is obtained. This is *tetrachloromesoporphyrin*, chlorine being substituted for hydrogen in the four methine groups uniting the pyrrole nuclei in pairs. On reduction of the tetrachloro-compound with sodium amalgam, porphyrinogen is obtained, whereas mesoporphyrin results on heating with sodium methoxide at 220—230°. The green compound is also formed when chlorine is passed into a solution of mesoporphyrin in acetic acid. Reduction with acetic acid and hydrogen iodide converts it into mesoporphyrin again and not into porphyrinogen. One of the chlorine atoms is much less firmly held than the others.
                                                        E. F. A.

Chondroitin-sulphuric Acid.   PHŒBUS A. LEVENE and FREDERICK B. LA FORGE (*J. Biol. Chem.*, 1913, 15, 69—79).—Chondrosine, the nucleus of chondroitin-sulphuric acid, when hydrolysed by means of sodium amalgam yields glycuronic acid, identified by the phenyl- and *p*-bromophenyl-hydrazine derivatives.

The glycuronic acid is not bound to the amino-group of the second component, since the nitrous acid process demonstrates the presence of an unsubstituted amino-group in chondrosine. Neither does the carbonyl group of glycuronic acid take part in the linking. On oxidation of chondrosine with nitric acid a product is obtained which on distillation with hydrochloric acid gives rise to a minimal quantity of furfuraldehyde, whilst chondrosine yields the quantity required by a complex composed of one molecule of glycuronic acid and one of a carbohydrate of about the same molecular weight. The oxidation product does not contain free saccharic acid until it has been hydrolysed with alkali. Hence chondrosine contains saccharic acid

in a conjugated form. In chondroitin-sulphuric acid both the carboxyl and the amino-groups are combined with other radicles.

<div align="right">E. F. A.</div>

Identity of Rennet, Casease, and Trypsin from the Same Latex. Existence of Two Types of Vegetable Proteolytic Ferments. C. GERBER (*Compt. rend.*, 1913, **157**, 241—243. Compare A., 1907, i, 1100; 1908, i, 745; 1909, i, 74, 278; ii, 512, 824; 1910, ii, 64; 1911, ii, 647; 1912, ii, 801; this vol., i, 806).—Rennet, casease, and trypsin obtained from the same latex exhibit the same resistance to heat, and their diastatic actions are influenced in the same manner by certain electrolytes and by certain substances, such as lactalbumin and lactoglobulin, which accompany the substances on which they act. A study of these enzymes obtained from *Ficus carica* and *Broussonetia papyrifera* shows further that their diastatic actions obey the same laws of mass, time, and temperature, and their variations in intensity, seasonal for the same plant or individual for the same period, are strictly parallel. From these results the author maintains that rennet, casease, and trypsin from the same latex are but three different or successive aspects of the same diastase, coagulating the milk and carrying the hydrolysis of the casein and the fibrin to the formation of amino-acids. The characteristics distinguishing the three proteolytic actions of the latex are due to differences in the action of calcifying and decalcifying salts, acids, and bases on the coagulation and diastatic digestion of milk. The proteolytic ferments of the latex belong to two groups, the one having for type the proteolytic disastase of *Ficus carica* and the other that of *Broussonetia papyrifera*, the former being inactive towards milk, whilst the latter are active.

<div align="right">W. G.</div>

Action of Hydrogen Chloride on a Diastase Preparation which had been Altered by Heating. IX. THEODOR PANZER (*Zeitsch. physiol. Chem.*, 1913, **86**, 322—339).—A diastase preparation of which the activity had been destroyed by heating was rendered slightly active again by treatment with dry hydrogen chloride and subsequently removing this in a vacuum. It is considered that the original active groups in the enzyme have not been restored by the acid, but that this has attacked other atomic groupings, which become active as enzymes when the hydrogen chloride is removed.

<div align="right">E. F. A.</div>

Identity of the Hydrolytic and the Synthetic Activities of Emulsin. ÉMILE BOURQUELOT and MARC BRIDEL (*J. Pharm. Chim.* 1913, [vii], **8**, 15—19).—Emulsin hydrolyses the β-glucosides of the alcohols and causes the combination of dextrose with the alcohol to a β-glucoside. Both these reactions are incomplete, and there is a tendency to attain an equilibrium. The position of this equilibrium is independent of the quantity of emulsin added and of the temperature, but it varies with the strength of the alcohol and with the amount of

dextrose present. It is shown experimentally that in a solution containing 30·2% by weight of methyl alcohol, and equivalent quantities of dextrose or β-glucoside together with emulsin, the rates of hydrolysis and synthesis are the same, and the same point of equilibrium is reached from both directions. The probability of emulsin acting synthetically in plants is emphasised.   E. F. A.

Reversibility of Enzyme Action: a-Glucosidase and a-Methylglucoside. ÉMILE BOURQUELOT and ÉMILE VERDON (*J. Pharm. Chim.*, 1913, [vii], 8, 19—21).—Bottom yeast extract was allowed to act in solutions containing 20 grams per 100 c.c. of methyl alcohol and equivalent quantities of dextrose or a-methylglucoside. In about twenty-nine days both solutions had the same rotatory power, indicating that the same equilibrium is attained starting from either end.   E. F. A.

The Rennin Coagulation of Milk from a Colloid Chemical Standpoint. JEROME ALEXANDER (*Eighth Inter. Cong. App. Chem.*, 1912, 6, 12—14).—Silver nitrate gives a clear silver chloride sol in presence of fresh lactalbumin, but, after digestion with pepsin, lactalbumin does not exert the influence of a protective colloid. The action of acids or rennin on milk is thus to destroy the colloidal protection of the lactalbumin for the unstable, irreversible suspensoid, casein (compare A., 1910, i, 530).   J. C. W.

New Function of the Catalyst termed "Peroxydase" and the Biochemical Transformation of Orcinol into Orcein. JULES WOLFF (*Eighth Inter. Cong. App. Chem.*, 1912, 26, 417—419. Compare A., 1912, i, 928).—Experiments are described which show that dilute solutions of orcinol are slowly oxidised by ammonia with production of orcein. This action is greatly accelerated by peroxydase, the effect of which is to promote the formation of the colouring matter rather than to increase the amount of oxygen absorbed.   E. G.

The Catalase of the Liver. LEONOR MICHAELIS and H. PECHSTEIN (*Biochem. Zeitsch*, 1913, 53, 320—355).—The ferment solution employed was a highly diluted extract of calves' liver, and hydrogen peroxide was used as the substrate. The course of the action was followed by determining the rate of destruction of the peroxide by titration with permanganate solution. It was found that for the catalase reaction, the ordinary equation $\Phi.t = f(x)$, where Φ is the quantity of the ferment, $t =$ time of action, and $f(x)$ a characteristic function of the ferment, does not hold, but must be replaced by the equation $\Phi^n.t = fx$, in which n is of the approximate value of 1·35, but varies slightly during the course of the reaction. The deviation from the ordinary law is due to the fact that the ferment is acted on by the hydrogen peroxide, as its action is weakened by previous treatment with this reagent. Oxygen itself does not act, and the same results are obtained when the reaction is carried out in a current of hydrogen

or in a corked flask. As determined by the wandering of the ferment in an electrical field, where the [H]˙ concentration was varied by different acetate mixtures, the isoelectric point of the ferment was found to be $4\cdot31.10^{-6}$. The rate of ferment action was determined in low salt concentrations (acetate mixtures) with varying hydrogen-ion concentrations. By the graphical methods already employed by Michaelis and his pupils, the amounts of ferment active in solutions of different hydrogen-ion concentrations were determined. The optimal condition of action is attained just after the hydrogen-ion concentration becomes less than the isoelectric point of the ferment. The conclusions drawn are, that catalase is an ampholyte with the acid dissociation constant $2\cdot88 \times 10^{-5}$, and that the catalytic action on hydrogen peroxide is due to the anions and electrically neutral particles. Neutral salts inhibit the action (hence all the experiments on the effect of the [H]˙ concentration were carried out with very dilute acetate mixtures). The inhibitory action is more marked in the neighbourhood of the isoelectric point than in more acid solutions. The conclusion is drawn that the anions of the salt exert the chief action, and affect chiefly the electrically neutral particles of the ferment. The order of the inhibitory action is $SO_4 > Cl > \text{acetate} > NO_3$. S. B. S.

Constitution of the Mercuriated Products of Acetylene. WILHELM MANCHOT and JULIUS HAAS (*Annalen*, 1913, **399**, 123—154). —Phenylacetylene and an excess of aqueous mercuric chloride at 47—50° yield a *substance*, $C_{16}H_{11}O_2Cl_5Hg_5$ or $C_{16}H_{13}O_3Cl_5Hg_5$, in which the mercury is very firmly held. It does not react with aqueous sodium hydroxide or ammonia, but yields mercuric sulphide by treatment with ammonium sulphide. By treatment with dilute hydrochloric acid, it yields phenylacetylene and acetophenone. This decomposition indicates that the substance is an additive compound of an acetylene, not a mercuriated ketone, and consequently the constitution may be $Hg(C:CPh)_2,2HgCl_2,HgO,HgCl\cdot OH$, which is supported by the fact that the same substance is produced by the action of an excess of aqueous mercuric chloride on mercury phenylacetylide in the presence of a little hydrochloric acid at 50°.

A similar *substance*, $C_{16}H_{10}OBr_4Hg_4$, is produced by the interaction of phenylacetylene and aqueous mercuric bromide at 50°. It also does not react with sodium hydroxide or ammonia, yields mercuric sulphide by treatment with ammonium sulphide, and is decomposed by hydrochloric acid to form acetophenone and phenylacetylene. Probably, therefore, its constitution is $Hg(C:CPh)_2,2HgBr_2,HgO$. Both of these substances, suspended in chloroform in a freezing mixture, absorb a large amount of bromine; ultimately, however, hydrogen bromide is evolved.

Piperonylacetylene reacts with mercuric chloride and bromide to form substances which are analogous to the preceding, but which yield only acetopiperone by treatment with hydrochloric acid. This is due to the fact that the piperonylacetylene which is initially formed unites with water with extraordinary ease in the presence of hydrochloric acid. Since the preceding substances are additive compounds of acetylenes,

it is probable that the substance obtained by the action of acetylene itself on aqueous mercuric chloride is an additive compound, not a mercuriated aldehyde, $C(HgCl)_3$·CHO, as suggested by Biltz and Mumm. The latter view is almost certainly incorrect, because the substance exhibits the reactions of mercurous and of mercuric salts. The substance, which is also obtained from mercury acetylide and aqueous mercuric chloride, yields only acetaldehyde by treatment with dilute hydrochloric acid, but is decomposed by ammonium sulphide to form acetylene and acetaldehyde. Probably, therefore, its constitution is $C_2Hg,HgCl_2,HgCl,H_2O$. A substance, exhibiting properties similar to those of the preceding substance is obtained from acetylene or mercury acetylide and an excess of aqueous mercuric bromide.

It is evident from the behaviour of the preceding mercury compounds that mercury can be retained very firmly in an organic compound without necessarily being attached to carbon in the place of hydrogen atoms.   C. S.

Physiological Chemistry

A Calorimeter for Small Animals. FRANZ TANGL (*Biochem. Zeitsch.*, 1913, **53**, 21—35).—The calorimeter is constructed on the compensation principle. Two exactly similar cylinders of copper, each insulated in a Dewar flask, are connected with one another by constantan wires, so as to form thermoelectric couples, and a Broca galvanometer is placed in circuit between the two, so as to indicate any differences of temperature between them. The whole apparatus is immersed in a large thermostat. The animal is placed in one cylinder in a cage, and the other cylinder contains a similar cage without an animal. The heat produced by the animal in one cylinder is approximately compensated for by the passage of a known electric current through the other, which produces an experimentally measurable quantity of heat. The small differences of heat in the two cylinders can be measured by the deflexions produced when the galvanometer is thrown into the circuit. The galvanometer deflexions can be calibrated by passing two measured but slightly different currents through the two cylinders. The total heat produced by the animal is therefore calculated both from the compensation current and the galvanometer readings; the calorimeter can also serve as a respiration calorimeter, by the analysis and measurement of the air led in (which is first carefully warmed to the temperature of the thermostat by a long passage through pipes immersed in the water it contains), and the analysis of the expired air, in the usual manner adapted for such calorimeters. Illustrations in the text indicate the exact method of construction of the apparatus (compare A. V. and Miss Hill, this vol., i, 666).   S. B. S.

The Response of the Respiratory Centre to Carbon Dioxide, Oxygen, and Hydrogen Ion Concentration. J. M. H. CAMPBELL, CLAUDE E. DOUGLAS, JOHN S. HALDANE, and F. G. HOBSON (*J. Physiol.*, 1913, **46**, 301—318).—A rise of 0·2% or 1·6 mm. in the pressure of carbon dioxide in the alveolar air doubles the pulmonary ventilation. A corresponding diminution causes apnœa. The alveolar oxygen pressure can be varied within wide limits without affecting the excitability of the respiratory centre to carbon dioxide. Summation of inhibitory vagus stimuli plays no part in causing apnœa in man. What the respiratory centre really responds to is the balance of hydrogen ion concentration in the blood. This balance is exquisitely regulated, probably for the most part by the kidneys. W. D. H.

Respiratory Mechanism in the Duck. J. B. ORR and ALEXANDER WATSON (*J. Physiol.*, 1913, **46**, 337—348).—In the duck, carbon dioxide in the inspired air acts inhibitingly on respiration. Lack of oxygen is stimulating to the respiratory rhythm. The vagus nerves probably play an essential part in the maintenance of respiratory movements. W. D. H.

The Influence of the Cerebrum on the Metabolism of Energy and of Matter. KARL HANNEMANN (*Biochem. Zeitsch.*, 1913, **53**, 80—99).—The experiments were carried out on frogs, the respiratory exchanges of which were measured in chambers made according to a method described in the text, from ordinary laboratory desiccators. These exchanges were measured in the cases of intact animals, and animals from which different parts of the brain had been extirpated. It was found that the extirpation of either the whole brain, or only the large hemispheres, or the optic lobe led to a considerable increase in the gaseous exchange, lasting for several days. Both the oxygen consumption and the carbon dioxide output were increased, especially the latter, which was not so much increased, however, when only the hemispheres were removed. The increase in the gaseous exchanges is accompanied by an increased heat production, which was measured in a Tangl calorimeter. S. B. S.

The Influence of Narcosis on the Gaseous Metabolism of the Brain. FRANZ G. ALEXANDER and STEPHAN CSERNA (*Biochem. Zeitsch.*, 1913, **53**, 100—115).—Dogs were used for the purpose of the experiments. They were tracheotomised under ether narcosis, hiradin was injected into the jugular vein and the femoral artery, and the sinus longitudinales was laid bare for the purpose of collecting blood samples. By means of blood-gas analyses, the gaseous metabolism could be determined when the animal had recovered from narcosis, and when it was under the influence of various anæsthetics. The rate of blood-flow was measured by Barcroft's method. It was found that the specific gaseous exchanges of the blood were considerable, the oxygen consumption of this organ being about 0·36 c.c. per gram per minute. During

narcosis the gaseous metabolism sinks considerably—from 60 to 90%
according to depth of the narcosis.   With ether, the carbon dioxide
output diminishes less than the oxygen consumption; the reverse
is the case in morphine narcosis.   The action of various narcotics
is different, and this fact must be taken into account in all theories
dealing with the phenomenon.   In narcosis with magnesium
sulphate, the higher centres of the nervous system are the last to
be paralysed.   The actual narcosis is preceded by a stage of
excitation, during which the gaseous metabolism of the brain is
increased.   S. B. S.

Blood-lipoids and Phagocytosis.   B. STUBER (*Biochem. Zeitsch.*,
1913, **53**, 493—500).—The addition of cholesteryl esters of oleic
and palmitic acids inhibits phagocytosis *in vitro*, and with the latter
substance also *in vivo*, when the blood is withdrawn (from cats)
half an hour after the injection.   Owing to the rapidity with which
clot formation takes place, experiments could not be extended
beyond this period, and for the same reason no *in vivo* experiments
were possible with the oleic acid derivative, which very readily
renders the blood so clottable that it clots directly on opening the
veins.   The inhibition is not removed by mixing the cholesterol
derivatives with lecithin, as is the case with free cholesterol.
Cholesteryl benzoate and acetate are without action on phagocytosis,
in which substances the free hydroxyl group no longer exists, and
to this group is ascribed the inhibitory action of cholesterol and its
derivatives on phagocytosis.   Wright's theory of opsonins is discussed,
and it is suggested that the opsonic index is not due to specific
opsonins, but rather to the different states of the lipoids in the
blood.   S. B. S.

The Effect of Fatty Acids and Soaps on Phagocytosis
HARTOG J. HAMBURGER and J. DE HAAN (*Proc. K. Akad. Wetensch.
Amsterdam*, 1913, **15**, 1290—1297).—Propionic acid itself diminishes
phagocytic action (as determined by Hamburger's charcoal method),
whereas sodium propionate increases it, within wide limits of con-
centration of the salt.   The former action is to be ascribed to the
hydrogen ions, whereas the latter action is due to the action of
the salt on the surface tension of the water.   This constant is
diminished, and this facilitates the pseudopodial action of the
phagocytes.   This action of sodium propionate and soaps is to be
distinguished from the action of fat-dissolving substances, which
exert their action owing to the fact that they dissolve in lipoids.
                                                             S. B. S.

The Blood of Ascidians.   III.   MARTIN HENZE (*Zeitsch. physiol.
Chem.*, 1913, **86**, 340—344).—The author's previous work has shown
that organic vanadium compounds occur in the blood-corpuscles of
Phallusia, and that these cells have an acid reaction due to sulphuric
acid.   It is now shown that vanadium also occurs in the blood
of other ascidians (*A. mentula, A. fumigata, Ciona intestinalis*,
and *Diazonia violacea*); in *Cynthia papillosa* its presence is
uncertain.

Much of the present paper deals with the kinds of blood-corpuscle found, and their reactions with staining fluids. The nature of the pigment in the red cells of *Ascidia mentula* is uncertain; it is not a lipoid, and is insoluble in all common reagents.

W. D. H.

The Application of the Second Law of Thermodynamics to Processes in the Animal Organism. JULIUS BÁRON and MICHAEL PÓLÁNYI (*Biochem. Zeitsch.*, 1913, **53**, 1—20).—A knowledge of the changes of free energy in the animal organism can be arrived at by the application of Nernst's heat theorem. These changes of free energy were calculated for the individual products taking part in metabolism. It was found that the changes correspond very nearly with the heat production. The results indicate that the processes in the organism take place in accordance with the second law of thermodynamics only when the organism does not work with absorption of heat. The thermodynamical efficiency of mechanical work and of fat synthesis from sugar was calculated, and the trustworthiness of the theory from the point of view of the second law was confirmed.

S. B. S.

The Influence of the Character of the Nutrition on the Metabolism During a Succeeding Period of Starvation. ARTHUR SCHLOSSMANN and HANS MURSCHHAUSER (*Biochem. Zeitsch.*, 1913, **53**, 265—299).—Dogs were starved for some days, and then fed with different diets, in one case containing large amounts of fats, in another large amounts of carbohydrates, and in a third case, chiefly proteins. When the animals had attained their original weights again on these diets, a short period of starvation was interposed, during which the metabolism was investigated by the ordinary methods. As a result of these and earlier experiments, the conclusion was drawn that the metabolism during a period of starvation in both man and dogs depends to a large extent on the character of the nutrition ingested in the foregoing period, and this influence can be demonstrated even when the effects of the last meal taken have vanished. The organism has got accustomed to the utilisation of either fats, carbohydrates, and proteins, and the habit thus acquired still lasts even when the animal is deprived of food. This influence is demonstrated chiefly by the respiratory quotients, which remain similar during starvation to those obtained during the period of feeding. The influence of the fat diet lasts longer than that of the carbohydrate diet, as the reserve glycogen is soon used up. Thus, in the case of the dog fed on fats, on the fifth as well as on the second day of starvation about 90% of the calories are derived from the fat, and 3% from carbohydrates. In the case of the carbohydrate-fed dog, on the second day of starvation 21% of the calories are derived from carbohydrates, and 65% from fats; and on the fifth day, only 8% from carbohydrates and 79% from fats. The organism can therefore be "trained" to adapt itself to various diets.

S. B. S.

The Action of Carbohydrates on the Energy Metabolism.
PAUL HÁRI (*Biochem. Zeitsch.*, 1913, 53, 116—139).—The experiments
were carried out with the employment of the Tangl respiration
calorimeter, and both the heat production and the nitrogen and
carbon metabolism were investigated at the same time. When
dextrose was subcutaneously administered to mice in 10% solution,
in quantities corresponding with 10 grams per kilo. of body-weight,
it caused a rise in the heat production of 8—13·2%. In quantities
of 28—32 grams per kilo. of body-weight, when administered to
starving rats, it caused a rise of 28—29·9%. This rise can be
partly explained as a result of sugar intoxication. The heat thus
produced is chiefly lost by radiation when the sugar is administered
in concentrated solutions, but chiefly by water evaporation when
given in dilute solution.   S. B. S.

The Biochemical Synthesis of the Fatty Acids. (Miss) IDA
SMEDLEY and (Miss) EVA LUBRZYNSKA (*Biochem. J.*, 1913, 7, 364—374).
—The hypothesis that pyruvic acid formed in the body from
carbohydrates is the starting point for the synthesis of the fatty
acids, is supported by a number of pieces of evidence, and
equations are given to represent the series of reactions which occur
                                                            W. D. H.

Fatty Acid Esters of Dextrose. W. R. BLOOR (*Eighth Inter.
Cong. App. Chem.*, 1912, 19, 29—36).—Attention is called to the fact
that fats are not completely metabolised in the absence of carbo-
hydrates, as is witnessed by the fact that such products as
β-hydroxybutyric acid, acetoacetic acid, etc., are excreted during
starvation. The suggestion is made that sugars may act cata-
lytically in the destruction of the fats in the animal body. It
was therefore of interest to prepare dextrose esters of fatty acids
and to investigate their action when administered to animals.
These esters were prepared by the interaction of the acid chloride
on dextrose in pyridine solution, and a preliminary account of
several such esters is given. They readily form colloidal solutions
with water. For physiological experiment a mixture of the esters
prepared from the fatty acids of cocoa-nut oil was employed.
When administered to cats by the mouth, these esters are readily
absorbed (up to more than 80%). They do not appear to be
adapted to administration either intraperitoneally or intravenously.
In the former case, they act as an irritant foreign substance, and
in the latter case they can act injuriously, even producing death
of the animal   S. B. S.

Is Inulin a Glycogen Former? ALFRED OPPENHEIM (*Chem.
Zentr.*, 1913, ii, 371; from *Zentr. Physiol.*, 1913, 27, 264—267).—
Rabbits freed from glycogen by injections of strychnine were fed
with inulin. Some glycogen was formed in the liver, and a good
deal in the muscles. Since feeding with lævulose leads to the
formation of glycogen in the liver, it is assumed that most of the
inulin administered passes the liver and is converted into glycogen
in the muscles.
                                                            E. F. A.

Action of the Digestive Juices on Alicyclic Compounds. JUHO HAMALAINEN (*Chem. Zentr.*, 1913, i, 2052; from *Skand. Arch. Physiol.*, 1913, **29**, 60—67).—When alicyclic compounds are shaken for ten hours at 37° with gastric juice, they become partly hydrated—the hydrocarbons the most easily, and the ketones the least so. Menthene, limonene, terpinolene, pinene, nopinene, and dihydrocarveol give rise to menthanol, terpin, terpineol, etc. Only terpinene and fenchene proved resistant. E. F. A.

Influence of the Melting Point of Non-emulsified Fats on their Rate of Disappearance from the Stomach. A. VON FEJÉR (*Biochem. Zeitsch.*, 1913, **53**, 168—178).—Various fats were mixed with a standard diet and administered to dogs. After a given interval these test-meals were quantitatively removed from the stomachs by a form of stomach-tube, which is described and illustrated in the text, and the fat content of the vomit was then analysed. It was found that the higher the melting point and viscosity of the fat, the more slowly it disappeared from the stomach. The fats, after emulsification with food, disappear more rapidly than when administered in a non-emulsified form. When not administered with foods, these disappear even more slowly still, with the exception of the liquid olive oil. Fats also inhibit the disappearance of the other food constituents from the stomach, and the more viscous fats exert the greater inhibitory action in this respect. A fat added to foods readily separates from other food constituents in the stomach, and is afterwards digested independently of them in the intestine. S. B. S.

The Influence on Nitrogenous Metabolism of Feeding on Sodium Nitrate. ERICH GRAFE and H. WINTZ (*Zeitsch physiol. Chem*, 1913, **86**, 283—314).—Experiments on dogs and pigs are recorded with sodium nitrate similar to those previously published in relation to ammonium salts. In one of the four experiments there was no retention of nitrogen; in the other three, from 10—15% of the nitrogen was retained. Large doses exert a toxic action and increase the output of nitrogen. Hypotheses are advanced to explain the retention of nitrogen W. D. H.

Utilisation of Individual Proteins by Man as Influenced by Repeated Fasting. PAUL E. HOWE and PHILIP B. HAWK (*Eighth Inter. Cong. App. Chem.*, 1912, **19**, 145—147).—The method of experiment was to administer to the same individual after a two days' fast, a standard diet containing 12·12 grams of nitrogen and 2500 cal. of energy. This diet was continued for two days, and was then increased for another two days, so that 18·18 grams of nitrogen and 3750 cal. were taken. Two days' fast then succeeded, and was followed by another five days of feeding with the quantities given above, but with nitrogen from another protein. By alternation of two fast days and five feeding days, in which various proteins were employed, the dietetic values of the latter

could be ascertained. The most efficiently utilised proteins were found to be meat and gliadin, of which 97·5% was absorbed, followed by plasmon, milk, and "standard" diet. The substances most efficient in maintaining a nitrogenous equilibrium (in both cases under the conditions of experiment, positive) were, however, meat and milk. It is noteworthy that in both cases the proteins were of animal origin.   S. B. S.

Nuclein Metabolism. MAX DOHRN (*Zeitsch. physiol. Chem.*, 1913, **86**, 130—136).—The results of an experiment in which 10 grams of nucleic acid were consumed in addition to a diet consisting of bread, 300 grams; butter, 80 grams; apples, 250 grams; eggs, 200 grams, and milk, 2 litres, showed that the nitrogen in the form of carbamide is not increased during the nucleic acid period. The nitrogen in uric acid increased 50%, or 9·7% of the nitrogen in purine bases. The rest of the nitrogen as purine bases was not recovered. The phosphoric acid increased considerably, the amount found in the urine and fæces exceeding the amount supplied by 0·76 gram. The results indicate that almost all the nucleic acid underwent cleavage before resorption, and that the slight increase in uric acid is due to resorbed bases.   N. H. J. M.

The Action of the Iron in Blood-powder on the Iron Metabolism when this Product is Administered to Animals. JULIUS GRÓH (*Biochem. Zeitsch.*, 1913, **53**, 256—258).—By the addition of blood-powder to a standard diet administered to pigs, no alteration was caused in the iron balance in the animal, the additional iron from the blood ingested being excreted in the fæces.   S. B. S.

The Localisation and Detection of Peroxydases in the Digestive Tract. ARTHUR SCHEUNERT, WALTER GRIMMER, and PETER ANDRYEWSKY (*Biochem. Zeitsch.*, 1913, **53**, 300—319).—A trustworthy oxydase reagent is guaiacol tincture, to 100 c.c. of which have been added 0·1 -0·2 c.c. of 3% hydrogen peroxide solution. This reagent is capable of detecting an oxydase in milk, saliva, etc., which contain a peroxydase, but not with blood, unless a superoxide solution, such as turpentine oil, ethyl hydroperoxide, etc., is also added. Rothenfusser's reagent (*p*-phenylenediamine + guaiacol) and the potassium iodide starch reagents are not trustworthy for the detection of oxydases. The extracts of tonsils contain no oxydase, the sublingual glands contain large quantities of the ferment, whereas the submaxillary and parotid glands vary largely as to oxydase content in different animals; the same is true with reference to the mucous membrane of the stomach and the small intestine. Liver extracts are free from substances giving the blue reaction with guaiacum tincture. Furthermore, the ferment giving this reaction is not identical with the ferment causing the oxidation of formic acid, as several tissues give one reaction, but not the other. The guaiacol peroxydase of the submaxillary gland of the ox possesses a considerable but not complete resistance to digestion with trypsin.   S. B. S.

Fluorine in the Animal Organism. III. Brain, Glands, Muscles, Blood, Milk, Excretions. ARMAND GAUTIER and PAUL CLAUSMANN (*Compt. rend.*, 1913, **157**, 94—100. Compare this vol., i, 677, 789).—Like phosphorus, fluorine exists in all animal organs and tissues, but in very varying proportions, the dental enamel having the highest content, 180—118 mg. per 100 grams of dry matter, and the muscle the lowest with 0·6—0·15 mg. per 100 grams. There is a fairly constant relation between the phosphorus and fluorine contents of the various organs, except in the case of the incompletely formed organs of young animals, the excretions, the dental enamel, and the blood. The fluorine increases with the phosphorus without being directly proportional to it. In the same organ the quantity of fluorine varies greatly with age. It increases generally up to the adult age, and then diminishes as the organ begins to degenerate. Muscular tissue is remarkably poor in fluorine. The fluorine content of human milk is very low, but, as in the case of phosphorus, it is about four times as great in cow's milk. About 1 mg. of fluorine per day is excreted by man, and since the amount of fluorine supplied by the food greatly exceeds this, the difference must be due to epithelial desquamation, loss of hair, growth of nails, etc W. G.

The Lipocytic Constant. Content of the Tissues in Phosphorus-containing Lipoids. ANDRÉ MAYER and GEORGES SCHAEFFER (*Compt. rend.*, 1913, **157**, 156—159. Compare this vol , i, 424). —In different individuals of the same species the content of phosphorus in the lipoid form in a given organ is practically constant, but it varies from tissue to tissue in the same animal. For different animal species the values found for a given organ are very close. This phosphorus content of the different organs does not seem to vary during inanition, but rather appears to be the measure of a fundamental and permanent constituent of the cells. In certain cellular types the ratio, fatty acids/phosphorus in lipoid form, is remarkably constant, but in certain organs, for example, the muscles, the ratio has a value pointing to the presence of reserves of neutral fats in these organs. The content of a fresh tissue in phosphorus, in lipoid form, is characteristic of the tissue. In all the species examined the order of the different organs with respect to their phosphorus content relative to their fresh weight is the same, and this indicates that this content is proportional to the physiological activity. W. G.

The Application of Calorimetry to the Measurement of the Work of the Kidneys. FRANZ TANGL (*Biochem. Zeitsch.*, 1913, **53**, 36—40).—The energy metabolism of the kidneys was estimated by determining the heat production of rats placed in a calorimeter both before and after the extirpation of the kidneys. This was found to amount to 8·2% of the whole energy production of the body, and about 0·75 cal. per gram of kidney. This is the same as that found in the dog. Direct calorimetric measurements yield the same results as those obtained by Barcroft's method in the

analysis of the blood gases, and the author's own methods in the measurement of respiratory exchanges in curarised animals.

<div align="right">S. B. S.</div>

The Magnitude of the Work of Diseased Kidneys. STEPHAN CSERNA and G. KELEMEN (*Biochem. Zeitsch.*, 1913, **53**, 41—68).—The respiratory method of Tangl was employed in these researches, the respiratory exchanges of the animal being measured both before and after extirpation of these organs in animals which had been treated with renal poisons. These results were compared with those obtained in the normal (unpoisoned) animals. Dogs were used in the experiments, and the following poisons were employed: uranyl acetate, potassium cantharidate, potassium dichromate. Experiments were also carried out on animals, in which the blood-supply to the kidneys had been ligatured. It was found that the work of the diseased kidneys was greater than that of healthy ones, the oxygen consumption and carbon dioxide production both being larger. Only when the poison had been sufficiently powerful to produce anuria were these factors below normal. When the kidney work is increased, both the absolute and relative carbon dioxide production is greater than normal in diseased kidneys. By injury to the parenchyma of the kidney tissue produced by the stoppage of the circulation, the gaseous metabolism in the other organs is also increased.

<div align="right">S. B. S.</div>

The Magnitude of the Work of the Spleen. FRITZ VERZÁR (*Biochem. Zeitsch*, 1913, **53**, 69—79).—No alteration can be detected with certainty in the respiratory exchange after extirpation of the spleen of curarised dogs. By the direct measurement of the gaseous exchange in the blood passing through the spleen of cats by Barcroft's method, the oxygen consumption was found to be 0·05 c.c. of oxygen per gram per minute. This is about the same as that of the resting submaxillary gland or anuric kidneys, according to the researches of Barcroft. Dextrose, intravenously injected, and soluble starch are readily burnt up in the body, even after extirpation of the spleen.

<div align="right">S. B. S.</div>

The Changes in the Chemical Constitution of the Animal Body After Extirpation of the Spleen, Testis, and Thyroid. KARL DROGE (*Pflüger's Archiv*, 1913, **152**, 437—477).—The experiments were performed on dogs during the suckling period. Extirpation of the spleen delays growth, but whether this is the result of removing the organ or of the operation of laparotomy is uncertain. An increase of total ash (especially in calcium and to a smaller degree in phosphoric acid) was the only chemical change in the body noted. Extirpation of the thyroid does not affect growth, and causes a decrease in total ash. Extirpation of the testis does not affect growth, and a small decrease in the phosphoric acid of the ash occurs. Water, fat, fat- and ash-free substance, and proteins are not affected in all these classes of experiments.

<div align="right">W. D. H.</div>

Muscle Chemistry. IV (Addendum). The Muscle Tissues of some Sea Animals when Dried by Heat. GIUSEPPE BUGLIA and A. COSTANTINO (*Zeitsch. physiol. Chem*, 1913, **86**, 137—140. Compare this vol., i, 219).—When dried at 100—102°, the muscle tissues of some sea animals lose substances having an alkaline reaction, produced by the decomposition of extractive substances. At a temperature of 110—112°, acid substances are lost.

In the case of *Scyllium catulus* it was found that the loss is chiefly to be attributed to ammonia, produced by the decomposition of carbamide.   N. H. J. M.

Catalase in Frogs' Muscles. EINAR HAMMERSTEN (*Chem. Zentr.*, 1913, i, 2051; from *Skand. Arch. Physiol.*, 1913, **29**, 46—59).— The action of a number of products of normal metabolism on the system catalase-hydrogen peroxide is investigated in a specially devised apparatus, frogs' muscles being used as the source of enzyme (compare Santesson, A., 1908, ii, 1061; 1910, ii, 331). The addition of creatinine causes a rapid increase in the rate of action at first; subsequently it falls owing to the using up of the peroxide. Creatinine decreases the rate of change similarly to Siegfried's "phosphor-meat acid." Choline hydrochloride and muscarine platinichloride have a direct harmful action on the enzyme. Acetaldehyde likewise lowers the activity, but reacts with hydrogen peroxide, fixing oxygen. Carhamide and alcohol are without effect. The muscle enzyme was more active in July and August than during December to June. When several substances act at once on the enzyme, the rate of change curves lie between those of the several constituents.   E. F. A.

Influence of Various Substances on the Gaseous Interchange of Surviving Frog's Muscle. XI. Action of Aromatic and Other Cyclic Compounds. TORSTEN THUNBERG (*Chem. Zentr.*, 1913, i, 2051; from *Skand. Arch. Physiol.*, 1913, **29**, 1—28. Compare A., 1911, ii, 56, 627).—The behaviour of a number of benzene derivatives on the gas exchange of surviving muscles is described. Monobasic carboxylic acids, such as benzoic acid and the toluic acids, lessen the exchange; hippuric acid behaves similarly, but is weaker. The introduction of a second carboxyl group overpowers the adverse influence of the first. Phthalic acid is hardly poisonous, isophthalic and terephthalic acids are slightly more so, and mellitic acid is very slightly poisonous. β-Phenylpropionic acid is as poisonous as phenylacetic acid. When the carboxyl group is in an unsaturated side-chain, the adverse effect on the exchange is much increased; this is exemplified by the behaviour of cinnamic, *allo*cinnamic, β-benzylidenepropionic, phenylpropiolic, and phenylmalonic acids. The salicylic acid grouping is more poisonous than the benzoic acid grouping. The para-compound is the least poisonous of the three hydroxytoluic acids. Anisic acid as a methoxy-compound is less poisonous than *p*-hydroxybenzoic acid. The presence of several hydroxy-groups does not greatly alter the action of the aromatic acids. The phenol-alcoholic acids, for

example, mandelic and phenylparaconic acids, are almost without effect.

Phenols are less poisonous than benzoic acid. It is considered that the benzene ring as such has a poisonous action on certain constituents of the cell concerned in the normal respiratory process. Nitration, as in mono- and di-nitrobenzoic acids, has little effect on the physiological action; sulphonation lessens the poisonous character of the ring. On the other hand, the hydrated six-membered ring in inositol and camphoric acid is inactive. The introduction of nitrogen into the ring, as in picolinic, nicotinic, and quinolinic acids, also counteracts the poisonous effect. Quinoline, which contains both pyridine and benzene nuclei, is strongly poisonous. Five-ring compounds are moderately poisonous.

E. F. A.

Organic Bases in the Roe of Herrings. KIYOHISA YOSHIMURA (*Zeitsch. physiol. Chem.*, 1913, **86**, 174—177).—The dry matter (92·093%) of the herring roe had the following composition: total N, 12·063; crude fat, 1·253; total P, 0·602; P as lecithin, 0·200; N as proteins, 0·601; N as ammonia and amines, 0·338; N as bases, 0·244%. One kilo. of the dried substance yielded 0·12 gram of trimethylamine, 0·02 gram of tetramethylenediamine, and 0·70 gram of choline.

N. H. J. M.

The Occurrence of Free Sulphuric Acid in the Mantle of Ascidia mentula. MARTIN HENZE (*Zeitsch. physiol. Chem.*, 1913, **86**, 345—346).—The cellulose mantle of *A. mentula* is acid, and this is due to sulphuric acid in the "bladder cells" of the mantle. Whether this is related to the acid cells of the blood is uncertain, for in *Phallusia mamillata*, although the blood-cells are acid, there is no acid in the mantle. There is less total sulphate in the expressed juice of *Phallusia* mantle than in the sea-water. The amount of chlorides in the two is equal.

W. D. H.

Presence of Carbamide in the Invertebrates and in their Excretion Products. ROBERT FOSSE (*Compt. rend.*, 1913, **157**, 151—154. Compare A., 1912, ii, 1203; this vol., i, 327, 432).—The author has proved the presence of carbamide in numerous invertebrates and their excretion products, and also in the water inhabited by them for any length of time, as follows:

Coelenterata: Actinia, and its products of excretion.

Echinoderm: Starfish, and products of excretion.

Worms: Sangsue officinale, cellular juice, and products of excretion.

Crustaceæ: Crayfish, cellular juice of the entire animal, of the flesh deprived of the organs, and of the liver; also in the products of excretion; spiny lobster, cellular juice, and excretion products; shrimp, cellular juice.

Insects: Silkworm, cellular juice; ant, eggs; fly, eggs.

Molluscs: Snail, entire animal, products of secretion and excretion; mussel, liquid in the shells; oyster, liquid in the shells.

W. G

The Mechanism of the Physiological Production of Light; Luciferase, Luciferin, and Luciferesceine. RAPHAEL DUBOIS (*Eighth Inter. Cong. App. Chem.*, 1912, 19, 83—89).—Phosphorescence in organisms is due, according to the author, to the interaction of two substances, which he has isolated more especially from the molluscular lamellibranch, *Pholades dactylus*. One of the substances, to which the name *luciferin* is given, can be extracted from the secreting organs by water, after heating to 70°, at which temperature it is stable. The other substance, *luciferase*, is, however, destroyed at 60°. By the action of one on the other in the presence of air, a phosphorescence is produced. The luciferase is of ferment-like character (oxydase), and it can be replaced by an oxidising agent, such as potassium permanganate, and by the blood of various cold-blooded animals, such as molluscs and marine crustaceans. Solutions of both substances give protein reactions, and the luciferin contains phosphorus and can be precipitated by picric acid. The term luciferesceine is adopted for the fluorescent substances in other animals, such as the fire-fly (compare McDermott, A., 1911, i, 396). S. B. S.

Indian Edible Swallows' Nests. HEINRICH ZELLER (*Zeitsch. physiol. Chem.*, 1913, 86, 85—106).—The substance, dried in a vacuum, contained 9·43% of total nitrogen, 1·35% of histidine, 1·20% of arginine, and 1·18% of lysine. When hydrolysed with 4% sulphuric acid, two reducing substances, not identified, were obtained. N. H. J. M.

The Ferments of the Milk Glands and of Milk. WALTHER GRIMMER (*Biochem. Zeitsch.*, 1913, 53, 429—473).—Both in resting and active milk glands proteoclastic ferments are present, which can digest the proteins of the glands themselves, but not other proteins, such as fibrin, gelatin, egg-white. Glycine, leucine, and other products of hydrolysis were formed. Tryptophan was found as hydrolysis product of the active, but not of the resting gland. The expressed juices, saline extracts, and autolysates of both resting and acting glands contain a peptoclastic ferment, which can set free tyrosine from milk peptone. Reasons are given for supposing that the peptoclastic and proteoclastic ferment are not identical. The active and resting glands contain a monobutyrinase, the activity of which is considerably weakened by dialysis. The milk glands of the ox and pig possess an amylolytic ferment both when active and resting. In the case of the cow, the amylolytic ferment is more active in the resting than in the active gland, whereas the resting glands of sheep possess no marked amylolytic capacity. All glands (expressed juices and saline extract) possess a ferment capable of hydrolysing salol, and it is shown that this action is not due to the alkalinity of the medium. A guaiacum peroxydase was only found in the lactating glands of ruminants. This is apparently not identical with the *p*-phenylenediamine oxydase, as no parallelism was found between the two ferments in the various glands, etc., investigated. S. B. S.

The Quantity of Alcohol Excreted by the Animal Organism Under Various Conditions. IV. The Influence of Dose and External Temperature on the Excretion of Alcohol by the Urine and Expired Air; the Absorption of Alcohol from the Urinary Bladder. WILHELM VÓLTZ and AUGUST BAUDREXEL (*Pflüger's Archiv*, 1913, **152**, 567—578. Compare A., 1912, ii, 466).—In doses of 3 c.c. of alcohol per kilo. of body weight in dogs, from 92 to 98% is oxidised in the body; at a low external temperature the figure is higher (96% at 16°, and 92% at 26°). A certain amount of alcohol is absorbed from the bladder when the concentration in the urine is not greater than the quantity found there after its ingestion.   W. D. H.

Respiration and Metabolism in Cardio-renal Disease. THOMAS LEWIS, JOHN H. RYFFEL, CHARLES G. L. WOLF, T. COTTON, G. L. EVANS, and JOSEPH BARCROFT (*Proc. physiol. Soc.*, 1913, liii—liv; *J. Physiol.*, **46**).—The fundamental factor in such cases is an increase in the proportion of acids (exclusive of carbon dioxide) in the blood. There is a fall in the alveolar carbon dioxide, and meionexy.   W. D. H.

The Combustion of Sugar in Pancreas Diabetes. FRITZ VERZÁR and A. VON FEJÉR (*Biochem. Zeitsch.*, 1913, **53**, 140—167).—Experiments were carried out on curarised tracheotomised dogs, with the object of ascertaining whether, after extirpation of the pancreas, the intravenous injection of sugar still caused a rise in the respiratory quotient, which serves as an indication that the sugar is being burnt in the body. Such a rise occurred up to the fourth day after the operation, after which no sugar was burnt up. In certain cases, when the animal is thus rendered diabetic, sugar injection causes a rise in oxygen consumption, but in others it does not. Neither by blood transfusion from another animal, nor by infusion of ordinary blood or of blood from the pancreas, could a rise in the respiratory quotient after sugar injection be brought about in depancreatised dogs; nor could any constant changes in this factor be produced by the pancreatic hormone of Knowlton and Starling.   S. B. S.

Blood-Dissociation Curves in Uræmia. EDWARD P. POULTON and JOHN H. RYFFEL (*Proc. physiol. Soc.*, 1913, xlvii—xlviii; *J. Physiol.*, **46**).—Four cases of uræmia were investigated; the alveolar carbon dioxide pressure is low (14 to 25 instead of 40 mm.), and the blood takes up oxygen with difficulty, so that the percentage saturation is from 37 to 43 instead of 52 to 63. The lactic acid of the blood was not increased except in one case. The urea in the blood was high in all (0·21 to 0·36 instead of 0·03%). The meionexy is not due to the urea; addition of urea to normal blood does not cause the shifting of the curve.   W. D. H.

The Influence of Hydroxyl and Carboxyl Groups on the Pharmacological Action of Nitric Esters. CHARLES R. MARSHALL (*Eighth Inter. Cong. App. Chem.*, 1912, **19**, 211—215).—The experiments were carried out on cats and rabbits with the following

substances: glycerol dinitrate, glyceryl methyl ether dinitrate, mannitol tetramethyl ether dinitrate, mannitol dimethyl ether tetranitrate, mannitol pentanitrate, dulcitol pentanitrate, and the nitric esters of tartaric, citric, and lactic acids, and of their ethyl ethers. It was found generally that the presence of hydroxyl or methoxyl groups considerably diminishes the vaso-dilating action of the nitric esters. When compared with completely nitrated alcohols containing the same number of nitro-groups, most (but not all) of the esters containing hydroxyl or methoxyl groups are much less active. Carboxyl groups diminish the vaso-dilating power even more than these, and the nitric esters of tartaric, citric, and lactic acids, after neutralisation with sodium carbonate, were completely inactive as vaso-dilators. S. B. S.

The Biological Behaviour of 6-Chloro m-hydroxytoluic Acid. ERNST SIEBURG (*Biochem. Zeitsch.*, 1913, **53**, 259—264).—The substance investigated [Me: OH: CO₂H: Cl=1: 3: 4: 6] acts antiseptically about six times more strongly than phenol, and thirty times more strongly than sodium salicylate. Kobert's method was employed, in which milk is mixed with sulphur, and the concentration of the drug just necessary to inhibit hydrogen sulphide formation was ascertained. Its antiseptic power was also confirmed when pure cultures in sterile human urine were employed. When administered to man, the acid is relatively non-toxic, and 2 grams can be tolerated when administered in one dose, without evil effects. It is excreted in the form of the sulphuric acid ester, which is crystalline, melts and decomposes above 200°, and can be synthetically prepared by Baumann's method, the synthetical substance and the substance isolated from urine after ingestion of the acid being identical. The acetyl ester is readily hydrolysed by ferments contained in beer-yeast, trypsin, taka-diastase, rabbit's pancreas, and rabbit's liver. S B. S.

[Pharmacological] Investigation of Two Bromo substituted Acidylcarbamides: Bromural and Adaline. Y. AIRILA (*Chem. Zentr.*, 1913, i, 2055; from *Skand. Arch. Physiol.*, 1913, **28**, 193 -277).—The pharmacological behaviour of bromural (monobromoisovalerylcarbamide), CHMe₂·CHBr·CO·NH·CO·NH₂, and of adaline (α-bromo-α-ethylbutyrylcarbamide),

$$CBrEt_2·CO·NH·CO·NH_2,$$

has been investigated. In rabbits both behave similarly, adaline being the more lethal; they cause a diminution in the blood pressure, but are without effect on the heart. E. F. A.

Action of Adrenaline on the Bronchioles. FREDERICK L. GOLLA and W. LEGGE SYMES (*Proc. physiol. Soc.*, 1913, xxxviii—xxxix; *J. Physiol*, 46).—In cat and rabbit, adrenaline causes constriction of the bronchioles, but after constriction has been established by other drugs, such as curare or muscarine, adrenaline then causes dilatation. The following drugs resemble adrenaline in this particular: epinine (3: 4-dihydroxyphenylmethylethylamine), tyramine (*p*-hydroxyphenylethylamine), methyl-

amine, ethylamine, and *iso*amylamine. Ergamine (β-amino-4-ethylglyoxaline) never produces bronchial dilatation.

W. D. H.

The Pharmacological Action of Bromostrychnines. CHARLES R. MARSHALL (*Eighth Inter. Cong. App. Chem.*, 1912, **19**, 217—223).—The two monobromostrychnines act like strychnine, but are eight to nine times weaker. Dibromostrychnine, although it still possesses a slight convulsant action in frogs and rabbits, produces in the former animals chiefly a paralytic effect, mainly due to a depression of the motor nerve-endings.

S. B. S.

Chemistry of Vegetable Physiology and Agriculture.

Favourable Action Exercised by Manganese on Acetic Fermentation. GABRIEL BERTRAND and ROBERT SAZERAC (*Compt. rend.*, 1913, **157**, 149—151).—The addition of minute quantities of manganese has a marked accelerating influence on the conversion of alcohol into acetic acid by *B. aceti*. At first the acceleration increases with the proportion of manganese, then it reaches a maximum, and begins to decrease. Under the experimental conditions stated, 1 part of manganese sulphate in 10,000 had the optimum effect.

W. G.

The Production of Acetaldehyde During the Anaerobic Fermentations of Dextrose by Bacillus coli communis (Escherich). EGERTON CHARLES GREY (*Biochem. J.*, 1913, **7**, 359—363). —By artificial selection of this bacillus by means of growth on sodium chloroacetate, strains have been obtained which produce little or no acetaldehyde. The formation of this product by the ordinary bacillus is related to the formation of alcohol, carbon dioxide, and hydrogen rather than to the other products. It is suggested that acetaldehyde is a primary product of the fermentation.

W. D. H.

Products of the Lactic Fermentation of Sugars. ALAN A. CLAFLIN (*Eighth Inter. Cong. App. Chem.*, 1912, **25**, 343—345).—There are considerable discrepancies between the statements of different authors with reference to the amount of lactic acid produced by the lactic fermentation of sugars, but the statement of Mayer and of Kayser is usually accepted, that the yield is not over 84%, and that considerable quantities of volatile acids are formed.

A further study of this question has shown that maltose, hydrolysed starch, and inverted sucrose give identical results when fermented with the same bacteria under the same conditions. It has been found that 95—97% of the sugar may be converted into

lactic acid with formation of not more than 0·5% of volatile acids, the balance consisting of unfermented sugars. If all the sugar is fermented, the yield of lactic acid is reduced to 90%, and that of the volatile acids increased to 5%, the balance probably disappearing as water and carbon dioxide. The volatile acids are formic, acetic, propionic, and butyric acids, acetic and butyric being present in the largest quantities. The formic acid does not amount to more than 1% of the original sugar. The propionic acid occurs in the proportion of one part to ten parts of acetic acid. The percentage of acetic acid depends on the degree of aeration, and may attain to as much as 30 parts to 70 parts of lactic acid.   E. G.

Influence of Some Colloids on Alcoholic Fermentation NICOLAAS L. SOHNGEN (*Chem. Zentr*, 1913, i, 2167—2168; from *Folia Microbiol., Holland. Bettr. gesamt. Microbiol*, 2).—Fermentation was effected between 38° and 40°, at which temperature the yeast no longer grows, but the fermentative function remains unchanged. The influence of a number of colloids on the process of alcoholic fermentation was investigated. Alkali humates have an adverse action. Colloidal iron, aluminium, or silicon oxides and humic acid have no measurable influence. Biocolloids, such as turf, bloodcharcoal, garden soil, have a markedly favourable action. This is attributed to the low concentration of carbon dioxide in these liquids, which favours the rapid formation and dissipation of bubbles, so that the medium does not become supersaturated. The aggregation of the gas bubbles at the colloidal surfaces accelerates their liberation and escape.   E. F. A.

Catalysts of Alcoholic Fermentation. HANS EULER and HENRY CASSEL (*Zeitsch. physiol. Chem*, 1913, 86, 122—129).—Whilst most of the substances known to accelerate fermentation have a comparatively slight effect—the maximum rarely exceeding 20%—it was found that addition of 0·04 gram of ammonium formate to 110 c.c. of water and 2 grams of sucrose resulted in an increase of 75%. Dry yeast was scarcely, if at all, influenced by ammonium formate.

Further experiments showed that the addition of ammonium formate affects the first phase of fermentation, in which an intermediate product, or products, are formed, more than the second phase (production of alcohol and carbon dioxide).

The effect of a given amount of organic salt is greater the less yeast is present.   N. H. J. M.

Influence of the Yeasts and of the Initial Constitution of the Musts on the Acidity of Fermented Liquids. JULES VENTRE (*Compt. rend*, 1913, 157, 154—156. Compare Fernbach. this vol., i, 231).—A study of the fermentation of sugar solutions by different yeasts in media of varying acidity, and of the effect of using different organic acids to produce the initial acidity. Each yeast produces a definite fixed and volatile acidity, the acidity increasing in neutral media, but diminishing in natural or artificial acid

media. Tartaric acid is preserved unchanged in original amount, but little being consumed by the different yeasts. Malic acid appears to be the most readily attacked by the yeasts. Each yeast has a power peculiar to itself of producing succinic acid.   W. G.

Fermentations with Yeast in Absence of Sugar. XII. Changes During Fermentation by Yeast. CARL NEUBERG and JOHANNES KERB (*Ber.*, 1913, **46**, 2225—2228; *Biochem. Zeitsch.*, 1913, **53**, 406—419).—Pyruvic acid, $CH_3 \cdot CO \cdot CO_2H$, is rapidly broken down by an enzyme in yeast into acetaldehyde and carbon dioxide (compare Neuberg and Kerb, A., 1912, ii, 973). The fermentation of a mixture of pyruvic acid and glycerol has been repeated on a large scale, using 100 litres of 1% pyruvic acid. Precautions were taken that the yeast had a high fermentative power, and allowance was made for the alcohol already present in the yeast used, and also for the alcohol formed by autofermentation. A considerable amount of alcohol is formed from pyruvic acid, and still more when both pyruvic acid and glycerol are present. It is considered that the influence of the glycerol is only indirect, in that it acts to protect the enzyme and increase its reducing power.

*iso*Butaldehyde and valeraldehyde are readily converted by yeast into the corresponding alcohols with a yield of 85% in the latter instance.   E. F. A.

The Separation of Life and Fermentative Power. THOMAS BOKORNY (*Pflüger's Archiv*, 1913, **152**, 365—436).—Experiments on yeast show that by chemical reagents of appropriate strength it is possible to kill the cells, but leave the enzymic power intact; for instance, this is accomplished by sulphuric acid from 0·1 to 0·5% concentration. Details regarding a large number of chemical reagents (inorganic and organic) are given. The kind of yeast used is one factor in the process.   W. D. H.

The Fat of Yeast. H. A. D. NEVILLE (*Biochem. J.*, 1913, **7**, 341—348).—The chief saturated acid in the fat of yeast is penta-decoic acid (Hinsberg and Roos, A., 1903, i, 56); arachidic acid and unsaturated acids with the formulæ $C_{16}H_{30}O_4$, $C_{18}H_{34}O_2$, and $C_{18}H_{32}O_2$ are also present. The cholesterol melts at 115 - 147°.
     W. D. H.

The Protein Substances of Yeast and their Products of Hydrolysis. PIERRE THOMAS and (Mme.) SOPHIE KOLODZIEJSKA (*Compt. rend.*, 1913, **157**, 243—246. Compare this vol., i, 912).— The authors have studied the products of hydrolysis of the two protein substances obtained from yeast (compare *loc. cit.*), one of which belongs to the casein group, and the other to the vegetable albumins. By hydrolysis with concentrated hydrochloric acid, followed by distillation with magnesium oxide, and then precipi-tation of the humic nitrogen by evaporation in acid solution, and of the amino-compounds with phosphotungstic acid, the nitrogen content has been determined as ammoniacal, humic, diamino· and

monamino-nitrogen.   The figures are in fairly close agreement with Osborne's values for casein.   Similar treatment of the cerevisine or vegetable albumin gives values agreeing well with Osborne's results for legumeline.

Hydrolyses have also been performed with sulphuric acid, and estimations made of the histidine, arginine, and lysine.   W. G.

A Forgotten Investigator.   A Contribution to the History of the Yeast Manufacture.   F. G. WALLER (*Chem. Weekblad*, 1913, **10**, 635—644).—A review of the development of the manufacture of yeast, in which the author contends that a practical technical method for its production by the air process was first devised by Eusebius Bruun.   A. J. W.

Potassium, Sulphur, and Magnesium in the Metabolism of Aspergillus niger.   H. J. WATERMAN (*Proc. K. Akad. Wetensch, Amsterdam*, 1913, **15**, 1349—1355).—Deficiency of potassium chloride allows the production of mycelium, but not of spore formation. Only in the concentration of $M/37,500$ does spore formation commence after eight days.   When potassium sulphate is added, larger quantities inhibit the formation of spore, which develop after two days, when potassium sulphate is absent.   After forty days, all the moulds were covered with spores in all the concentrations of sulphate added.   During the growth, sulphur accumulates in the cells, and is afterwards partly excreted.   Relatively large quantities of magnesium are necessary to produce a perceptible growth of mycelium, as none visible to the naked eye appeared even in the concentration of $M/2,470,000\text{-}MgSO_4,7H_2O$ per litre.   In the concentration $2M/247,000$, considerable growth only appeared after some days.   S. B. S.

Amygdalase and Amygdalinase in Aspergillus niger and Some Allied Hyphomycetes.   MAURICE JAVILLIER and (Mme.) HÉLÈNE TSCHERNORUTZKY (*Ann. Inst. Pasteur*, 1913, **27**, 440—449).—*Sterigmatocystis nigra* and most of the mosses examined contain unequal amounts of amygdalase and amygdalinase.   The amounts of both diastases is diminished in absence of zinc.   The diastases are active in solutions which are neutral or slightly acid to helianthin, and the optimum temperature is higher than that of the same diastases of almonds.

The percentage amount of the diastases in the plants varies with the age of the mycelium, and reaches its maximum at the time of sporulation.   The two diastases pass into the culture medium very unequally.   N. H. J. M.

Biological and Toxicological Studies on Penicillium stoloniferum (Thom.).   CARL L. ALSBERG and OTIS F. BLACK (*Eighth Inter. Cong. App. Chem.*, 1912, **19**, 15—23).—Cultures of *Penicillium stoloniferum* were obtained by Thom from spoiled Italian maize.   When grown on Raulin's medium, these were found to produce an acid, $C_{17}H_{20}O_6$, white needles, m. p. 140°, which was of phenolic character, almost insoluble in water, but soluble in

most organic solvents, to which the name *mycophenolic acid* is given. It gives with ferric chloride the colour which is character-istic of spoiled Italian maize, and resembles in many respects the lichen acids.   S. B. S.

Sterigmatocystis nigra and Lactose. HENRI BIERRY and (Mlle) F. COUPIN (*Compt. rend*, 1913, **157**, 246—247).—By cultivation of *Sterigmatocystis nigra* on Raulin's liquid for three days, then on a similar liquid deprived of all carbohydrate, and finally on this liquid with the sucrose replaced by lactose, lactase is produced in the plant, but in an endocellular form, and in con-sequence it does not pass into water when the crop is macerated with it.   W. G.

The Influence of the Chemical Constitution of Certain Organic Hydroxyl and Aminic Derivatives on their Germicidal Power. GILBERT T. MORGAN and E. ASHLEY COOPER (*Eighth Inter. Cong. App. Chem.*, 1912, **19**, 243—257).—The antiseptic value of several series of substances was investigated by Chick and Martin's modification of the Rideal-Walker process. The antiseptic value of the following classes of substances was ascertained. The aliphatic alcohols: The "carbolic acid coefficients" of these were all low. Certain phenols: The influence of the addition of alcohol to these was also investigated, and found to vary in different cases. The carbolic acid coefficients of the dihydroxybenzenes were as follows. (With *B. Typhosus*) Resorcinol, 0·29; catechol, 0·48; quinol, 1·1. The results with the nitrophenols were as follows (*Staphylococcus py. aur.*): *p*-Nitrophenol, 2·3; potassium *p*-nitrophenoxide, 0·52; *m*-nitrophenol, 3·5; picric acid, 7·5. The coefficients for coumarin, the coumaric acids and salts were low. The coefficients for the dihydroxynaphthalenes were, for the 2.3-derivative, 4·4, and for the 2:7-derivative, 2·8. The coefficients of several series of both aliphatic and aromatic amines were also determined. The chief results are the following (with *B. Typhosus*), ethylamine, 1·27; *iso*amylamine, 2·8; *n*-heptylamine, 24·3; *ac*-tetrahydro-β-naphthyl-amine, 5·3; aniline, 0·57; the toluidines, ortho-, 1·00; meta, 1·30; para-, 1·25; pyridine, 0·18.   S. B. S.

Compounds Obtained from Plant Seeds by the Methods for Extracting Lecithin. I. Introduction: Bean Seeds. GEORG TRIER (*Zeitsch. physiol. Chem.*, 1913, **86**, 1—32).— A summary is given of previous work on plant phosphatides, and the opinion is expressed that the apparent differences between plant and animal phosphatides is due to the incomplete investigation of the former and to incorrect interpretation of the experimental results. The preparation and purification of the lecithin contained in *Phaseolus vulgaris* is described.   E. F. A.

Compounds Obtained from Plant Seeds by the Methods for Extracting Lecithin. II. Hydrolysis of Egg-albumin. III. Oat Seeds. GEORG TRIER (*Zeitsch. physiol. Chem.*, 1913, **86**, 141—152, 153—173).—Previous experiments having shown that

aminoethyl alcohol is obtained by hydrolysing the lecithin of bean seeds, it became desirable to ascertain whether the compound could be obtained from other lecithins. Egg-lecithin, when hydrolysed, yielded, in addition to choline, small amounts of aminoethyl alcohol and glycerolphosphoric acid. Evidence was obtained that the aminoethyl alcohol is attached to the lecithin by the hydroxyl group, the amino-group being free.

Further experiments, with oats, showed that the phosphatides of the seeds of cereals are very similar to egg-lecithin and the lecithins of leguminous seeds. N. H. J. M.

Quantitative Experiments on the Effect of Formaldehyde on Living Plants. SARAH M. BAKER (*Ann. Bot.*, 1913, **27**, 411—442).—The results of experiments on the growth of seeds in atmospheres containing known amounts of formaldehyde showed that in presence of light, formaldehyde is utilised to some extent for the synthesis of food materials. In absence of light, formaldehyde is not assimilated; it seemed, however, to stimulate respiration.

Acetaldehyde is not assimilated in presence of light. The change in the dry weight of the cultures, when compared with the carbon dioxide respired, gave a ratio closely agreeing with that calculated for the complete oxidation of a carbohydrate. With cultures kept in darkness, no change occurred in the relations between loss in dry weight and the respired carbon dioxide. Formaldehyde was therefore not converted into carbon dioxide, and was not used as a source of food materials in absence of light.

It is probable that formaldehyde may function as a stage in photosynthesis; but the production of sugars and other food materials requires light energy. N. H. J. M.

Action of Sulphites, Thiosulphates, and Sulphur in Soils on the Growth of Plants. WALTER THALAU (*Landw. Versuchs-Stat.*, 1913, **82**, 161—209).—The results of pot experiments with different plants showed that, in a loamy soil, ammonium sulphite has the same effect as ammonium sulphate; in sand, ammonium sulphite has somewhat less effect than the sulphate; whilst in peat the yield was much less with sulphite.

In water cultures, ammonium sulphite is very injurious; germination is retarded in 0·4% solutions.

When exposed to air for a short time, ammonium sulphite is oxidised to sulphate; the rate of oxidation is increased by dissolving the salt in water, and still more in presence of soil.

Calcium sulphite was found to have no injurious action in loamy and sandy soils; in water cultures, and perhaps in peat, it reduced the yields. Sodium thiosulphate had no injurious effect. Flowers of sulphur had no very appreciable effect, and further experiments will be necessary. N. H. J. M.

Presence of Hemicelluloses in Root-stock, Rhizomes, and Tubers. ANTON STIEGER (*Zeitsch. physiol. Chem.*, 1913, **86**, 270—282).—The investigation of root-material from a number of

plants showed that in every case hemicellulose was present, a mixture of galactose and arabinose in approximately equal quantities being obtained on hydrolysis, whilst in no instance was either mannose or fructose present. The root and rhizome of *Asparagus officinalis* yielded only arabinose. The presence of much or little starch in the roots had no apparent effect. , It is left undecided whether the hemicelluloses act as a reserve or as a skeletal material in the vegetative parts of plants.   E. F. A.

Distribution of Asparagine, Glutamine, Arginine, and Allantoin in Plants. ANTON STIEGER (*Zeitsch. physiol. Chem.*, 1913, **86**, 245—269).—Asparagine and glutamine were sought for in the roots, underground shoots, portions above ground, or in the seedlings of a large variety of plants. It is characteristic of some families that they contain asparagine alone; in others only glutamine is present, whilst a few contain both amides. The last may contain either amide in excess or both in equal proportions. The results show a remarkable parallelism between the morphological-anatomical classification of the plants and their chemical behaviour. Certain irregularities are recorded where plants, in which normally only asparagine is present, sometimes contain more or less glutamine as well. Such variations are attributed to the altered conditions of environment.

Arginine almost always accompanies asparagine, but is less often present with glutamine. It is found when neither amide is present, where it probably acts as a reserve material.

The presence of allantoin in a number of plants is established.

E. F. A.

Antiaris Latex. HEINRICH KILIANI (*Ber.*, 1913, **46**, 2179—2188. Compare this vol., i, 381).—A fresh supply of preserved Antiaris latex was received from Mid-Borneo. It contained a deposit of, the protein in the form of well-defined, short columns. The latex is therefore a saturated solution of the protein, which must be a original ingredient, and not the product of subsequent fermentation. On this occasion, the most exhaustive extraction, full details of which are described, failed to yield more than one-sixth of the amount of glucosides which was previously obtained, and only β-antiarin (0·1% of the latex), but no α-antiarin could be isolated. The crude glucoside contained, however, a new active substance, which is easily soluble in water, and is designated *γ-antiarin*.

Ether extracted from the alcoholic solution of the glucosides a new *acid*, $C_{16}H_{14}O_7$ (?), which forms pale yellow, glistening crystals, sinters at 178—184°, is strongly acid, gives a *calcium* salt, and develops a green coloration with ferric chloride, changing to deep red with a drop of ammonia. The alkaline solutions rapidly darken in the air, from which it appears that the acid is a pyrogallol derivative, probably metameric with lecanoric acid.

J. C. W.

Alcohol From the Fruit of Arbutus unedo (Ellerone).
GIOVANNI SANI (*Atti R. Accad. Lincei*, 1913, [v], 22, i, 884—885).—
Fermentation of this fruit yields a product containing 9·15—9·75%
of alcohol. The alcohol recovered from it by distillation had an
acidity of 0·132 gram per litre (as acetic acid), contained esters
(1·757 grams per litre, as ethyl acetate), furfuraldehyde, methyl
alcohol, and fusel oil (2·321 grams per litre), but no free or combined
hydrogen cyanide.   R. V. S.

Chemical Examination of the Seeds of the Cacao Tree.
L. REUTTER (*Compt. rend.*, 1913, 156, 1842—1844).—Ground cocoa
beans were treated with steam at 110°, deprived of oil, and extracted
with warm dilute methyl alcohol. On spontaneous evaporation,
the reddish-violet solution deposits white, microscopic crystals,
m. p. 184—185°. This substance, termed *cacaorine*, $C_{16}H_{20}O_6N_3$,
yields a neutral solution in water, which is optically inactive. On
hydrolysis, it yields theobromine and a small quantity of a reddish-
brown precipitate.

The mother liquor from cacaorine, when further concentrated,
yields *cacao-red*, $C_{40}H_{60}O_{27}N$, reddish-violet leaflets, which slowly
oxidise on exposure to air, becoming brown. It is soluble in water
and in methyl alcohol. The aqueous solution is coloured yellowish-
brown by alkalis, bright red by acids. It reduces Fehling's
solution, but is optically inactive. When hydrolysed by dilute
sulphuric acid, it yields carbon dioxide, a dextrorotatory sugar,
and *cacao-brown*, $C_{76}H_{78}O_{34}N$.   H. W.

Ash of the Castor Bean. MARSTON LOVELL HAMLIN (*Biochem.
Bull.*, 1913, 2, 410—411).—The following were the results obtained :

	SiO₂.	CaO.	MgO.	P₂O₅.	Mn.	Total ash.
Per cent. in dry oil-free kernel...	0·04	0·28	1·51	3·52	0·00056	7·3
Per cent. in ash	0·5	3·9	20·7	48·2	0·0076	—

Schulze and Godet obtained the following figures from dry,
but not oil-free, kernels :

	CaO.	MgO.	P₂O₅.	Total ash.
Per cent. in dry substance ...	0·15	0·72	1·16	3·64
Per cent. in ash	4·0	19·8	31·9	—

W. D. H.

The Composition of Coffee Essence ; Presence of Pyridine.
GABRIEL BERTRAND and GUSTAVE WEISWEILLER (*Compt. rend.*, 1913,
157, 212—213).—The authors have proved the presence of pyridine
in the infusion of freshly roasted and ground coffee, by precipitation
with silicotungstic acid and subsequent preparation of its platini-
chloride. Pyridine is present to the extent of 200—250 mg. per
kilo. of freshly roasted coffee.   W. G.

**Nitrogenous Constituents of the Fungus, Cortinellus
shiitake (P. Henn.).** KIYOHISA YOSHIMURA and M. KANAI (*Zeitsch.
physiol. Chem.*, 1913, 86, 178—184).—The sample examined contained
87·355% of dry matter of the following composition :

Nitrogen.			Crude fat.	Ash.	P_2O_5.
Total.	As proteins.	As ammonia.			
3·993	2·406	0·085	0·641	5·781	0·804

The following substances were obtained from 2 kilos. of the air-dried fungus: adenine, 0·40; choline, 0·41; alanine, 1·60; leucine, 2·30; copper glutamate, 0·50; proline, 0·30; mannitol, 50·00 grams: also a trace of trimethylamine and a little phenylalanine.

<div align="right">N. H. J. M.</div>

Latex of Ficus coronata; an Incomplete Vegetable Pancreatic Juice Containing a Proteolytic Enzyme, but no Amylase. C. GERBER (*Compt. rend.*, 1913, **156**, 1917—1919. Compare A., 1911, ii, 647; 1912, ii, 801, 977).—The latex has no action on starch paste or soluble starch, and consequently contains no amylase. Judging from its action on egg-yolk, it contains a lipase twice as active as that in the latex of *Ficus carica* (*loc. cit.*), and slightly more resistant to the influence of heat and of acids. It also contains a very active proteolytic ferment, which from its activity in coagulating milk appears to be four times as active as the similar ferment in *Ficus carica* latex, and more resistant to heat than the latter. The rennet of *Ficus coronata* is affected by acids and salts in the same way as that of *Ficus carica*. The latex is like that of *Morus nigra*, an incomplete vegetable pancreatic juice, but differs from this in containing a rennet more active towards boiled than raw milk.

<div align="right">T. A. H.</div>

The Influence of the Carbonates of the Rare Earths (Cerium, Lanthanum, Yttrium) on Growth and Cell Division in Hyacinths. WILLIAM HOWEL EVANS (*Biochem. J.*, 1913, **7**, 349—355).—The concentration of the carbonates of the rare earths necessary to produce physiological effects is very small. Lanthanum and cerium are favourable to growth and cell-division; yttrium is unfavourable. The lanthanum ion has a special effect on the flower-stalk, causing an increase in length.

<div align="right">W. D. H.</div>

Value of Caoutchouc in Kickxia-elastica. DAVID SPENC and WILLIAM F. RUSSELL (*Kolloid. Zeitsch.*, 1913, **13**, 41—46) —The authors have worked up six specimens of indiarubber latex by different methods with the object of ascertaining whether the kickxia caoutchouc could be converted into a good commercial product. They conclude that when carefully worked, this substance, as far as its physical properties are concerned, gives a good caoutchouc, but as far as its composition and other properties are concerned, the kickxia latex is inferior to the Plantagen-Hevea latex.

<div align="right">J. F. S.</div>

Analyses of Some Wyoming Larkspurs. I. FREDERICK W. HEYL, F. E. HEPNER, and SYLVESTER K. LOY (*J. Amer. Chem. Soc.*, 1913, **35**, 880—885).—Analyses are given of the various parts of *Delphinium Nelsoni*, *Delphinium glaucum*, and *Delphinium geyeri*.

The leaves of all three varieties were found to contain d-mannitol, whilst the last variety is found to yield the highest proportion of mixed alkaloids. D. F. T.

Constituents of the Berries of Kuko (Lycium chinense). T. Furuya (*Chem. Zentr.*, 1913, i, 1823; from *Arb. Pharm. Inst. Univ. Berlin*, **9**, 117—120).—The berries of Kuko (*Lycium chinense*) yield 0·0912% of betaine. E. F. A.

Constituents of the Roots of Stemona sessilifolia. T. Furuya (*Chem. Zentr.*, 1913, i, 1823—1824: from *Arb. Pharm. Inst. Univ. Berlin*, **9**, 112—116).—The powdered roots contain an alkaloid *hodorine*, $C_{19}H_{31}O_5N$, which was not obtained crystalline. The *hydrobromide* forms a colourless, odourless, crystalline powder, m. p. 258—259°. The *hydrochloride* has m. p. 244—247° (decomp.). E. F. A.

Manketti Seed Oil. Hermann Thoms (*Chem. Zentr.*, 1913, i, 1823; from *Arb. Pharm. Inst. Univ. Berlin*, **9**, 225—227).— Manketti seeds yield a pale yellow oil of nutty odour and agreeable flavour. The oil becomes cloudy at $-2°$. It is optically inactive, and has the following constants: Saponification number, 195·2; Reichert-Meissl, 1·085; Polenske, 0·6; iodine number, 130·4; Hehner number, 98·5; m. p. of the fatty acids, 40°; iodine number of these, 140·7; acetyl number, 163·2. The crude oil consists of the above oil, a half solid fat, m. p. 33°, and a watery fluid. E. F. A.

"Tannin Masses" in the Persimmon Fruit. Ernest D. Clark (*Biochem. Bull.*, 1913, **2**, 412—418).—On hydrolysis of tannin masses from the persimmon, tannin, phloroglucinol, and much colloidal residue are obtained, but no hexose or pentose. The union between the two first-mentionel substances is probably similar to that of phloroglucintannoids in various plants. The colloidal residue is cellulose-like. In the presence of phloroglucinol, the ferric chloride test for tannin is untrustworthy. W. D. H.

Investigation of Puccinia graminis Persoon. A. von Pomarski (*Chem. Zentr.*, 1913, ii, 288; from *Sep. Zool. Lab.*, 1912, **8**, 85—120).—The air-dried spores of *Puccinia graminis* contain 12·1% of moisture, 3·25% of nitrogen, 5·1% of fat, and 9·15% of cell membrane. The last yields dextrose, formic and acetic acids on hydrolysis, it contains about 7% of nitrogen, and is analogous to chitin or chitosan.

The fat contains lauric acid, heptoic acid, oleic acid, and glycerol, also 32% of a wax and dioleinlecithin.

Dextrose, mannitol, and an unknown disaccharide are present, also the enzymes, invertase, catalase, diastase and lipase, as well as brownish-red and green pigments. E. F. A.

Arsenic and Manganese in Some Seaweeds. Henri Marcelet (*Chem. Zentr.*, 1913, ii, 278; from *Bull. Sci. Pharmacol.*, 1913, **20**, 271—275).—Seaweeds contain from 0·005 to 0·5 mg. of

arsenic per 100 grams of dry material. Apparently the proportion of arsenic is greatest when that of chlorophyll is least; this is the opposite of the relation in land plants. In *Posidonia* the leaves contain 0·045 mg.; the roots, 0·035 mg.; and the whole plant, 0·04 mg. of arsenic per 100 grams.   E. F. A.

Occurrence of Trehalose in Selaginella lepidophylla. OTTO ANSELMINO and E. GILG (*Ber. deut. Pharm. Ges.*, 1913, **23**, 326—330). —On extraction with alcohol, *Selaginella lepidophylla* furnished trehalose, which was identified by means of its melting point, composition, etc. *S. Galeottii* and *S. Kraussiana* yielded no trehalose.   T. A. H.

The Unsaponifiable Constituents of Sesame Oil. ALFRED HEIDUSCHKA (*Eighth Inter. Cong. App. Chem.*, 1912, **11**, 13—16).— Sesame oil contains three unsaponifiable substances, namely, phytosterol, sesamin, and a thick yellow oil. The phytosterol, m. p. 136·2—136·8°, is a definite compound, and cannot be separated, by fractional crystallisations, into fractions having different melting points. Sesame oil yields about 0·17% of sesamin; this contains 67·36% of carbon and 5·43% of hydrogen, and has a molecular weight of 341·8. From these figures the formula $C_{20}H_{19}O_6$ is deduced for the substance. The yellow oil could not be separated into any characteristic or definite substances.
                          W. P. S.

Chemical Examination of Wheat Germ. FREDERICK B. POWER and ARTHUR H. SALWAY (*Pharm. J.*, 1913, **91**, 117—120).— Wheat germ was found to contain sitosterol, choline, betaine, allantoin, sucrose, dextrose, and raffinose; no evidence was obtained of the presence of asparagine, which has been recorded as a constituent of wheat germ by Frankfurt (A., 1897, ii, 67). About 7% of fatty oil was obtained from the wheat germ under examination, the oil consisting of the glycerides of stearic, palmitic, and linolic acids; the quantity of linolic acid was about three times as much as that of the total solid acids. The amount of resinous substance present was 0·04%, as was also a small quantity of an amorphous glucosidic substance. It was ascertained that wheat germ contains a very small amount of sinapic acid, probably present as sinapine, a choline ester of sinapic acid.   W. P. S.

Influence of the Lime-Magnesia Ratio. P. L. GILE and C. N. AGETON (*J. Ind. Eng. Chem.*, 1913, **5**, 564—567).—Experiments are described in which bush beans were grown for three years on plots 30 × 60 dcm., the soil of which contained varying proportions of lime and magnesia.

The results indicate that bush beans are independent of lime-magnesia ratio in the soils employed; and that the amount of lime in the plants remained the same, with increasing amounts of lime in the soil.

The conclusion is drawn that whilst the ratios of different salts,

including lime and magnesia, affect plant growth under certain conditions, the hypothesis of the lime-magnesia ratio cannot be considered as applying to all soil conditions. N. H. J. M.

Unfermentable Sugar (Pentose) and the Formation of Furfuraldehyde in Wine. RUDOLF HAID (*Chem. Zentr.*, 1913, i, 2170; from *Zeitsch. Gärungsphysiol*, 1913, **2**, 107—109. Compare Pasquero and Cappa, A., 1912, ii, 103).—The furfuraldehyde formed on the distillation of wine cannot be derived from *l*-arabinose, since this pentose, when distilled with malic or tartaric acid, does not yield furfuraldehyde. An unknown pentose is assumed to be the source of the aldehyde. E. F. A.

The Advance and Prospects of the Newer Agricultural Chemistry (Chiefly Land Chemistry) since the Discoveries of Modern Physical Chemistry and Colloidal Chemistry Have been Employed. HANS BREHM (*Kolloid. Zeitsch*, 1913, **13**, 19—35).—The author considers the work which has been done in connexion with agricultural soil and the processes taking place in it, from the colloidal chemistry point of view. The various substances occurring in the soil are individually considered, and a long bibliography of the chief researches on the subject from 1901 to the present time is given. J. F. S.

Mineralogical Soil Analysis. WILLIAM J. McCAUGHEY (*J. Ind. Eng. Chem.*, 1913, **5**, 562—564).—The potassium minerals usually present in soils are orthoclase, microcline, muscovite, and biotite. Muscovite is the most resistant, and probably contributes very little to the soil solution; biotite is the most readily decomposed. Orthoclase is the commonest, and occurs in amounts varying from 3 to 30%.

The commonest calcium minerals are epidote, hornblende, plagioclase, and garnet. Epidote is a normal constituent of most soils, whilst garnet, which is formed by contact metamorphism, occurs less frequently. Hornblende is the common calcium mineral, and weathers generally, forming chlorite.

Quartz crystals occur so frequently in limestone soils and are so exceptional in others, that their presence seems to indicate origin from limestone. N. H. J. M.

Quantitative Investigations on the Reaction of Aqueous Extracts of Soils. TEODOR SAIDEL (*Bull. Acad. Sci. Roumaine*, 1913, **2**, 38—44).—An electrical method for estimating the reaction of soil extracts is described with sketch of the apparatus employed. The difficulty due to loss of carbon dioxide when hydrogen is passed through the solution can be overcome by mixing the hydrogen with a definite amount of carbon dioxide, or else by boiling off the carbon dioxide.

The results of estimations obtained with several soils shows that there is a considerable difference in reaction between forest soils and the soils of the steppes on the one hand, and podsol soils on the other. N. H. J. M.

Alkaline Reactions Caused by Acids and their Acid Salts in Soils. GIULIO MASONI (*Chem. Zentr.*, 1913, i, 1999 ; from *Staz. sperim. agrar. ital.*, 1912, **46**, 219—240. Compare A., 1912, ii, 677).— Organic and mineral acids and their acid salts are able to cause an alkaline reaction in soils. In calciferous soils, calcium carbonate is formed, which in aqueous solution, on the addition of acid, parts with hydroxyl. The alkaline reaction may also be due to the action of acids on basic salts of magnesium, calcium, or aluminium. Acid alkali salts will give rise to alkali carbonates. The influence of the alkaline reaction on the biological function of the roots is discussed.   E. F. A.

Behaviour of Amino-acids in the Soil. SAMUEL L. JODIDI (*Eighth Inter. Cong. App. Chem.*, 1912, **26**, 119—134. Compare A., 1911, ii, 820 ; 1912, ii, 292).—In connexion with a study of the proteins contained in soils, experiments have been undertaken to ascertain the rate at which amino-acids in the soil eliminate their nitrogen in the form of ammonia and whether the process is quantitative. In these experiments, definite quantities of various amino-acids were mixed thoroughly with weighed portions of soil and kept in covered vessels at 22—27° ; after the lapse of some days the quantity of ammoniacal nitrogen formed was estimated. The various amino-acids yielded under these conditions the following maximum proportions of ammonia: glycine, 81·03% ; alanine, 75·58% ; leucine, 59·62% ; aspartic acid, 72·74% ; glutamic acid, 72·19% ; phenylalanine, 54·31% tyrosine, 59·65% asparagine, 77·47%.

The results do not show whether amino-acids can be quantitatively de-aminated in the soil. It is possible that during the course of the process, some of the ammonia produced is oxidised to nitrites and nitrates. There are also other factors to be taken into consideration. It has been demonstrated, however, that the amino-acids examined readily lose nitrogen in the form of ammonia, and that the rate of the change is greatly influenced by the structure of the acids, acids of similar structure yielding about the same proportion of ammonia.   E. G.

Normal and Abnormal Constituents of Soil Organic Matter. ELBERT C. LATHROP (*Eighth Inter. Cong. App. Chem.*, 1912, **15**, 147—151).—The following compounds may be considered as normally present in soils : pentosans, pentoses, histidine, xanthine, hypoxanthine, cytosine, and, perhaps, creatinine. Arginine and adenine only occur infrequently, whilst dihydroxystearic and picolinecarboxylic acids, being injurious to plants, must be classed as abnormal soil constituents.

It is uncertain whether agroceric, lignoceric, paraffinic and mono-hydroxystearic acids, agrosterol, phytosterol, and hentriacontane should be considered as normal or abnormal constituents of soils.
                                                N. H. J. M.

Organic Chemistry.

Determination of the Critical Constants of Methane. ETTORE CARDOSO (*Arch. Sci. phys. nat.*, 1913, [iv], **36**, 97—100).—Preliminary details are given of the apparatus employed in the determination of critical constants; the following values are found for methane : critical temperature, 82·85° ; critical pressure, 45·60 atm. ; critical density, 0·1623. J. F. S.

Preparation of Erythrene and Isoprene. FARBENFABRIKEN VORM. FRIEDR. BAYER & Co. (D.R.-P. 261876).—When the hydrochlorides of δ-dimethylamino-Δ*ᵅ-isoamylene* and of δ-dimethylamino-Δ*ᵅ*-butylene (this vol., i, 342) are heated at 200—240°, they decompose into dimethylamine and isoprene or erythrene respectively. F. M. G. M.

Preparation of Halogenated Propanes. HENDRIK JACOBUS PRINS (D.R.-P. 261689).—Compounds of general formulæ C_3X_7H, $C_3X_6H_2$ and $C_3X_5H_3$ (where X is Cl or Br), are readily prepared from a mixture of halogenated methane and halogenated ethylenes (of formulæ $CX_3 \cdot CHX$ and $CHX \cdot CHX$) by mixing together in the required proportions in the presence of aluminium chloride or bromide at about 20°.

aaaβγγ-Hexachloropropane, $CCl_3 \cdot CHCl \cdot CHCl_2$, obtained from chloroform (or carbon tetrachloride) and dichloroethylene, is a colourless liquid, b. p. 216° ; when treated with alcoholic potassium hydroxide at the ordinary temperature, it gives rise to *aaβγγ-pentachloropropylene*, $CCl_2 \cdot CCl \cdot CHCl_2$, b. p. 184°, from which *aββ-trichloroacraldehyde*, $CCl_2 \cdot CCl \cdot CHO$, b. p. 164°, is obtained by the action of concentrated sulphuric acid, which latter can further be converted into *aβ-dichloroacrylic acid*, $CHCl \cdot CCl \cdot CO_2H$, and its *amide*, $CHCl \cdot CCl \cdot CO \cdot NH_2$, m. p. 132°.

aaaβγγγ-Heptachloropropane, $CCl_3 \cdot CHCl \cdot CCl_3$, is an oil with a penetrating odour, m. p. 11—12°, b. p. 164—166°/90 mm., D^4 1·9, $n_D^{16·5}$ 1·5418, and in a similar manner furnishes *hexachloropropylene*, C_3Cl_6, b. p. 210°, and *trichloroacrylic acid*.

aaβγγ-Pentachloropropane, $CHCl_2 \cdot CHCl \cdot CHCl_2$, a colourless liquid, b. p. 198—200°, gives rise to *aβγγ-tetrachloropropylene*,
$$CHCl \cdot CCl \cdot CHCl_2,$$
b. p. 65°, and the *aldehyde*, $OH \cdot CH \cdot CCl \cdot CHO$, m. p. 145°.

aaβ-Pentabromopropane, $CHBr_2 \cdot CHBr \cdot CHBr_2$, has b. p. 163—165°/18 mm. F. M. G. M.

Catalytic Action of Certain Manganese Salts on Alcohols (Spirits) in the Presence of Hydrogen Peroxide. A. C. CHAUVIN (*Ann. Fal.*, 1913, **6**, 463—466).—The addition of 1% of hydrogen peroxide solution (perhydrol) to crude alcohol, spirits, and liqueurs, produces, after thirty days' contact, an increase in the quantities of the usual impurities (aldehydes, esters, higher alcohols, etc.), which were

present originally, but the furfuraldehyde tends to disappear. The action of the peroxide is augmented by the addition of about 0·01% of manganese salts, the acetate having the greatest effect. In the case of kirsch liqueur the hydrocyanic acid is decomposed by the treatment, whilst the essential oils present in absinthe are resinified. W. P. S.

Preparation of Esters from Alcohols and Organic Acids. OTTO HAUSER and ADOLF KLFOTZ (D.R.-P. 261878).—An account of work previously described (Hauser and Klotz, this vol., i, 246). tert.-*Butyl* n-*nonoate* has b. p. 242°, and tert.-*butyl* n-*octoate*, b. p. 231°.
F. M. G. M.

Alkylation of Ethyl Cyanoacetate. JOHN O. HESSLER (*J. Amer. Chem. Soc.*, 1913, 35, 990—994).—The ethylation of ethyl cyanoacetate has already been studied (Hessler, A., 1908, i, 182; 1904, i, 830; Hadley, A., 1912, i, 699), and the author has now turned his attention to the substitution of other alkyl groups into this ester.

Crude ethyl a-cyanopropionate, obtained by the action of sodium ethoxide and methyl iodide on an alcoholic solution of ethyl cyano-acetate (Henry, A., 1887, 796), after shaking with 10% sodium hydroxide solution and subsequent fractionation yielded about 12% of ethyl a-cyano-a-methylpropionate, b. p. 77°/9 mm., 185°/ord. pressure, D^{26} 0·971. The sodium hydroxide extract contained a-cyanopropionic acid, b. p. 142—145°/11 mm., D^{20} 1·14, from the silver salt of which pure ethyl a-cyanopropionate, b. p. 89—90°/20 mm., 192—193°/ord. pressure, D^{22} 0·998, was obtainable by the action of ethyl iodide.

Crude ethyl a-cyano*iso*valerate, prepared in a similar manner to the above methyl derivative, was submitted to like treatment with sodium hydroxide; it yielded about 10% of ethyl a-cyano-a-*iso*propyl-*iso*valerate, b. p. 240°, $D^{29·4}$ 0·918, and also cyano*iso*valeric acid, b. p. 166—168°/28 mm.; the silver salt of the latter reacted vigorously with ethyl iodide, giving pure ethyl a-cyano*iso*valerate, b. p. 113°/25 mm., 211°/739 mm., $D^{29·2}$ 0·962.

Crude ethyl a-cyano-a-*iso*heptoate contained 28% of ethyl a-cyano-a-*iso*amyl*iso*heptoate, b. p. 158—159°/16 mm., D^{22} 0·909, which was unaffected by long standing with cold 10% sodium hydroxide solution; the sodium hydroxide extract yielded a-cyano*iso*heptoic acid, m. p. 47—48°, which was converted through the ammonium salt into the silver salt; this reacts with ethyl iodide, giving ethyl a-cyano*iso*-a-heptoate, b. p. 125°/12 mm., 241°/749 mm., D^{21} 0·939, which is readily hydrolysed by 10% sodium hydroxide solution.

a-Cyano-a-*iso*heptoamide, m. p. 142°, obtained by the action of con-centrated ammonia solution on the ester, when heated in a vacuum with phosphorus pentachloride to 120—130° undergoes conversion into a-cyano-a-*iso*heptonitrile, b. p. 121—122°/18 mm., D^{25} 0·899.
D. F. T.

Glycerol Esters of Benzoic and Myristic Acids, and the Partial Saponification of Triglycerides. ANDREAS LIPP and P. MILLER (*J. pr. Chem.*, 1913, [ii], 88, 361—394).—The author reviews

previous work on the hydrolysis of fats, and points out that, although it is now generally accepted that the hydrolysis of triglycerides takes place in stages with the intermediate formation of diglycerides and monoglycerides, only in the case of sulphuric acid as a hydrolytic agent has this view been placed beyond all doubt by the isolation of the intermediate products (compare Thieme, A., 1912, i, 333; Grün and Corelli, *ibid.*, 409). The work described in the present paper deals with the hydrolysis of tribenzoin and trimyristin by means of water and alkali hydroxides in aqueous, alcoholic and acetone solutions. It is definitely proved by the isolation of the corresponding di- and mono-glycerides from the product obtained by partial saponification of the triglycerides, that in these cases also a similar hydrolysis in stages takes place.

When heated in sealed tubes at 225° in an atmosphere of carbon dioxide an equimolecular mixture of benzoic acid and glycerol yields as main product a-monobenzoin, which is freed from the accompanying aa-dibenzoin by taking advantage of its solubility in water; the latter compound forms the chief product if the benzoic acid is in excess (2 mols.).

In agreement with the observations of Thieme (A., 1912, i, 333) on the simultaneous formation of mono- and di-glycerides by the inter-action of the sodium salts of acids and glycerol a-monochlorohydrin, the authors find that the latter compound reacts at 175° with sodium benzoate, yielding a mixture of a-mono- and aa-dibenzoin.

Glycerol ay-dichlorohydrin and sodium benzoate at 190° give rise to a-monobenzoin, aa-dibenzoin, and tribenzoin. aa-Dibenzoin is an oil; the solid dibenzoin, described by Baumann (A., 1887, 229) and Grün (this vol., i, 157), probably consists of impure tribenzoin. The latter compound is obtained by shaking glycerol with benzoyl chloride (5 mols.) and aqueous sodium hydroxide at a low temperature. If less than this amount of benzoyl chloride is used, it is accompanied by varying amounts of mono- and di-benzoin (compare Baumann, *loc. cit.*, and Balbiano, A., 1903, i, 547).

The separation of mono-, di-, and tri-benzoin can be accomplished by taking advantage of the solubility of the monobenzoin in water and the greater solubility of the dibenzoin in alcohol as compared with that of the tribenzoin. When treated in alcoholic solution with 5% of the amount of potassium hydroxide, theoretically necessary for complete hydrolysis, and the mixture maintained for twenty-four hours at the ordinary temperature, tribenzoin undergoes complete decomposition into glycerol, ethyl benzoate, and potassium benzoate; if the reaction is allowed to proceed for only two minutes and the excess of potassium hydroxide at once neutralised by the addition of hydrochloric acid, then monobenzoin and dibenzoin are also formed.

The latter compounds were also isolated from the product obtained by partly hydrolysing the tribenzoin by means of potassium hydroxide in acetone at the ordinary temperature, and by heating with water in sealed tubes at 200°, both the water and potassium hydroxide being present in insufficient amount for complete hydrolysis. Partial saponification with 10% aqueous sodium hydroxide gave only di-

benzoin; the absence of the monobenzoin is referred to its solubility in water and consequent rapid hydrolysis by the sodium hydroxide.

When heated at 250° in sealed tubes in an atmosphere of carbon dioxide, a mixture of myristic acid and glycerol in equimolecular proportions yields trimyristin, αα-dimyristin and α-monomyristin, the latter compound forming the main product. The method adopted in separating the three compounds is based on the sparing solubility of the monomyristin in cold light·petroleum, and the greater solubility in alcohol of the dimyristin in comparison with that of the trimyristin. Monomyristin (Krafft, A., 1904, i, 136) has m. p. 68°; when heated to 70° and allowed to cool slowly it solidifies at 54°; if the temperature is allowed to fall to 44° and the substance again heated, it has m. p. 55°; on further heating it solidifies at about 60° and then shows the original m. p. of 68°.

αα-Dimyristin has m. p. 64·5° (compare Grün and Theimer, A., 1907, i, 463; also *ibid.*, 464, and this vol., i, 159). ·

Trimyristin exists in two forms of m. p. 56·5° and 49° (compare Reimer and Will, A., 1885, 1197).

The results obtained in the partial hydrolysis of trimyristin resemble those described above in the case of tribenzoin.   F. B.

The Glycerides of Butter Fat. CONRAD AMBERGER (*Zeitsch. Nahr. Genussm.*, 1913, **26**, 65—85).—Glycerides of definite composition were isolated from butter fat by subjecting the latter to fractional solution and crystallisation in ether. The most insoluble glyceride was found to consist of tristearin in the case of some butters; with other butters it was palmityldistearin.

Stearyldipalmitin was also obtained from butter fat, proving the presence of stearic acid.   W. P. S.

Tripropionin. RUDOLF W. SEUFFERT (*Zeitsch. Biol.*, 1913, **61**, 551—553).—*Tripropionin* is readily obtained by the gradual addition of the calculated amount of propionic anhydride to glycerol heated at 150—165°. It has b. p. 177—182°/ca. 20 mm., n_D^{19} 1·43175. The compound is not formed by heating glycerol with propionic acid in the presence of sodium acetate, whilst, when propionyl chloride is employed under varying conditions, the product obtained invariably contains chlorine.   H. W.

Catalytic Decomposition of Esters of Dibasic Organic Acids by Alumina. LOUIS MICHIELS (*Bull. Soc. chim. Belg.*, 1913, **27**, 227—230).—Senderens (this vol., i, 342) has observed that ethylene, carbon dioxide, carbon monoxide, and hydrogen are formed by the decomposition of ethyl succinate in the presence of alumina at 390° and 420°, and has surmised that a diketone may also be formed under these conditions. The author has investigated this action at 260°. The main gaseous product is ethylene mixed with some carbon dioxide. The distillate consists almost entirely of succinic anhydride. Diketones or their condensation products are only present in very small quantity, since the crude distillate is almost completely soluble in alkalis.

Similarly, ethyl glutarate under the influence of alumina at 270° yields mainly ethylene and glutaric acid. In one experiment, ethyl hydrogen glutarate was also isolated. In like manner, ethyl adipate at 300—320° yields an acid distillate. The general course of the reactions is shown by the equation :

$$CO_2Et\cdot[CH_2]_x\cdot CO_2Et = CO_2H\cdot[CH_2]_x\cdot CO_2H + 2C_2H_4.$$
H. W.

The Nitrogenous Constituent of Kephalin. A. BAUMANN (*Biochem. Zeitsch.*, 1913, **54**, 30—39).—The kephalin was hydrolysed with dilute hydrochloric or sulphuric acid at 60°. From the aqueous solution, after separation of the insoluble products and the glycero-phosphates (by means of lead acetate), the salt of an organic base could be separated by means of alcohol, which contains the amino-groups pre-existent in kephalin. This could be identified by means of the auri- and platini-chlorides as hydroxyethylamine. S. B. S.

Catalytic Acceleration of the Absorption of Oxygen by Lecithin with Iron Salts. TORSTEN THUNBERG (*Zeitsch. physiol. Chem.*, 1913, **87**, 82); OTTO WARBURG (*Ibid.*, 83—84).—A claim for priority. Thunberg (A., 1910, ii, 323) had previously noticed that the oxidation of lecithin was accelerated by the presence of iron salts (compare Warburg and Meyerhof, this vol., i, 698). Thunberg also claims priority with reference to the influence of freezing and finely powdering the cells. Warburg denies this; he comes to precisely the opposite conclusions to Thunberg. E. F. A.

Preparation of Acetic Acid. CHEMISCHE FABRIK GRIESHEIM-ELEKTRON (D.R.-P. 261589).—The oxidation of acetaldehyde to acetic acid by air or oxygen proceeds satisfactorily at 70—100° or at lower temperatures (30—80°) in the presence of a catalyst, such as ferrous oxide, uranium oxide, acetic anhydride, or acetyl chloride.

F. M. G. M.

Decomposition of Trichloroacetic Acid by Mercuric Oxide. KURT BRAND (*J. pr. Chem.*, 1913, [ii], **88**, 342—357).—When mercuric oxide is added to a concentrated solution of trichloroacetic acid and the mixture heated to boiling, a vigorous reaction occurs, resulting in the formation of carbon monoxide, carbon dioxide, chloroform, hydrogen chloride, mercuric and mercurous chlorides ; at 60° the reaction proceeds according to the equation :

$$2CCl_3\cdot CO_2H + 5HgO = 4CO_2 + 4HgCl + HgCl_2 + H_2O.$$

The author considers that the mercuric trichloroacetate first produced decomposes into dichloromethylene, carbon dioxide, and mercuric chloride, thus : $Hg(CCl_3\cdot CO_2)_2 = 2CCl_2 + 2CO_2 + HgCl_2$, the dichloromethylene being converted by the action of water into dihydroxymethylene, which is transformed at 60° into formic acid, and at 100° into formic acid and carbon monoxide. The formic acid is then oxidised by the mercuric chloride to carbon dioxide. The formation of chloroform during the reaction is referred to the decomposition of free trichloroacetic acid, formed from the mercuric trichloroacetate, either by hydrolysis or by the action of hydrochloric acid. F. B.

Cholic Acid. III. MARTIN SCHENCK (*Zeitsch. physiol. Chem.*, 1913, **87**, 59—73. Compare A., 1910, i, 10 ; 1911, i, 10).—A re-investigation of cilianic acid and its methyl ester (compare Pregl, A., 1903, i, 318) establishes it as a tetrabasic acid, $C_{24}H_{34}O_{10}$ or $C_{24}H_{22}O_{10}$, the ester being a tetramethyl derivative. Cilianic acid is accordingly an oxidation and not a degradation product of cholic acid. The carbon dioxide formed during the oxidation is derived from the decomposition of part of the cilianic acid.   E. F. A.

Senecioic Acid. YASUHIKO ASAHINA (*Arch. Pharm.*, 1913, **251**, 355—356).—Senecioic acid, $C_5H_8O_2$, the unsaturated acid obtained from the rhizomes of *Ligularia tussilaginea* (*Senecio kaempferi*) is proved to be identical with $\beta\beta$-dimethylacrylic acid by the direct comparison of the two acids, m. p. 69—70°, and of their calcium salts, $(C_4H_7 \cdot CO_2)_2Ca, 4H_2O$.   C. S.

Action of Cyanides on Aldehydes and Ketones. HARTWIG FRANZEN and WALTER RYSER (*J. pr. Chem.*, 1913, [ii], **88**, 293—306). —It has been shown previously (A., 1909, i, 804) that ethyl acetoacetate, ethyl benzoylacetate, and acetylacetone, when shaken with aqueous solutions of calcium, barium, strontium, and magnesium cyanides, yield crystalline salts, which were considered to be metallic derivatives of cyanohydrins, having a similar structure to that of the calcium derivative of mandelonitrile, obtained by the action of calcium cyanide on benzaldehyde.

The authors now find that the products are not nitriles, but the metallic derivatives of the ketonic esters and diketone.

The preparation of the calcium, barium, strontium, and magnesium derivatives of ethyl acetoacetate, and the *calcium, strontium,* and *magnesium* derivatives of acetylacetone is described.

The metallic derivatives of ethyl benzoylacetate decompose very rapidly, and, therefore, could not be isolated in a pure condition.

The calcium derivative of mandelonitrile, $Ca(O \cdot CHPh \cdot CN)_2$, has been obtained in a state of purity by using an aqueous solution of calcium cyanide, prepared from calcium hydroxide and hydrocyanic acid, instead of the mixture of calcium chloride and potassium cyanide employed previously (*loc. cit.*). Its constitution has been established by its conversion into the benzoyl derivative of mandelonitrile by the action of benzoyl chloride.

The *calcium* derivative of *o*-chloromandelonitrile, prepared from *o*-chlorobenzaldehyde and aqueous calcium cyanide, forms a light yellow powder.

The *calcium* derivatives of *p*-methylmandelonitrile and *p*-methoxymandelonitrile are also described.

The colourless, crystalline substance obtained by Kohn (A., 1900, i, 205) by the action of calcium cyanide on formaldehyde in aqueous solution is considered to have the constitution

$$Ca[O \cdot CH(CN) \cdot Ca \cdot OH]_2.$$

Acetaldehyde yields a similar crystalline compound,

$$Ca[O \cdot CMe(CN) \cdot Ca \cdot OH]_2.$$

The action of potassium cyanide on acetaldehyde in aqueous solution results in the formation of alanine and α-iminodipropionic acid.

F. B.

The Action of Silicon Tetrachloride on Aldehydes and Ketones. JAMES N. CURRIE (*J. Amer. Chem. Soc.*, 1913, **35**, 1061).— It has been observed that a mixture of pure acetone with silicon tetrachloride in a few hours sets to a gelatinous mass, which when broken up with water gives a brown oil consisting mainly of mesityl oxide.

Analogous results were obtained in qualitative experiments with other aldehydes and ketones. D. F. T.

Photochemical Synthesis of Carbohydrates. JULIUS STOKLASA, JOHANN ŠEBOR, and WENZEL ZDOBNICKÝ (*Biochem. Zeitsch.*, 1913, **54**, 330—332. Compare this vol., i, 18).—A further reply to the criticisms of Walther Löb (this vol., i, 250).

Behaviour of Cellulose Towards Pure Nitric Acid. II. CARL HAEUSSERMANN (*Zeitsch. angew. Chem.*, 1913, **26**, 456. Compare *Zeitsch. angew. Chem.*, 1910, **23**, 1761).—"Sulphite cellulose" is converted by cold concentrated nitric acid into nitrates without undergoing marked structural change. Treatment with nitric acid, D 1·495, 1·48, 1·47, 1·46 and 1·40, leads to the formation of nitrates containing 11·1%, 9·6%, 8·0%, 7·5%, and 2·3% of nitrogen respectively. "Sulphite cellulose" dissolves readily in warm concentrated nitric acid, and the solution, when poured into cold water, yields an amorphous product, part of which is soluble in a mixture of alcohol and ether.

Hydrocellulose prepared from cotton when treated with nitric acid, D 1·5, 1·485, 1·48, and 1·40, yields hydrocellulose nitrates containing 13·0%, 9·5%, 8·9%, and 2·3% of nitrogen respectively, whilst hydrocellulose nitrates containing 11·2%, 8·8%, 6·6%, and 2·1% of nitrogen are obtained by the action of nitric acid, D 1·495, 1·48, 1·45 and 1·40 respectively, on hydrocellulose prepared from "sulphite cellulose."

The esters derived from "sulphite cellulose" closely resemble those derived from cotton in their behaviour towards solvents, but the higher cellulose and hydrocellulose nitrates prepared from "sulphite cellulose" are not completely soluble in acetone. W. H. G.

Benzoyl Esters of Cellulose. HERMANN OST and F. KLEIN (*Zeitsch. angew. Chem.*, 1913, **26**, 437—440. Compare Hauser and Muschner, this vol., i, 363; Briggs, this vol., i, 594).—An investigation on the benzoylation of cellulose, carried out primarily with the object of preparing a tribenzoate corresponding with the triacetate and trinitrate of cellulose.

Cellulose when treated with alkali hydroxide and benzoyl chloride yields a mixture of benzoates, the benzoic acid content of which is between 0 and 77%, and is dependent mainly on the proportions in which the reacting substances interact and to a slight degree on the physical state of the cellulose employed. A maximum yield of 218% of product is obtained by using a 22·4% sodium hydroxide solution in

the molecular proportions of 30 of sodium hydroxide to 1 of cellulose and 3 of benzoyl chloride to 4 of sodium hydroxide, whilst by using a 31·4% potassium hydroxide solution a maximum yield of 211% of product is obtained, the molecular proportions being the same as those just cited. The yields of product increase regularly with increase in the concentrations of the alkali up to the strengths quoted; at higher concentrations of the alkali the yields gradually decrease, and curves representing the relationship between alkali concentration and percentage of benzoic acid in the product do not show a "break" as do curves connecting alkali concentrations with the proportion of sodium combined with the cellulose (compare Vieweg, A., 1907, i, 893). A second and third treatment with alkali and benzoyl chloride increases the yield to 224% and 226% respectively, but it has not been found possible by the Schotten-Baumann method to pass beyond these values; the portion of the latter product soluble in chloroform contained 72·7% of benzoic acid, corresponding approximately with 2·5 benzoyl groups to the $C_6H_{10}O_5$ complex.

The crude benzoates may be fractionally separated by solvents; chloroform extracts 5 to 10% of a mixture containing 68 to 70% benzoic acid; aniline extracts from the portion insoluble in chloroform a mixture containing 61 to 65% of benzoic acid, whilst aniline-phenol (1:1) extracts from the residue a mixture containing 59 to 60% of benzoic acid.

Benzoates containing up to 77% of benzoic acid (a tribenzoate would contain 77·2%) are obtained by treating cellulose with benzoyl chloride in the presence of nitrobenzene and pyridine at 110—130°; the highest esters are formed when the quantity of pyridine employed is insufficient to keep the solution basic or neutral.

Solutions of cellulose benzoates in chloroform are dextrorotatory; the following values are given: tribenzoate, $[\alpha]_D$ 26—27°; ester with 70—72% of benzoic acid, $[\alpha]_D$ 20—22°.

Mercerised cellulose does not react more readily than finely divided cotton. Cellulose regenerated from "young" viscose is more reactive than that from "old" viscose; the benzoate from the former gave elastic films, whilst the benzoate from the latter gave films which were very brittle.

The yield of benzoate from hydrocellulose is less than that from cellulose, but 50% of the product containing 71—72·4% of benzoic acid is soluble in chloroform.   W. H. G.

Chemical Reactions Induced by Bacteria aceti. H. J. WATER-MAN (*Chem. Weekblad*, 1913, 10, 718—730).—*B. aceti* isolated at low temperature rapidly transform aldoses, such as dextrose and galactose, into the corresponding monobasic acids, but has no action on ketoses. *B. aceti* isolated at high temperature does not react with either aldoses or ketoses. A summary of previous work on the action of *B. aceti* is given.   A. J. W.

d-Ribose. W. ALBERDA VAN EKENSTEIN and JAN J. BLANKSMA (*Chem. Weekblad*, 1913, 10, 664).—d-Ribose has been synthesised by converting d-gluconic acid into d-arabinose by the action of hydrogen peroxide, transformation of the pentose into d-arabonic acid by means

of, bromine water, and conversion of this acid into *d*-ribonic acid by heating with pyridine. The ribonic acid was separated from arabonic acid by fractional crystallisation of the phenylhydrazides, and had m. p. 80° and $[a]_D$ +18·4°. On reduction with sodium amalgam, it yielded *d*-ribose, purified by conversion into its *p*-bromophenylhydrazone, m. p. 164°. The hydrazone was transformed into *d*-ribose by the action of benzaldehyde. It forms colourless, hygroscopic crystals, m. p. 95°, $[a]_D$ − 21·5°.　　　　　　　　　　　　　A. J. W.

The Oxidation of *d*-Glucose in Alkaline Solution by Air as Well as by Hydrogen Peroxide. J. W. E. GLATTFELD (*Amer. Chem. J.*, 1913, **50**, 135—157).—The author has repeated the oxidation of *a*-glucose by hydrogen peroxide and air in potassium hydroxide solution, and finds that in addition to glycollic acid, formic acid and carbon dioxide, isolated by Spoehr (A., 1910, i, 221) from the oxidation product, *d*-erythronic, *l*-threonic and *dl*-glyceric acids are produced.

Spoehr's *a*-hydroxymethyl-*d*-arabonic acid is found to be identical with *d*-arabonic acid.

The formation of the latter acid proves that glucose in the form of its *aβ*-dienol, $HO\cdot CH:C(OH)\cdot CH(OH)\cdot CH(OH)\cdot CH(OH)\cdot CH_2\cdot OH$, dissociates into hydroxymethylene, $HO\cdot CH:$, and the methylenenol of *d*-arabinose, $:C(OH)\cdot CH(OH)\cdot CH(OH)\cdot CH(OH)\cdot CH_2\cdot OH$, which is then oxidised to *d*-arabonic acid. Oxidation of the dissociation products of the *βγ*-dienol,

$$HO\cdot CH_2\cdot C(OH):C(OH)\cdot CH(OH)\cdot CH(OH)\cdot CH_2\cdot OH,$$

gives rise to glycollic, *d*-erythronic and *l*-threonic acids, whilst the glyceric acid is formed by the dissociation and subsequent oxidation of the *γδ*-dienol, $HO\cdot CH_2\cdot CH(OH)\cdot C(OH):C(OH)\cdot CH(OH)\cdot CH_2\cdot OH$ (compare Nef, A., 1908, i, 5).

For details of the method employed in separating the oxidation products, the original must be consulted.

The following new salts are described : *cinchonine* d-*arabonate*, m. p. 170—180°, $[a]_D^{20}$ +120·3° in water, and the corresponding *strychnine* salt, decomp. 167—170°, $[a]_D^{20}$ −26·08°, *quinine* salt, m. p. 172—173°, $[a]_D^{20}$ − 106·2°, and *brucine* salt, m. p. 167—170°, $[a]_D^{20}$ − 26·33°.

The *strychnine* salt of *d*-erythronic acid has m. p. 198—199°, $[a]_D^{20}$ − 16·84° ; the *quinine* salt, m. p. 166°, $[a]_D^{20}$ − 106·9°.　　F. B.

Biochemical Synthesis of Galactosides of Alcohols. V. *β-iso*Butylgalactoside. ÉMILE BOURQUELOT and MARC BRIDEL (*J. pharm. chim.*, 1913, [vii], **8**, 108—109).—A mixture of 95 parts of *iso*butyl alcohol by weight and 5 parts of water was kept for four months with galactose and emulsin. *β-isoButylgalactoside* was obtained in colourless needles of bitter taste, $[a]_D$ − 11·23°.

　　　　　　　　　　　　　　　　　　　E. F. A.

Phosphates of Magnesium and Amines. LÉONCE BARTHE (*Bull. Soc. chim.*, 1913, [iv], **13**, 821—824).—The only double phosphate of magnesium and amines that has been prepared is magnesium methylamine phosphate (Barthe, A., 1905, i, 546 ; François, A., 1908,

i, 505). Unsuccessful attempts to prepare the corresponding salt from ethylamine are now described.

When ethylamine is added to a solution of magnesium hydrogen phosphate in dilute phosphoric acid in quantity more than sufficient for saturation, a colloidal precipitate is formed which becomes crystalline after several hours and consists entirely of magnesium phosphate. The mother liquors, when concentrated, deposit ethylamine phosphate and a further quantity of magnesium phosphate. If an excess of ethylamine is avoided, a crystalline precipitate is obtained after some hours, analysis of which shows it to be a mixture of magnesium ethylamine phosphate and magnesium phosphate or of ethylamine phosphate and magnesium phosphate. When the phosphoric acid is replaced by hydrochloric or sulphuric acids, magnesium phosphate is similarly precipitated. Analogous results are obtained by the solution of magnesium hydrogen phosphate in ethylamine hydrochloride and subsequent addition of the free amine.

Magnesium hydrogen phosphate, $MgHPO_4,7H_2O$, is most readily obtained by mixing equal volumes of 2% magnesium sulphate solution and 3% disodium hydrogen phosphate solution. A gelatinous precipitate is immediately obtained, which is rapidly transformed into a mass of fine needles.   H. W.

Preparation of the Nitrites of the Primary, Secondary, and Tertiary Amines by the Interaction of the Hydrochlorides of the Bases and Alkali Nitrites. PANCHANAN NEOGI (*Chem. News*, 1913, 108, 53—55, 62—65).—A full account of work of which an abstract has already appeared (P., 1913, 29, 112).   W. G.

The Double Cadmium and Mercuric Iodides of Substituted Ammonium Bases. RASIK LAL DATTA (*J. Amer. Chem. Soc.*, 1913, 35, 949—955).—The following cadmium compounds were prepared either by adding cadmium chloride to an excess of the substituted ammonium iodide (compare T., 1913, 103, 426), or by mixing solutions of cadmium iodide and the ammonium iodide in the requisite proportions. Two types of salts are obtained, namely, $2NR_4I,CdI_2$ and NR_4I,CdI_2, of which the latter is produced only in exceptional cases. The salts are white powders, sparingly soluble in water.

The double salts of cadmium iodide with *tetramethylammonium, tetraethylammonium,* p-*tolyltrimethylammonium, pyridinium,* a-*picolinium,* and *quinolinium* iodides are of the type $2NH_4I,CdI_2$; *tetrapropylammonium iodide* gives the salt NPr_4I,CdI_2.

When an aqueous solution of mercuric chloride is added to an excess of alkylammonium iodide, a white to yellowish-white precipitate is formed, of the type $2NR_4I,HgI_2$. If the addition of mercuric chloride be continued, the precipitate changes to yellow and the salt is of the type $2NR_4I,3HgI_2$; further addition of mercuric chloride gives mercuric iodide. A solution of mercuric iodide in potassium iodide may be used instead of mercuric chloride; when the interacting solutions are strong, the type $2NR_4I,HgI_2$ is produced, but this is decomposed by water and changed to the type $2NR_4I,3HgI_2$, which is the most stable of all, and is prepared by the interaction of dilute

solutions, using an excess of potassium mercuric iodide solution. The following substituted ammonium iodides give salts of both types: *Tetramethylammonium, tetraethylammonium,* and *trimethylsulphonium* (compare Smiles, T., 1900, **77**, 160) *iodides.* The following iodides give salts of the type $2NR_4I,HgI_2$: *tetrapropylammonium,* p-*tolyl-trimethylammonium, pyridinium* and *quinolinium iodides.* p-*Tolyl-trimethylammonium iodide* also gives the salt, $C_6H_4Me \cdot NMe_3I,HgI_3$.

The above salts, for the most part, vary in colour from a pale to a bright lemon yellow. They are all decomposed quantitatively into mercuric iodide on boiling with dilute nitric acid. T. S. P.

Platini-iodides of Substituted Ammonium and Sulphonium Bases. RASIK LAL DATTA (*J. Amer. Chem. Soc.,* 1913, **35**, 1185—1188).—It is found that although the platini-iodides of sodium and of the alkaline-earth metals cannot be obtained as precipitates by the interaction of chloroplatinic acid with concentrated solutions of the iodides (Datta, T., 1913, **103**, 426), this method proves very convenient for the preparation of the platini-iodides of potassium, ammonium, and the amines. The method failed with hydrazine hydriodide on account of the reduction of the chloroplatinic acid to metallic platinum. In other cases the condition necessary to success is the employment of an excess of the iodide of the metal or base.

The following substances were prepared : potassium platini-iodide, very soluble, black, crystalline powder ; ammonium platini-iodide, black powder ; *dipropylammonium platini-iodide,* black ; *tetrapropylammonium platini-iodide,* chocolate coloured ; a-*picolinium platini-iodide,* black ; *quinolinium platini-iodide,* jet black ; *trimethylsulphonium platini-iodide,* black powder ; *triethylsulphonium platini-iodide,* chocolate coloured.

D. F. T.

Non-equivalence of the Five Valencies of Nitrogen. EMIL FROMM (*Annalen,* 1913, **399**, 366—370).—By reason of the great importance of the subject, Meisenheimer's recent proof (this vol., i, 595) of the non-equivalence of the five valencies of the nitrogen atom must be submitted to searching criticism before being accepted. The author is of opinion that Meisenheimer's experiments can be interpreted in another, and more probable, manner. Meisenheimer assumes that hydrogen chloride and methyl iodide both attack trimethylamine oxide at the same point and in the same manner, yielding the additive compounds $NMe_3{<}^{OH}_{Cl}$ and $NMe_3{<}^{OMe}_{I}$ respectively. From the former by the action of sodium methoxide, and from the latter by moist silver oxide, are obtained the substances $NMe_3{<}^{OH}_{OMe}$ and $NMe_3{<}^{OMe}_{OH}$; the different behaviour of the two substances during decomposition is the foundation of Meisenheimer's proof of the difference of the fifth "unique" valency of nitrogen from the other four. The author takes exception to this. The two substances $NMe_3{<}^{OH}_{OMe}$

and $NMe_3{<}^{OMe}_{OH}$, being alcoholates of a very feeble base, $NMe_3(OH)_2$, must both be hydrolytically dissociated by water, and yield MeOH and $NMe_3(OH)_2$ if they have the constitutions given above. He is of opinion that hydrogen chloride and methyl iodide do not attack trimethylamine oxide in the same manner. With methyl iodide the oxide forms the methiodide, $NMe_3{:}O{<}^{Me}_{I}$; the product of the action of moist silver oxide is then $NMe_3{:}O{<}^{Me}_{OH}$, which would be expected to yield trimethylamine, formaldehyde, and water by its decomposition, as is actually the case.

The formula $NMe_3{:}O{<}^{Me}_{I}$ has been discussed and rejected by Meisenheimer (*loc. cit.*); the author, however, shows that the reasons for its rejection are insufficient.   C. S.

Non-equivalence of the Five Valencies of Nitrogen. JAKOB MEISENHEIMER (*Annalen*, 1913, **399**, 371—376).—The author replies to Fromm's criticisms (preceding abstract). In answer to his contention that two isomeric compounds should be produced by the addition of hydrogen chloride at the double linking of trimethylamine oxide if the fourth and the fifth valencies of the nitrogen atom are fundamentally different, the author claims that the whole behaviour of ammonium compounds proves that four of the valencies of the nitrogen atom are negative and the fifth is positive ; therefore, in the addition of hydrogen chloride to trimethylamine oxide, the negative chlorine will become attached only to the fifth positive valency of the nitrogen atom, and only one additive compound will be produced.

To Fromm's criticism that the two isomerides, $NMe_3{<}^{OH}_{OMe}$ and $NMe_3{<}^{OMe}_{OH}$, should both be hydrolysed by water, the author replies that only one, namely, that in which the methoxy-group is attached to the fifth positive valency of the nitrogen atom, should be hydrolytically dissociated ; the other isomeride, in which the methoxy-group is bound by a negative valency, should be as little affected by water as is methoxylamine, $OMe{\cdot}NH_2$.

The author also criticises adversely Fromm's reasons for ascribing oxonium formulæ to substances of the types $NMe_3Cl{\cdot}OMe$ and
$$NMe_3(OEt){\cdot}OMe.$$ C. S.

[**Non-equivalence of the Five Valencies of Nitrogen.**] EMIL FROMM (*Annalen*, 1913, **399**, 377).—The author agrees with Meisenheimer (preceding abstract) that in ammonium compounds the fifth "positive" valency of the nitrogen atom is different from the other four "negative" valencies, but is of opinion that the results of observations on ammonium compounds cannot be applied to the case of the amino-oxides without further consideration. He claims that in amino-oxides there are two "positive" valencies which differ from the other three "negative" valencies.   C. S.

Decomposition of Glucosamine by Bacteria. EMIL ABDER-
HALDEN and ANDOR FODOR (*Zeitsch. physiol. Chem.*, 1913, 87,
214—219).—Glucosamine hydrochloride, when decomposed by micro-
organisms of the *B. subtilis* group, yields propionic acid and *d*-lactic
acid.   E. F. A.

Fermentative Decomposition of Creatinine. DANKWART
ACKERMANN (*Zeitsch. Biol.*, 1913, 62, 208—216).—Creatinine, mixed
with a little dextrose and peptone, was inoculated with bacteria from
a decomposing pancreas. Neither methyl- nor dimethyl-guanidine
was formed, the main product of the change being l-methylhydantoin,
$$CO\underset{NMe\cdot CH_2}{\overset{NH-CO}{\big<}}.$$
                                                                     E. F. A.

The Changes Produced in Asparagine by Heating its
Aqueous Solutions. FELIX EHRLICH and FRITZ LANGE (*Biochem.
Zeitsch.*, 1913, 54, 256—276).—By heating the ordinary asparagine
with water for twelve hours and allowing the substance to crystallise
out in fractions, a very small amount was obtained which has
$[\alpha]_D^{20}\ 46\cdot2°$; this apparently *d*-asparagine (compare Erlenmeyer, this
vol., i, 836). The authors also show that when asparagine solutions
are heated, ammonia is evolved, and on crystallisation, crystals
together with a non-crystallising syrup are obtained. The longer the
heating takes, the smaller is the amount of crystals, the larger
the amount of syrup obtainable, and the larger is the quantity of
ammonia evolved. The uncrystallisable syrup is not readily freed
from ammonia, and the evidence obtained indicates that it contains
ammonium aspartate. The latter substance readily crystallises from
water, but if its solution is heated, an uncrystallisable syrup is also
obtained. It appears, therefore, to be an intermediate product
produced by the action of heat on asparagine solutions. The actual
nature of the final products has not yet been ascertained. S. B. S.

Resolution of *dl*-Aminohexoic Acid (Norleucine) into the
Optically Active Components by means of the Formyl
Compound. Polypeptides Derived from α-Aminohexoic Acid.
EMIL ABDERHALDEN, C. FROEHLICH, and DIONYS FUCHS (*Zeitsch. physiol.
Chem.*, 1913, 86, 454—468).—*dl*-α-Aminohexoic acid, which E. Fischer
resolved by means of the brucine salt, is readily resolved when the
brucine salts of the formyl derivatives are crystallised. The acid, for
which the name norleucine is proposed, has been combined with
glycine and leucylglycine to form polypeptides in the usual manner.

Formyl-dl-α-*aminohexoic acid* crystallises in lustrous needles, which
soften at 110—111°, m. p. 114°. The optical antipodes resemble each
other very closely, crystallising in slender, lustrous, short or long
needles aggregated in bunches. They soften at 111°, m. p. 114°, and
have $[\alpha]_D^{20}\ -15\cdot85°$ and $+15\cdot53°$ respectively.

Chloroacetyl-d-*norleucine* crystallises in colourless, transparent
lamellæ, which soften at 70°, m. p. 104—106°, $[\alpha]_D^{20}\ +3\cdot56°$.

Glycyl-d-*norleucine*, $CH_2\cdot[CH_2]_3\cdot CH(CO_2H)\cdot NH\cdot CO\cdot CH_2\cdot NH_2$, forms

prisms growing into long needles, which become brown at 220°, sinter at 230°, m. p. 239—240°; they have $[a]_D^{20} - 8·71°$.

Glycyl-l-norleucine is almost identical in crystalline form and behaviour on heating ; it has $[a]_D^{20} + 8·24°$.

Chloroacetyl-dl-*norleucine* forms long prisms, m. p. 104—107°.

Glycyl-dl-*norleucine* separates in fatty plates or bundles of prisms ; it sinters at 210°, decomp. 215°.

a-Bromoisohexoylglycyl-dl-*norleucine* crystallises in platelets, m. p. 140°.

dl-*Leucylglycyl*-dl-*norleucine* separates as a crystalline skin. It sinters at 220°, decomp. 250°. It could not be hydrolysed by means of yeast juice with any certainty. The same applies to glycyl-*dl*-norleucine.   E. F. A.

Preparation of Derivatives of α-Bromoisovaleric Acid. ARTHUR LIEBRECHT (D.R.-P. 261877).—*a-Bromoisovalerylmethylamide*, needles, m. p. 103°, is obtained when α-bromoisovaleryl bromide is slowly dropped into a cooled 20% aqueous solution of methylamine (2 mols.) ; the corresponding *ethylamide*, needles, m. p. 120°, is prepared in a similar manner with ethylamine.   F. M. G. M.

Action of Hydrazine Hydrate on Dicyanodiamide and Biuret. ROBERT STOLLÉ and K. KRAUCH (*J. pr. Chem.*, 1913, [ii], 88, 306—314).—The authors have investigated the action of hydrazine hydrate on dicyanodiamide under various conditions, and find that in addition to guanazole, obtained by Hofmann and Ehrhart (A., 1912, i, 919), the following substances may be formed : aminodicyanodiamidine, 1-amino-2 : 5-dehydrazino-1 : 3 : 4-triazole, carbohydrazide, aminodiguanide, mono-, di- and tri-aminoguanidine.

With the exception of guanazole and the triazole, all the above-mentioned substances were isolated in the form of their benzylidene derivatives by acidifying the product of the reaction with hydrochloric acid and shaking with benzaldehyde.

The action of hydrazine hydrate on dicyanodiamide, both at 40° and at the ordinary temperature, results in the formation of guanazole, diaminoguanidine and triaminoguanidine ; if the reaction is carried out at 50°, these compounds are accompanied by aminoguanidine and *aminodiguanide*, which forms a *benzylidene* derivative, m. p. 287°, NH:C(NH$_2$)·NH(NH)·NH·N:CHPh.

Guanazole is best prepared by heating a mixture of dicyanodiamide (1 mol.) and hydrazine hydrate (2½ mol.) at 60—70° ; if the temperature is raised to 100—110°, carbohydrazide is formed simultaneously.

Nitrosoguanazole, $C_2H_4ON_6$, obtained as canary-yellow precipitate by the addition of sodium nitrite to a solution of guanazole in dilute acetic acid, is insoluble in the ordinary solvents, and on reduction with zinc dust and sulphuric acid yields guanazole and probably guanazine. When a large excess of hydrazine hydrate (5 mols.) is employed and the reaction carried out at 40°, dicyanodiamide yields guanazole and aminodicyanodiamidine (Thiele and Uhrfelder, A., 1899, i, 119) ; at the ordinary temperature, guanazole, mono-, di- and tri-aminoguanidine are formed, whilst at 70° 1-amino-2 : 5-hydrazino-1 : 3 : 4-triazole

(Stollé and Bowles, A., 1908, i, 474) is the main product. Excess of hydrazine hydrate at 100—110° leads to the formation of carbohydrazide.

When heated with hydrazine hydrate (4 mols.) at 108—118°, biuret yields the *hydrazine* salt of hydrazidicarboxylimide [2 : 5-diketotetrahydro-1 : 3 : 4-triazole], $\underset{\text{NH·CO}}{\overset{\text{NH·CO}}{\gtrdot}}$ NH,N₂H₄, which crystallises in needles, m. p. 195°, and is converted by shaking with benzaldehyde and dilute hydrochloric acid into benzalazine and hydrazidicarboxylimide (compare Pellizzari, A., 1895, i, 73) ; if the reaction is carried out at 80—85°, the hydrazine salt is accompanied by aminobiuret, which was isolated in the form of its benzylidene derivative, m. p. 207° (compare Thiele and Uhrfelder, A., 1899, i, 118).   F. B.

Some Hydrazine Derivatives of Chloral and Trichloroacetic Acid. ROBERT STOLLÉ and FR. HELWERTH (*J. pr. Chem.*, 1913, [ii], 88, 315—318).—Chloralhydrazine (Knöpfer, A., 1911, i, 704 ; this vol., i, 703) is readily obtained by the gradual addition of hydrazine hydrate to a well cooled ethereal solution of chloral hydrate. It separates from alcohol in white needles, m. p. 100° (Knöpfer gives 85°), and decomposes when kept, yielding hydrazine hydrochloride. With benzaldehyde in aqueous solution it forms the *benzylidene* derivative, CCl₃·CH(OH)·NH·N:CHPh, crystallising in small needles, m. p. 65° (decomp.).

s-Bistrichloroacetylhydrazide, m. p. 195°, N₂H₂(CO·CCl₃)₂, prepared by heating hydrazine monohydrochloride with trichloroacetyl chloride on the water-bath (compare L. and P. Spiegel, A., 1907, i, 507), reacts with alcoholic silver nitrate and ammonia, yielding a yellow *silver* derivative, and when heated with phosphorus pentachloride or thionyl chloride is converted into 2 : 5-*bistrichloromethyl*-1 : 3 : 4-*oxadiazole*, $CCl_3 \cdot C \underset{O}{\overset{N:N}{\gtrdot}} C \cdot CCl_3$, which has m. p. 121°/9 mm., and separates from ether in long prisms, m. p. 48°.   F. B.

*iso*Butyl Ester of Phosphorous Acid. I. ALEXANDER E. ARBUZOV and A. A. IVANOV (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 681—690).—*Diisobutylphosphorous acid*, P(O·C₄H₉)₂OH, obtained by Arbuzov's method for obtaining esters of this type (A., 1907, i, 8, 174, 275), is a colourless, mobile liquid with a pleasant, fruity odour, b. p. 117·5°/14 mm., 235—236°/760 mm., D_0^0 0·9941, D_{20}^{20} 0·9776, D_4^0 0·9940, D_4^{20} 0·9759. With metallic sodium it yields a sodium salt stable at high temperatures ; the *silver* salt, P(OC₄H₉)₂OAg, was analysed.

iso*Butyl phosphite*, P(O·C₄H₉)₃, separated from its mixture with the preceding compound (A., 1907, i, 8) by converting the latter into sodium salt and distilling, is a colourless, mobile liquid with an intense peculiar odour, b. p. 100·5°/4·5 mm., 234—235°/760 mm., D_0^0 0·9193, D_{20}^{20} 0·9052, D_4^0 0·9193, D_4^{20} 0·9036. It reacts with bromine according to the equations :

$$P(O \cdot C_4H_9)_3 + Br_2 = PBr_2(O \cdot C_4H_9)_3 = 2C_4H_9Br + PO_2 \cdot O \cdot C_4H_9.$$
With cuprous iodide it forms the *compound*, $CuI,P(O \cdot C_4H_9)_8$, m. p. about 48°.

It is evident that the impossibility of separating the two esters, $P(O \cdot C_4H_9)_2 \cdot OH$ and $P(O \cdot C_4H_9)_8$, by fractional distillation is due to the fact that the two liquids and mixtures of them have almost identical boiling points.   T. H. P.

Isomeric Change of $P(OC_4H_9)_8$ **into** $C_4H_9 \cdot PO(OC_4H_9)_2$. II. ALEXANDER E. ARBUZOV and A. A. IVANOV (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 690—694).—When heated with *iso*butyl iodide, *iso*butyl phosphite (see preceding abstract) undergoes isomeric change in accordance with the equations :

$$C_4H_9I + P(O \cdot C_4H_9)_8 = I \cdot P(C_4H_9)(O \cdot C_4H_9)_3 =$$
$$PO(C_4H_9)(OC_4H_9)_2 + C_4H_9I.$$
The *isobutyl isobutylphosphite* thus obtained is a colourless, mobile liquid, b. p. 133·5—134°/10 mm., 258—259°/760 mm., D_0^0 0·9630, D_{20}^{20} 0·9475, D_4^0 0·9628, D_4^{20} 0·9459. The corresponding *iso*butylphosphorous acid was obtained in crystals, $2O \vdots P(C_4H_9)(OH)_2,H_2O$, m. p. 124°; this acid was originally prepared by Hofmann (A., 1873, 883) as a waxy and evidently impure mass, m. p. 100°.   T. H. P.

Compounds of Boric Acid and Mannitol. FERNANDO AGENO and ELENA VALLA (*Gazzetta*, 1913, **43**, ii, 163—174).—Solubility measurements indicate that the combination of boric acid and mannitol takes place in equimolecular proportions. The stability constant at 25° is 0·598; it decreases when the temperature increases. The concentration of the hydrogen ions in solutions of mannitoboric acid has been determined, the dissociation constant being of the same order of magnitude as those of the monobasic organic acids, and it is proportional to the concentration of the mannitol. The rotatory power of solutions of sodium metaborate and mannitol is proportional to the concentration of the mannitol.   R. V. S.

Preparation of Readily Soluble Stable Compounds of Perborates. VEREINIGTE FABRIKEN FÜR LABORATORIUMSBEDARF (D.R.-P. 261633).—The following complex salts are prepared by mixing the required proportions of the components in aqueous solution and evaporating to dryness: *sodium borotartrates*, $C_4H_4O_6(BONa)$ or $C_4H_3NaO_6(BONa)$; *sodium borocitrates*, $(C_6H_5O_7)_2(BONa)_3$ or
$$(C_6H_4NaO_7)_2(BONa)_3;$$
aluminium sodium tartrates, $NaOAl(C_4H_4O_6)_2Na_2$ or $Al(C_4H_4O_6)_2Na_3$ When moist they are of a syrupy consistency, but can be dried to masses resembling water glass and then reduced to powder.
                                  F. M. G. M.

Preparation of Chlorobenzenedisulphonic Acid. FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R.-P. 260563).—When *p*-chlorobenzenesulphonyl chloride is heated with fuming sulphuric acid (4 parts) at 160—180° with continual stirring, it furnishes a chlorobenzenedisulphonic acid (compare A., 1892, 331).   F. M. G. M.

Preparation of *meso*Halogenanthracene-β-sulphonic Acids. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 260562).—*Dichloroanthracenesulphonic acid*, a yellow powder, somewhat soluble in and exhibiting a blue fluorescence in water, is obtained when dichloroanthracene (1 part) in chloroform (100 parts) at 30° is treated with chlorosulphonic acid and the temperature subsequently maintained at 40° for four hours; the reaction can also be carried out in fuming sulphuric acid.

Dibromoanthracenesulphonic acid is obtained in a similar manner from dibromoanthracene. F. M. G. M.

Preparation of Iodo-derivatives of *p*-Hydroxy-β-phenylethylamine and of its *N*-Alkyl Derivatives. F. HOFFMANN-LA ROCHE & Co. (D.R.-P. 259193).—The iodo-derivatives of *p*-hydroxy-β-phenylethylamine have an enhanced therapeutic value. *Di-iodo-p-hydroxy-β-phenylethylamine*, glistening, colourless needles, m. p. 189—190°, is obtained when an aqueous solution of *p*-hydroxy-β-phenylethylamine is slowly treated with iodine and sodium hydroxide; any great excess of alkali is to be avoided during the reaction; the *hydriodide* separates in yellowish-brown leaflets, and is decomposed with sodium carbonate in the usual manner.

N-Benzyl-p-hydroxy-β-phenylethylamine hydrochloride,

$$OH \cdot C_6H_4 \cdot CH_2 \cdot CH_2 \cdot NH \cdot CH_2Ph, HCl,$$
needles, m. p. 216°, is prepared from benzaldehyde and *p*-hydroxy-β-phenylethylamine with subsequent reduction (with sodium amalgam) of the Schiff *base*, $OH \cdot C_6H_4 \cdot CH_2 \cdot CH_2 \cdot N:CHPh$; when treated with iodine, it furnishes N-*benzyldi-iodo*-p-*hydroxy-β-phenylethylamine*, yellow needles, m. p. 159—160° (decomp.).

Piperonyl p-*hydroxyphenylethylamine*, m. p. 115° (the *hydrochloride* has m. p. 219°), on similar treatment gives rise to a N-*piperonyldi-iodo*-p-*hydroxyphenylethylamine*, decomp. m. p. 165°. F. M. G. M.

Preparation of *N*-Alkylaryl Derivatives of *p*-Hydroxy-β-phenylethylamines. F. HOFFMANN-LA ROCHE & Co. (D.R.-P. 259874). —The Schiff base obtained from benzaldehyde and *p*-hydroxy-β-phenylethylamine (compare preceding abstract) has m. p. 148°; N-*benzyl*-p-*hydroxy-β-phenylethylamine* forms colourless needles, m. p. 143°; whilst the Schiff *base* (*loc. cit.*) prepared from piperonaldehyde and *p*-hydroxy-β-phenylethylamine has m. p. 151°.

When *p*-hydroxy-β-phenylethylamine is combined with veratraldehyde it furnishes a Schiff *base*, m. p. 114°, which on reduction gives rise to N-*veratryl*-p-*hydroxy-β-phenylethylamine*, m. p. 118°; the *hydrochloride* has m. p. 215°, whilst with salicylaldehyde it yields a Schiff *base*, yellow needles, m. p. 145°, and on reduction N-*o-hydroxybenzyl*-p-*hydroxy-β-phenylethylamine*, colourless needles, m. p. 115°.

F. M. G. M.

The Condensation of Vanillin and Piperonal with Certain Aromatic Amines. ALVIN S. WHEELER (*J. Amer. Chem. Soc.*, 1913, **35**, 976—978. Compare A., 1909, i, 673; 1908, i, 332; 1903, i, 246). —An extension of the earlier investigations. In boiling toluene

solution, vanillin slowly condenses with p-aminobenzoic acid with formation of *4-hydroxy-3-methoxybenzylidene-p-aminobenzoic acid*, deep yellow plates, m. p. 211—212°, which on recrystallisation from water separates as a brilliant red substance with one molecule of water ; on expelling the water at 100° the original yellow colour is restored.

Vanillin condenses with ethyl p-aminobenzoate in boiling benzene solution, giving *ethyl 3-methoxy-4-hydroxybenzylidene-p-aminobenzoate*, thin, yellow plates, m. p. 145° (corr.).

Under similar conditions to the last, vanillin and p-anisidine produce *4-hydroxy-3-methoxybenzylidene-p-anisidine*, pale yellow crystals forming radiating clusters, m. p. 133·5° (corr.) ; with piperonal and p-anisidine, *3 : 4-methylenedioxybenzylidene-p-anisidine*, very pale yellow needles, m. p. 117·5° (corr.), is obtained.

Piperonal and p-aminobenzoic acid condense slowly in boiling toluene solution, yielding *3 : 4-methylenedioxybenzylidene-p-aminobenzoic acid*, pale yellow prisms, 233—234°. If the heating is less prolonged, or if an excess of the acid is taken, a *substance*, m. p. 171—173°, is obtained in considerable quantity.

When heated together in boiling benzene solution, piperonal and ethyl p-aminobenzoate undergo condensation to *ethyl 3 : 4-methylenedioxybenzylidene-p-aminobenzoate*, long, pale yellow needles, m. p. 109° (corr.).   D. F. T.

Preparation of Benzoylchloroamide. RASIK LAL DATTA and TARAPADA GHOSH (*J. Amer. Chem. Soc.*, 1913, **35**, 1044—1045).— Benzoylchloroamide is conveniently prepared by passing chlorine into an aqueous suspension of powdered benzamide until a sample of the solid, after separation and recrystallisation, has m. p. 116° ; the process usually occupies several hours.

If the method used by Bender (*Ber.*, 1882, **15**, 410) for the preparation of this substance is modified by adding acetic acid and then a concentrated solution of bleaching powder to an aqueous suspension of benzamide, the product is a *substance*, m. p. 153—163°.
                                                                           D. F. T.

Molecular Rearrangements of Carbon Compounds. II. Aromatic (N)-Acylamines and the Beckmann Rearrangement. CLARENCE G. DERICK and J. H. BORNMANN (*J. Amer. Chem. Soc.*, 1913, **35**, 1269—1289. Compare Derick, A., 1910, i, 805).—Further experimental evidence is produced in favour of the decision in the earlier investigation that non-reversible intramolecular rearrangements of carbon compounds take place in the direction to decrease the ionisation constant. For the purpose of determination of the small ionisation constants of acylamines, a colorimetric method based on the colours produced with suitable indicators has been developed, by means of which the ionisation constant of sufficiently soluble acids and bases may be estimated with a mean error of 2%.

In accord with the view expressed above it is found that each of such substances as acetanilide, propionanilide, benzanilide, and chloroacetanilide, which do not rearrange to monoacylaminoketones, has a

lower ionisation constant (basic) than the corresponding isomeride of the latter type. On the other hand, the aromatic diacylamides, for example, diacetanilide and dipropionanilide, which can undergo rearrangement (Chattaway, T., 1904, 386, 1181, etc.), are found to have higher ionisation constants (acidic) than their isomerides, p-acetylaminoacetophenone and p-propionylaminopropiophenone, which ionise as bases.

The results generally indicate that acyl radicles derived from acids with ionisation constants between 1.4×10^{-5} and 1.55×10^{-3} at 25° must be twice substituted at the nitrogen atom of aniline before isomeric change will be possible.

In the case of the Beckmann rearrangement, which has been studied with acetophenoneoxime and benzophenoneoxime, it is again found that the ionisation constants (basic) of these substances are greater than those of acetanilide and benzanilide, into which they pass by isomeric change.

p-*Propionylaminopropiophenone*, long, colourless needles, m. p. 151° (corr.), was obtained by the action of propionyl chloride on p-aminopropiophenone, and also by warming propionylanilide with propionyl chloride and aluminium chloride in carbon disulphide. The method adopted by Čech (A., 1878, 51) proved unsatisfactory for the preparation of chloroacetanilide, and it was found that much better results were obtainable by allowing aniline and chloroacetic acid to react in cooled ethereal solution and keeping the resulting aniline chloroacetate with the calculated quantity of phosphoric oxide in a well stoppered bottle for several weeks. D. F. T.

A New Method of Synthesising the Higher Phenols. TREAT B. JOHNSON and WILLARD W. HODGE (*J. Amer. Chem. Soc.*, 1913, 35, 1014—1023).—It is found that mixed ketones containing hydroxyl or alkyloxyl radicles in the benzene nucleus are readily and smoothly reducible by zinc amalgam and hydrochloric acid to form the corresponding alkyl-substituted phenols or ethers. The reaction appears to be a general one. Only those products which are described for the first time are mentioned below.

1-Acetyl-2 : 4-dihydroxybenzene is reduced by the above agent to 2 : 4-*dihydroxy-1-ethylbenzene*, prismatic crystals, m. p. 98—99°. The corresponding propionyl compound gives 2 : 4-*dihydroxy-1-propylbenzene* prisms, m. p. 82—83°.

2-Propionyl-1 : 4-dihydroxybenzene becomes converted into 1 : 4-*dihydroxy-2-propylbenzene*, microscopic needles, m. p. 86°. 2-*Propionyl-1 : 4-dimethoxybenzene*, a pale yellow oil, b. p. 167—169°/13 mm., obtained by the action of propionyl chloride and aluminium chloride on a solution of quinol dimethyl ether in light petroleum, on reduction yields 1 : 4-dimethoxy-2-propylbenzene (Thoms, A., 1903, i, 415).

It is noteworthy that whereas the reduction of 1-chloroacetyl-3 : 4-dihydroxybenzene by this new method proceeds satisfactorily giving a good yield of 3 : 4-dihydroxy-1-ethylbenzene, the action of zinc and hydrochloric acid, as has already been shown (Dziergowski, A., 1894, i, 73), leads only to the formation of 1-acetyl-3 : 4-dihydroxybenzene. D. F. T.

Triphenylmethyl. XXIII. Tautomerism of the Hydroxy-triphenylcarbinols. MOSES GOMBERG (*J. Amer. Chem. Soc.*, 1913, **35**, 1035—1042).—The conflicting results as to the properties of *p*-hydroxy-triphenylcarbinol (Bistrzycki and Herbst, A., 1903, i, 639; 1904, i, 44; Baeyer and Villiger, A., 1903, i, 813; Auwers and Schröter, A., 1903, i, 820) are readily explicable when it is borne in mind that tautomerism has been observed with such related compounds as triphenylmethyl and the triarylcarbinyl haloids (A., 1909, i, 144). There exist two forms of hydroxytriphenylcarbinol, probably of the benzenoid structure, $OH \cdot CPh_2 \cdot C_6H_4 \cdot OH$, and the quinonoid structure, $CPh_2 : C_6H_4 \diagdown_{OH}^{H}$, respectively.

The hydroxycarbinol is best prepared by demethylating *p*-anisyl-diphenylcarbinol with aluminium chloride in benzene. The product is digested with 3% sodium hydroxide solution, when, after filtration, the addition of excess of acetic acid precipitates the yellow quinonoid modification; this, after recrystallisation from 40—50% acetic acid, has m. p. 139—140°, whilst separation of the carbinol from the alkaline solution by addition of ammonium chloride solution gives the colourless benzenoid form, which, after crystallisation from aqueous alcohol containing a little ammonia, forms needles or plates, m. p. 157—159°, or sometimes 162—163° (compare Auwers and Schröter, *loc. cit.*).

The two forms are not physical isomerides, for a solution of each crystallises only in the original form even when inoculated with a crystal of the other. On heating the solids, the quinonoid modification commences to undergo dehydration below 60°, whilst the benzenoid modification begins to turn yellow in the neighbourhood of 100°, probably due to isomerisation, and simultaneously commences to lose water.

The yellow modification is always obtained when either form is crystallised from acetic acid, whilst the colourless modification is invariably the result if an alkaline solution is treated with ammonium chloride or if crystallisation is effected from alcohol containing some ammonia. Recrystallisation of either form from alcohol containing hydrochloric acid usually gives a mixture of yellow and colourless crystals, whilst alcohol alone induces tautomerisation but slowly.

Exposure to sunlight or ultraviolet radiation causes a fairly rapid and complete change of the colourless benzenoid to the yellow quinonoid tautomeride, so that, from analogy to the stereoisomeric ethylenic compounds, the latter is presumably the labile modification.

Hydrogen chloride is absorbed by both isomerides in the solid state with formation of the same chloride, $CPh_2 : C_6H_4 \diagdown_{OH}^{Cl}$, a deep red, iridescent solid apparently identical with the product of the action of hydrogen chloride on fuchsone; when treated with molecular silver this *p*-hydroxytriphenylcarbinyl chloride loses hydrogen chloride and gives rise to fuchsone.

It is found that this behaviour is apparently general for the *p*-hydroxytriphenylcarbinols, and that, also, *o*-cresyldiphenylcarbinol (compare Bistrzycki and Zurbriggen, A., 1904, i, 44) gives two modifications which can be best isolated by the methods applied above;

there exists similar relations between the modifications of high and low m. p., as regards colour and behaviour towards light. D. F. T.

Identification of "Jambulol" as Ellagic Acid. FREDERICK B. POWER and THOMAS CALLAN (*Pharm. J.*, 1913, **91**, 245).—Further examination of the substance present in jambul seeds, to which the name "jambulol" was given previously by the authors (A., 1912, ii, 480) shows that it is identical with ellagic acid (compare T., 1905, 87, 1412). W. P. S.

The Crystalline Deposit Occurring in the Timber of the "Colonial Beech" [Gmelina Leichhardtii, F.v.M.]. HENRY G. SMITH (*J. Roy. Sci. New South Wales*, 1913, **46**, 187—200).—The author has examined the white deposit which frequently fills the cells of the wood and accumulates in the cracks of *Gmelina Leichhardtii*; he proposes to name this, *gmelinol*. It separates from hot water in needle prisms or plates. In the crystalline state it has m. p. 122° (corr.) and, after cooling, solidifies to a transparent, resin-like substance, m. p. 62—63°. The latter m. p. remains unchanged after many weeks if the material is preserved in the glassy condition in the lump, but, if the fused substance is powdered, the m. p. immediately commences to rise, and, after a comparatively short time, has reached about 120—121°, but does not appear to revert quite to the m. p. of the original crystals. It has $[a]_D$ +123·3° when dissolved in chloroform. It dissolves in 1470 parts of water at 22°. Analyses and determination of molecular weight indicate the formula $C_{19}H_{14}O_4$. Nitric acid converts it into a *dinitro*-compound, $C_{19}H_{12}O_4(NO_2)_2$, m. p. 128—129°. Sodium acetate and acetic anhydride transform it into a *monoacetyl* derivative, m. p. 110°.

When an excess of bromine water is added to an aqueous solution of the substance, a light drab *substance*, $C_{12}H_{13}O_4Br$, is formed, which is not distinctly crystalline, and melts at about 100°, after much darkening at about 90°. The bromine atom must have been introduced into the side-chain, since it can be eliminated by boiling with alcoholic silver nitrate solution. Zeisel determinations indicate the presence of two methoxy-groups, and this is confirmed by the production of veratric acid when the substance is oxidised by a
solution of chromic acid in glacial acetic acid, or by alkaline permanganate. When fused with potassium hydroxide at a temperature not exceeding 200°, phenolic substances are formed, whilst, at 210—225°, protocatechuic acid is produced, together with small quantities of a volatile acid.

From the above experiments, and from the red and green colorations given by the vapour of the substance to pine wood moistened with hydrochloric acid, the author is led to propose tentatively the annexed formula for gmelinol. H. W.

Preparation of *N*-Monoalkyl Derivatives of *p*-Aminophenols. EMMANUEL MERCK (D.R.-P. 260234. Compare A., 1909, i, 222).— *N*-Alkyl derivatives of *p*-aminophenols are readily prepared by the

action of primary aliphatic amines on the alkali derivatives of quinol at a temperature of 200—250° for five to twenty hours, either in the presence or absence of condensing agents ; this reaction, moreover, can be carried out in aqueous solution or in the absence of a solvent.

Details are given of several modifications of these methods for preparing N-methyl-p-aminophenol from methylamine and quinol in the presence of sodium ethoxide, or of sodium carbonate either with or without the addition of zinc chloride or other condensing agents.   F. M. G. M.

Derivatives of Phenacyl Sulphide and their Stereoisomerism. EMIL FROMM and WILHELM SCHÖMER (*Annalen*, 1913, 399, 353—365).—*Dibenzylidenediphenacyl sulphide*, $S(CBz:CHPh)_2$, m. p. 270°, leaflets, is obtained from phenacyl sulphide, benzaldehyde, and sodium hydroxide in 50% alcohol. Diphenacyl sulphide and bromine in chloroform at 0° yield at first a yellow precipitate of the unstable *diphenacyl sulphide dibromide*, but ultimately *dibromodiphenacyl sulphide*, $C_{16}H_{12}O_2SBr_2$, m. p. 107°, white crystals, is obtained. The *di-iodide*, $I_2S(CH_2 \cdot COPh)_2$, m. p. 121°, red needles, is more stable, and is prepared in a similar manner.

Equal molecular quantities of diphenacylsulphoxide and phenylhydrazine in neutral or in acid solution yield *diphenacylsulphoxidephenylhydrazone*, $C_{22}H_{20}O_2N_2S$, m. p. 186°. Diphenacylsulphoxide and hydroxylamine hydrochloride, with or without sodium carbonate, yield *diphenacylsulphoxidedioxime*, $C_{16}H_{16}O_3N_2S$, m. p. 206°; no other oxime or dioxime has been obtained.

Dimethyldiphenacylsulphone has the symmetrical formula,
$$SO_2(CHMe \cdot COPh)_2,$$
since it is decomposed by boiling dilute sodium hydroxide into benzoic acid and diethylsulphone. Unlike diphenacylsulphone itself, dimethyldiphenacylsulphone does not condense with phenylhydrazine, semicarbazide, or hydroxylamine in acid, neutral, or alkaline solution. This inactivity apparently must be due to steric hindrance ; it is not to be attributed to the existence of the sulphone in the form $SO_2(CMe:CPh \cdot OH)_2$, because the substance does not react with acetic anhydride, benzoyl chloride, or sodium and chlorodinitrobenzene.
Diphenacylsulphone and aqueous bromine in daylight yield *dibromodiphenacylsulphone*, $C_{16}H_{12}O_4Br_2S$, m. p. 186°, prisms, after eight days, and *tetrabromodimethylsulphone*, $SO_2(CHBr_2)_2$, m. p. 151°, and benzoic acid after three months. Dibromodiphenacylsulphone forms a *dioxime*, $C_{16}H_{14}O_4N_2Br_2S$, m. p. 184°, needles, by boiling with hydroxylamine hydrochloride (two equivalents) and sodium carbonate, and an *oxime*, $C_{16}H_{13}O_4NBr_2S$, m. p. 158°, white needles, by boiling with alcohol and hydroxylamine hydrochloride ; isomeric oximes cannot be isolated.

The behaviour of the oximes and the dioximes of diphenacylsulphone has been partly described by Fromm and Flaschen. The dioxime, m. p. 204°, has the *syn.*-configuration (see below). It yields only an acetyl derivative with acetic anhydride, but by treatment with benzoyl chloride and sodium hydroxide is converted into a *dibenzoyl* derivative, $C_{30}H_{24}O_6N_2S$, m. p. 150°. The *anti*-dioxime has m. p. 209°, not 190°, as stated previously; it forms a *diacetyl* derivative, $C_{20}H_{20}O_6N_2S$,

m. p. 152°, and a *dibenzoyl* derivative, $C_{30}H_{24}O_6N_2S$, m. p. 168°. Its *anti*-configuration is proved by the behaviour of the dioxime with phosphorus pentachloride in boiling ether, whereby, after treatment with water, a *substance*, $C_{16}H_{16}O_4N_2S$, m. p. 215°, is obtained, which must be *sulphonediacetanilide*, $SO_2(CH_2 \cdot CO \cdot NHPh)_2$, since it is decomposed into aniline and sulphuric and acetic acids by aqueous sodium hydroxide. Consequently the dioxime, m. p. 204°, must have the *syn.*-configuration, since the dioxime-anhydride, m. p. 167°, being formed from each of the phenacylsulphoneoximes, must have the *amphi*-configuration.

The configurations of the diphenacylsulphoneoximes follow from the preceding. The *syn.*-dioxime can only result from the *syn.*-oxime; the latter, therefore, must be the oxime, m. p. 144°, since this yields the *syn.*-dioxime by treatment with hydroxylamine hydrochloride and calcium carbonate. The oxime, m. p. 173°, must therefore have the *anti*-configuration.

syn.-Diphenacylsulphonedioxime is unchanged by rapid treatment with phosphorus pentachloride and ether. When the mixture is kept for many days, it yields, after treatment with water, a *substance*, $C_{16}H_{13}O_2N_2Cl_3S$, m. p. 174°, yellow crystals, which is probably trichlorodiphenacylsulphonedioxime or its transformation product, trichlorosulphonediacetanilide; the substance, which can also be obtained from the *anti*-dioxime, is receiving further examination.　C. S.

Preparation of Condensation Products from Phenol-sulphonic Acids. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 260379).—An account of the preparation of *compounds*, colourless powders, soluble in water, which are obtained by heating a mixture of *o*- and *p*-phenolsulphonic acids during twenty-four to seventy-two hours at 130—140° under 20 mm. with condensing agents, such as phosphorus trichloride or thionyl chloride.　F. M. G. M.

α-Hydroxy-γ-phenylcrotonic Acid. J. BOUGAULT (*Compt. rend.*, 1913, **157**, 377—379).—The author puts forward an alternative constitution for the γ-hydroxyphenylcrotonic acid obtained from the α-hydroxy-acid by boiling in aqueous solution with oxalic acid (compare this vol., i, 727). From the behaviour of the new isomeride he is unable to decide between the two formulæ:

(I.) $HO \cdot CPh:CH \cdot CH_2 \cdot CO_2H$　(II.) $HO \cdot CHPh \cdot CH:CH \cdot CO_2H$,

but is now inclined to support formula II, by reason of the behaviour of the acid on oxidation with potassium permanganate. Further, he notes that the original transformation is reversible.　W. G.

Isomerisation of the α-Hydroxy-βγ-unsaturated Acids to γ-Ketonic Acids. J. BOUGAULT (*Compt. rend.*, 1913, **157**, 403—405. Compare Thiele, A., 1902, i, 152; Erlenmeyer, A., 1904, i, 1015).—The author considers that the transformation of α-hydroxyphenyl-crotonic acid into *p*-benzoylpropionic acid takes place in two stages, namely: $CHPh:CH \cdot CH(OH) \cdot CO_2H \longrightarrow HO \cdot CHPh \cdot CH:CH \cdot CO_2H \longrightarrow COPh \cdot CH_2 \cdot CH_2 \cdot CO_2H$.

The first stage has already been shown to take place under the

influence of dilute acids (compare preceding abstract), and since the second step can be brought about equally well by acids and alkalis, the intermediate formation of lactones (compare Thiele and Erlenmeyer, *loc. cit.*) is not necessary.   W. G.

Action of Light on Esters of α-Cyanocinnamylideneacetic Acid. II. MARIE REIMER and ELEANOR KELLER (*Amer. Chem. J.*, 1913, **50**, 157—171).—In continuation of previous work (A., 1911, i, 447), the authors have examined the behaviour of the methyl, ethyl, propyl, *iso*propyl, and *iso*butyl esters of α-cyanocinnamylideneacetic acid on exposure to light, both in the solid condition and also in solution. Without solvent all the esters polymerise to a dimeric form, the reaction being practically quantitative, except in the case of the stable ethyl ester, which is considerably oxidised. In alcoholic solution only the methyl ester undergoes polymerisation ; the ethyl ester is transformed into an unstable isomeride, whilst the remaining esters undergo slight oxidation. Similar results were obtained in benzene solution. The behaviour of the isomeric ethyl and *iso*butyl esters has also been studied. On exposure to light without solvent, the isomeric ethyl esters polymerise to dimeric forms, which are not identical but structurally isomeric (compare *loc. cit.*) ; at the same time the stable form is partly oxidised, whilst the unstable form is not.

In benzene and alcoholic solution the stable ethyl ester is transformed into the unstable isomeride ; the reverse reaction does not take place. The isomeric *iso*butyl esters behave in a similar manner.

From these results the conclusion is drawn that the action of light on ethylenic compounds is determined, not only by the nature of the groups, but also by the spatial configuration of the molecule.

The anomalous behaviour of the cinnamylidene compounds described by Stobbe (this vol., i, 177) may be explained on the assumption that in this series, compounds of different configuration were compared.

The unstable ethyl α-cyanocinnamylideneacetate crystallises in flat, straw-coloured needles, m. p. 113°.

Propyl α-cyanocinnamylideneacetate, prepared by the condensation of cinnamaldehyde with propyl cyanoacetate by means of potassium propyloxide in propyl-alcoholic solution, forms long, flat, orange crystals, m. p. 107°, and is converted by light into *propyl* 1 : 3-*diphenylcyclobutane-2 : 4-di-α-cyanoacrylate,*

$$CO_2Pr^a \cdot C(CN):CH \cdot HC \begin{matrix} CHPh \\ CHPh \end{matrix} CH \cdot CH:C(CN) \cdot CO_2Pr^a,$$

which crystallises in white needles, m. p. 107—108°, and is oxidised by potassium permanganate in acetone solution to α-truxillic, benzoic and oxalic acids.

iso*Propyl α-cyanocinnamylideneacetate,* prepared in a similar manner, forms lemon-yellow plates, m. p. 111—112°, and on exposure to light yields *isopropyl* 1 : 3-*diphenylcyclobutane-2 : 4-di-α-cyanoacrylate,* crystallising in needles, m. p. 136°. The stable form of iso*butyl α-cyanocinnamylideneacetate,* prepared by esterifying the acid by the hydrogen chloride method, forms yellow plates, m. p. 114°, and is converted by light into iso*butyl* 1 : 3-*diphenylcyclobutane-2 : 4-di-α-cyanoacrylate,* crystallising in glistening, white needles, m. p. 123°.

The unstable iso*butyl* ester is prepared by the condensation of cinnam-aldehyde with *iso*butyl cyanoacetate. It forms yellow plates, m. p. 110—111°, and by boiling with an *iso*butyl-alcoholic solution of hydrogen chloride is transformed into the stable form. On exposure to light, it polymerises to a dimeric form, $C_{32}H_{34}O_4N_2$, m. p. 114—115°, the constitution of which has not yet been established. F. B.

Phototropy. II. FERDINANDO GRAZIANI and F. BOVINI (*Atti R. Accad. Lincei*, 1913, [v], 22, ii, 32—41. Compare this vol., i, 984).— The hydrazones described in the present paper of the type

R'R''N·N:CHR

are not phototropic, resembling in this respect those of the type R'R'N·N:CHR previously investigated. The phenomenon is there-fore associated only with hydrazones of the type R'NH·N:CHR, and these must not contain a substituent in the ortho-position of the nucleus of the group R'. The explanation of the phototropy of the hydrazones would then be the mobility of the hydrazinic hydrogen atom, which is displaced to the ortho-position of the nucleus of the group R' by waves of short length, whilst those of great length, including those of heat, reproduce the original, stable form of the hydrazone. Of the hydrazones mentioned in this paper, the following have not previously been prepared:

Cuminaldehydephenylmethylhydrazone, MePhN·N:CH·C₆H₄·CHMe₂, forms pale yellow needles, m. p. 54°.

Cinnamaldehydephenylmethylhydrazone, MePhN·N:CH·CH:CHPh, crystallises in intensely yellow needles, m. p. 114°.

Salicylaldehydephenylmethylhydrazone has m. p. 74° (Labhardt and V. Zembruski, A., 1900, i, 125, gave 71°).

Piperonaldehydephenylmethylhydrazone has m. p. 88° (Goldschmidt, A., 1897, i, 54, gave 85°).

p-*Tolualdehydephenylmethylhydrazone,* MePhN·N:CH·C₆H₄Me, crys-tallises in soapy, yellowish-green leaflets, m. p. 122°.

Vanillinphenylmethylhydrazone, MePhN·N:CH·C₆H₄(OH)·OMe, forms colourless needles, m. p. 122°.

Cinnamaldehydephenylbenzylhydrazone,

CH₂Ph·NPh·N:CH·CH:CHPh,

is a lemon-yellow, crystalline powder, m. p. 167—168°.

Piperonalphenylbenzylhydrazone, CH₂Ph·NPh·N:CH·C₆H₃:O₂:CH₂, forms pale yellow needles, m. p. 124°.

p-*Tolualdehydephenylbenzylhydrazone,* CH₂Ph·NPh·N:CH·C₆H₄Me, crystallises in colourless, silky needles, m. p. 123—124°.

Phenyl-β-naphthylhydrazine may be prepared by reducing the cor-responding nitrosoamine with zinc and acetic acid.

Benzaldehydephenyl-β-naphthylhydrazone, C₁₀H₇·NPh·N:CHPh, forms yellow needles, m. p. 92—93°.

Anisaldehydephenyl-β-naphthylhydrazone,

C₁₀H₇·NPh·N:CH·C₆H₄·OMe,

crystallises in almost colourless, prismatic needles, m. p. 116—117°.

Cuminaldehydephenyl-β-naphthylhydrazone,

C₁₀H₇·NPh·N:CH·C₆H₄·CHMe₂,

forms colourless needles, m. p. 118°.

Cinnamaldehydephenyl-β-naphthylhydrazone,
$$C_{10}H_7 \cdot NPh \cdot N : CH \cdot CH : CHPh,$$
forms pale yellow, acicular crystals, m. p. 156°.

p-*Tolualdehydephenyl-β-naphthylhydrazone* forms yellow, acicular crystals, m. p. 154°.　　　　　　　　　　　　　　　　　R. V. S.

Reduction of Aromatic Ketones. JACOB BÖESEKEN and W. D. COHEN (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **16**, 91—99).—The authors have made an approximate quantitative study of the reduction of benzophenone by zinc dust and aluminium amalgam in neutral, faintly acid, faintly alkaline, and strongly alkaline alcoholic solutions. For this purpose, quantities of 5 grams of benzophenone were boiled under reflux for definite intervals, with the requisite amount of reducing agent in 50 c.c. of 80% alcohol, filtered hot, made up to 100 c.c., and shaken at 25° for a day. Benzopinacone, being practically insoluble, was then filtered off, if produced at all, and some of the filtrate was evaporated and the residue weighed and examined.

In a neutral solution, zinc dust had no action, but aluminium amalgam produced 32% of pinacone and 68% of pure benzhydrol. In a very faintly acid solution, in a current of carbon dioxide or in presence of ammonium chloride, zinc dust gave rise exclusively to the pinacone. In acetic acid solution both metals produced the pinacone, together with some pinacoline and diphenylmethane, but no benzhydrol. In presence of free ammonia the product was almost exclusively the hydrol, although a small amount of the pinacone was obtained. In a strongly alkaline solution the sole product with zinc dust was benzhydrol (compare Montagne, A., 1907, i, 14), whilst aluminium and magnesium amalgams and sodium gave, in addition, traces of diphenylmethane.

The chief controlling factor is therefore the reaction of the medium. As long as it is acid the pinacone is the sole product, but as soon as hydroxyl ions are present the hydrol appears. In the case of aluminium amalgam in aqueous alcohol it is assumed that a slight excess of these ions occurs at the surface of the metal. As the excess of hydroxyl ions increases, the pinacone can no longer exist, since it is easily converted into a mixture of benzophenone and benzhydrol,
$$[Ph_2COH]_2 \longrightarrow Ph_2CH \cdot OH + Ph_2CO.$$
The first product of the reduction is assumed to be, in all cases, the half-pinacone, Ph_2COH; this would polymerise at once to the pinacone, which would remain unchanged, unless the concentration of hydroxyl ions were such that it would be resolved into the hydrol and the ketone with appreciable velocity. In alkaline solution the half-pinacone might also be reduced directly to the hydrol, but the above assumption would account for the occurrence of a little pinacone in solutions with very low hydroxyl-ion concentration.
The latter point was verified by the reduction of several substituted benzophenones by means of aluminium amalgam in 80% alcohol. The methoxy- and methyl groups appear to favour the formation of pinacone, but halogens in the nucleus, and especially a number of them, have the opposite effect; thus *pp'*-dichlorobenzophenone gave 96% of hydrol and 4% of pinacone. In dilute acetic acid solution with zinc

dust, however, it gave a quantitative yield of *tetrachlorobenzopinacone*, $C_{26}H_{18}O_2Cl_4$, m. p. 180°.   J. C. W.

Action of Magnesium Phenyl Bromide on Di-α-bromoiso-propyl Ketone. (Mlle.) ANNA I. UMNOVA (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 881—884).—From a study of the products obtained by the interaction of magnesium methyl bromide (or iodide) and di-α-bromoisopropyl ketone (this vol., i, 7), it is supposed that the reaction is represented by the equation :

$$CMe_2Br\cdot CO\cdot CMe_2Br + 2MgMeX =$$
$$CH_3X + MgBrX + CMe_3\cdot CO\cdot CMe_2\cdot MgBr,$$

the action of water then yielding *iso*propyl *tert.*-butyl ketone. This supposition is supported by the liberation of a gas burning with a green flame when methyl bromide is employed, and by the formation of silver iodide when the ethereal extract of the products obtained with methyl iodide is treated with silver nitrate ; the formation of methyl iodide was not, however, directly proved.

If, however, magnesium phenyl bromide is used in the reaction in place of the magnesium methyl compound, bromobenzene is found to be liberated. In one case, the complex magnesium ketonic compound was treated with water so as to yield α-phenyl*iso*propyl *iso*propyl ketone, and in another with carbon dioxide to give the corresponding β-ketonic acid.

α-*Phenyliso*propyl *iso*propyl *ketone*, $CPhMe_2\cdot CO\cdot CHMe_2$, b. p. 118—119°/12 mm., 243—244°/760 mm., could not be obtained quite free from diphenyl. Its *bromo*-derivative, $C_{13}H_{17}OBr$, forms stout prisms, m. p. 64—65°, apparently containing alcohol of crystallisation, and has the normal molecular weight in freezing benzene.

The *ketonic acid*, $CPhMe_2\cdot CO\cdot CMe_2\cdot CO_2H$, m. p. 90—91° (decomp.), exhibits marked association in freezing benzene. Its *silver* salt was analysed.   T. H. P.

Condensation Products of *m*-Methoxybenzaldehyde. HUGO BAUER and P. VOGEL (*J. pr. Chem.*, 1913, [ii], **88**, 329—342).—It has been shown previously (A., 1903, i, 479 ; 1904, i, 385 ; 1911, i, 881) that the introduction of alkyloxy-groups in the ortho- and para-position of the benzene nucleus in compounds of the type

$$CHPhBr\cdot CHBr\cdot R$$
is accompanied by a marked increase in the reactivity of the bromine atom adjacent to the aromatic group; the bromine atom is readily replaced by alkyloxy-groups when the dibromides are boiled in alcoholic solution.

The reactivating influence of the alkyloxy-groups is apparently confined to the ortho- and para-positions, for the dibromides of *m*-methoxy-styryl methyl ketone and phenyl *m*-methoxystyryl ketone may be boiled with alcohol without undergoing change.

m-*Methoxystyryl methyl ketone*, $OMe\cdot C_6H_4\cdot CH\!:\!CH\cdot COMe$, obtained as an oil, b. p. 173°/8 mm., by the condensation of *m*-methoxybenz-aldehyde with acetone in the presence of aqueous sodium hydroxide, forms a *semicarbazone*, slender, yellow needles, m. p. 197—198°, and a yellow, crystalline *phenylhydrazone*, m. p. 116—117°, which decomposes when kept and is converted by boiling in glacial acetic acid solution

into 1-*phenyl*-5-m-*methoxyphenyl*-3-*methylpyrazoline*,

$$\begin{array}{c} CMe \cdot CH_2 \\ N\!\!-\!\!-\!\!NPh \end{array}\!\!\!>\!\!CH \cdot C_6H_4 \cdot OMe,$$
m. p. 93—94°. It reacts with bromine (2 mols.), yielding *αβ-6-tri-bromo-α-3-methoxyphenylbutan-γ-one*, OMe·C_6H_3Br·CHBr·CHBr·COMe. This forms slender, white crystals, m. p. 112°, and when heated with pyridine loses hydrogen bromide with the formation of *β-6-dibromo-α-3-methoxyphenyl-Δ^α-buten-γ-one*, OMe·C_6H_3Br·CH:CBr·COMe, which crystallises in extremely slender, colourless, down-like needles, m. p. 64°. The position of the bromine atom in the benzene nucleus of the preceding compounds has been established by the formation of 6-bromo-3-methoxybenzoic acid (Pschorr and others, A., 1912, i, 775) on oxidising the dibromo-compound with aqueous permanganate.

Phenyl m-*methoxystyryl ketone*, OMe·C_6H_4·CH:CH·COPh, prepared by the condensation of *m*-methoxybenzaldehyde and acetophenone in alcoholic solution by means of sodium hydroxide has b. p. 247°/12 mm., m. p. 65°, and is converted by phenylhydrazine in boiling alcoholic solution into 1 : 3-*diphenyl*-5-m-*methoxyphenylpyrazoline*, which crystallises in slender, green needles, m. p. 98°, yields green, fluorescent solutions in alcohol and acetone, and is oxidised by aqueous potassium permanganate to 1 : 3-*diphenyl*-5-m-*methoxyphenylpyrazole*, $C_{22}H_{18}ON_2$, crystallising in large, yellow needles, m. p. 140°.

It reacts with bromine in glacial acetic acid solution, yielding *αβ-6-tri-bromo - β - 3 - methoxyphenylpropiophenone* (*phenyl αβ - 6-tribromo-β-3-methoxyphenylethyl ketone*), OMe·C_6H_3Br·CHBr·CHBr·COPh. This forms stout, colourless crystals, m. p. 140°, and is oxidised by potassium permanganate to 6-bromo-3-methoxybenzoic acid. When heated with pyridine or alcoholic ammonia, it is converted into *phenyl α-6-dibromo-3-methoxystyryl ketone*, OMe·C_6H_3Br·CH:CBr·COPh, which forms slender needles, m. p. 105°. With alcoholic sodium ethoxide it forms *phenyl α-6-dibromo-β-ethoxy-β-3-methoxyphenylethyl ketone*,

$$OMe \cdot C_6H_3Br \cdot CH(OEt) \cdot CHBr \cdot COPh,$$
m. p. 109—110°.

Ethyl m-*methoxybenzylidenemalonate*, OMe·C_6H_4·CH:C(CO$_2$Et)$_2$, prepared by maintaining a mixture of *m*-methoxybenzaldehyde and ethylmalonate, containing a little pyridine, for eight days at the ordinary temperature has m. p. 47°, b. p. 204—206°/10 mm., and is hydrolysed by aqueous sodium hydroxide to the corresponding *acid*, m. p. 163°, which forms a crystalline *barium* and amorphous *silver* salt, and reacts with bromine (1 mol.) in ethereal solution, yielding *α-bromo-α-m-methoxyphenylmethylenemalonic acid*, OMe·C_6H_4·CBr:C(CO$_2$H)$_2$, slender, yellow needles, m. p. 188°.

The *ethyl* ester of the last-mentioned acid is obtained as a viscid oil, b. p. 208°/10 mm., by the addition of bromine to ethyl *m*-methoxybenzylidenemalonate in glacial acetic acid.

m-Methoxybenzylidenemalonic acid reacts with bromine (2 mols.) in acetic acid solution, yielding *α-6-dibromo-α-3-methoxyphenylmethylene-malonic acid*, OMe·C_6H_3Br·CBr:C(CO$_2$H)$_2$, slender, pale yellow needles, m. p. 167°. When heated at 180°, it loses carbon dioxide with the formation of *m*-methoxycinnamic acid, m. p. 117° (compare Tiemann and Ludwig, A., 1883, 188), which is successively converted by the

action of bromine in glacial acetic acid solution int₃ β-bromo-m-*methoxycinnamic acid*, slender, colourless needles, m. p. 186°, and β-6-*dibromo-3-methoxycinnamic acid*, OMe·C₆H₃Br·CBr:CH·CO₂H, white needles, m. p. 160°.

6-Bromo-3-methoxybenzoic acid is readily prepared by shaking m-methoxybenzaldehyde with water and the theoretical amount of bromine.

If excess of bromine is used, it is accompanied by a *dibromo-m-methoxybenzoic acid*, which crystallises in slender, felted needles, m. p. 201—202°, and is separated from the monobromo-acid by taking advantage of its sparing solubility in water.   F. B.

Some Acetylenic Compounds. ÉMILE ANDRÉ (*Ann. Chim. Phys.*, 1913, [viii], **29**, 540—596).—The paper is mainly a résumé of work previously abstracted (A., 1910, i, 563; 1911, i, 269, 277, 545; 1912, i, 628). The following points are, however, new.

Unsuccessful attempts have been made to prepare phenylpropinene, CH₂Ph·C⋮CH, by the elimination of hydrogen bromide from allylbenzene dibromide.

Phenylbutinene has b. p. 189—191°/760 mm., D⁰ 0·9375.

iso*Heptylene*, b. p. 84—85°/762 mm., D⁰ 0·7087, is obtained by the addition of an ethereal solution of allyl iodide to a solution of magnesium *iso*butyl chloride in the same solvent. It unites with bromine, yielding a *dibromide* which, when heated with solid potassium hydroxide at about 130°, is converted into iso*heptinene*, CHMe₂·CH₂·CH₂·C⋮CH, b. p. 92—93°, D⁰ 0·7515.

α-*Propionyl-δ-phenylbutinene*, CH₂Ph·CH₂·C⋮C·COEt, is prepared by the gradual addition of a suspension of the potassium compound of δ-phenylbutinene in benzene to a solution of propionyl chloride in benzene. It is a pale yellow liquid, b. p. 162—163°/15 mm., D⁰ 1·0156; the *piperidyl* compound has m. p. 44°.

Propionylisoheptinene, b. p. 100—101°/15 mm., D⁰ 0·8902, is obtained in a similar manner, the benzene, however, being replaced by anhydrous ether.

ε-*Diethylamino-β-methyl-Δᵋ-nonen-η-one*, b. p. 163°/13 mm., is obtained by mixing its constituents at a low temperature.

α-*Propionyl-δ-phenylbutan-β-one*, CH₂Ph·CH₂·CO·CH₂·COEt, has b. p. 166°/13 mm., D⁰ 1·0460, and α-*propionylisoheptan-β-one*,

$$CHMe_2·CH_2·CH_2·CO·CH_2·COEt,$$

b. p. 106°/14 mm., D⁰ 0·9262.

Ethylenic β-substituted amino-ketones react with hydroxylamine in a complex manner. Thus diethylaminobenzoylstyrene yields a small quantity of 3 : 5-diphenyl*iso*oxazole, O⟨N⁼⁼CPh / CPh:CH , m. p. 142°, together with two other *substances*, one of which has m. p. 163°.

Hexoylphenylacetylene and *iso*valerylphenylacetylene react with hydroxylamine to yield 5-*phenyl-3-amylisooxazole*, m. p. 25—26°, b. p. 186—187°/13 mm., and 5-*phenyl-3-isobutylisooxazole*, b. p. 172°/13 mm., respectively, neither of which regenerates hydroxylamine when heated with dilute hydrochloric acid.

3-Phenyl-5-*amylpyrazole*, plates, m. p. 77—78°, is formed by the action of hydrazine on hexoylphenylacetylene.

Reduction of ethylenic β-substituted amino-ketones by sodium or sodium amalgam in alcoholic solution, or by aluminium amalgam in neutral solution, causes a quantitative separation of the amine. A regular hydrogenation of the remainder of the molecule has not yet been achieved.   H. W.

Action of Ethyl Oxalate on Cyclic Ketones. ARTHUR KÖTZ and J. MEYER (*J. pr. Chem.*, 1913, [ii], **88**, 261—272).—In previous papers (A., 1906, i, 88, 666, 667, 668), Kötz and others have shown that cyclic ketones condense with ethyl oxalate under the influence of sodium alkyloxides, yielding ketonic esters of the formula

$$R\!\!<^{CO}_{CH\cdot CO\cdot CO_2Et}\cdot$$
It is now found that in the case of certain derivatives of *cyclo*-hexanone, alcohol may be eliminated from the ketonic esters during the condensation, resulting in the formation of lactones derived from the following formulæ:

$$\begin{matrix} CH_2\cdot CH{=}C\cdot O\cdot CO \\ CH_2\cdot CH_2\cdot CH{-}CO \end{matrix}\ or\ \begin{matrix} CH_2\cdot CH{=}C\cdot O\cdot CO \\ CH_2\cdot CH_2\cdot C{=}C\cdot OH \end{matrix}\cdot$$
One example of the formation of a lactone of this type has already been recorded (this vol., i, 179).

From the authors' results it would appear that ketonic esters are produced when the time during which the reaction is allowed to proceed is short and the temperature low, whilst a high temperature and a more prolonged action favour the formation of lactones.

Ethyl suberone-2-*oxalate* (*ethyl* 2-*cycloheptanonylglyoxylate*), prepared from *cyclo*heptanone, ethyl oxalate, and alcoholic sodium ethoxide, has b. p. 146—148°/13 mm.

3-Methyl-Δ²-*cyclohexen*-2-*ol*-1-*glyoxylolactone* (this vol., i, 179) yields with acetic anhydride an *acetyl* derivative,

$$\begin{matrix} CH_2\cdot CMe{:}C\cdot O\cdot CO \\ CH_2\cdot CH_2\cdot C{=}C\cdot OAc \end{matrix},$$
m. p. 78°.

The methyl derivative of the lactone (*loc. cit.*) is hydrolysed by aqueous potassium hydroxide (1 mol.) to 3-*methyl*cyclohexan-2-onylidene-methoxyacetic acid, m. p. 139°, $CH_2\!\!<^{CHMe\cdot CO}_{CH_2-CH_2}\!\!>C{:}C(OMe)\cdot CO_2H$ or

$CH_2\!\!<^{CMe{:}C(OH)}_{CH_2-CH_2}\!\!>C{:}C(OMe)\cdot CO_2H.$
2-Methoxy*cyclo*hexanone condenses with ethyl oxalate, yielding 3-*methoxy*-Δ²-*cyclohexen*-2-*ol*-1-*glyoxylolactone*,

$$\begin{matrix} CH_2\cdot C(OMe){:}C\cdot O\cdot CO \\ CH_2\cdot CH_2{-}{-}CH{-}CO \end{matrix}\ or\ \begin{matrix} CH_2\cdot C(OMe){:}C\cdot O\cdot CO \\ CH_2\cdot CH_2{-}{-}C{=}C\cdot OH \end{matrix},$$
which has m. p. 51°.

3:6-*Dimethyl*-Δ²-*cyclohexen*-2-*ol*-1-*glyoxylolactone*, from 1:4-dimethyl-*cyclo*hexan-3-one, has m. p. 158—159°.

6-Methyl-3-isopropyl-Δ²-cyclohexen-2-ol-1-glyoxylolactone,

$$CH_2\cdot CMe\vdots C\!\!-\!\!CO$$
$$CH_2\cdot OPr^\beta\vdots C\cdot O\cdot CO \text{ ,}$$
prepared from menthone, ethyl oxalate, and sodium in the presence of light petroleum, has m. p. 142·5° (decomp.), and decomposes on exposure to air.

In addition to ketonic esters and lactones, the condensation of ethyl oxalate with *cyclo*hexanone and its methyl derivatives gives rise to triketones or pyrone derivatives, which are found in the higher boiling fractions of the condensation product.

Thus, the condensation of 2-methyl*cyclo*hexanone and ethyl oxalate yields, as a by-product, *bis*-3-*methyl*cyclohexan-2-onyl *ketone*,

$$CH_2{<}^{CHMe\cdot CO}_{CH_2\!-\!CH_2}{>}OH\cdot CO\cdot OH{<}^{CO\cdot CHMe}_{CH_2\!-\!CH_2}{>}CH_2,$$
which has b. p. 170°/13 mm., and gives a reddish-violet coloration with ferric chloride.

Biscyclohexan - 2 - onyl ketone, from *cyclo*hexanone, has b. p. 181°/14 mm.

3-Methyl*cyclo*hexanone yields the *pyrone* derivative, m. p. 121°,

$$CHMe\cdot OH_2\cdot C\!-\!O\!-\!C\cdot OH_2\cdot CHMe$$
$$OH_2\cdot OH_2\!-\!C\cdot CO\cdot C\cdot OH_2\cdot OH_2 \text{ ; the } pyrone \text{ derivative from 4-methyl-}$$

*cyclo*hexanone has m. p. 91°.

The formation of the above-mentioned products is probably due to the intermediate formation of tetraketones of the type:

$$CH_2{<}^{CH_2\!-\!CO}_{CH_2\cdot CH_2}{>}OH\cdot CO\cdot CO\cdot OH{<}^{CO\!-\!CH_2}_{CH_2\cdot CH_2}{>}CH_2,$$
by the condensation of one molecule of the ester with two molecules of the ketone, the tetraketone being subsequently converted into the triketone and pyrone derivatives by loss of carbon monoxide and water. F. B.

Unsaturated β-Diketones. I. HUGH RYAN and JOHN M. DUNLEA (*Proc. Roy. Irish Acad.*, 1913, **32**, 1—8).—Some typical unsaturated β-diketones have been prepared by condensing cinnamic esters with saturated ketones in presence of sodium or sodamide. All attempts to prepare similar compounds by condensing acetic and benzoic esters with unsaturated ketones have, however, failed, and consequently the chief aim of the research, the formation of the parent substance of curcumin, $CH_2(CO\cdot OH\vdots CHPh)_2$, from a cinnamic ester and styryl methyl ketone, could not be realised.

For the preparation of *a-phenyl-Δª-hexene-yε-dione,*

$$OHPh\vdots OH\cdot CO\cdot OH_2\cdot COMe,$$

sodium wire was added during the course of some hours to a cold mixture of acetone and methyl cinnamate, and the sodium salt of the diketone was dissolved in water and decomposed by carbon dioxide. The compound crystallises in faintly yellow needles, has m. p. 83—84°, gives a yellow solution in concentrated sulphuric acid, and a red coloration with alcoholic ferric chloride, and dyes mordanted wool. On heating with hydroxylamine hydrochloride in alcohol, it yields

3-*styryl*-5-*methyl*isooxazole, $CHPh{:}CH{\cdot}C{<}^{CH{:}CMe}_{N—O}$, which forms pearly plates from alcohol or colourless needles from light petroleum, m. p. 88°. *αε-Diphenyl-Δ*α-*pentene-*γε-*dione*, $CHPh{:}CH{\cdot}CO{\cdot}CH_2{\cdot}COPh$, from acetophenone and ethyl cinnamate in the presence of sodamide, forms long, pale yellow needles, m. p. 109°, and yields 5-*phenyl*-3-*styryl*isooxazole, $CHPh{:}CH{\cdot}C{<}^{CH{:}CPh}_{N—O}$, in small, colourless needles, m. p. 137—138°.

*α-Phenyl-Δ*α-*heptene-*γε-*dione*, $CHPh{:}CH{\cdot}CO{\cdot}CH_2{\cdot}COEt$, from methyl cinnamate and methyl ethyl ketone, requires a stronger acid than carbon dioxide for the decomposition of its sodium compound. It forms small, colourless prisms, which soften at 154° and melt to a yellow liquid at 161—163°. Similarly, *α-phenyl-Δ*α-*isooctene-*γε-*dione*, $CHPh{:}CH{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}CHMe_2$, crystallises in thin plates which are probably rhombic, and softens at 165° and melts to a yellow liquid at 173—175°. These diketones are soluble in potassium hydroxide, but do not give coloured solutions in sulphuric acid or colorations with ferric chloride, nor do they dye mordanted wool. That their constitution is not represented by the alternative formulæ was proved by methylating α-phenyl-Δα-hexene-γε-dione, when it was found that *α-phenyl-δ-methyl-Δ*α-*hexene-*γε-*dione*, $CHPh{:}CH{\cdot}CO{\cdot}CHMe{\cdot}COMe$, was not identical with the above α-phenyl-Δα-heptene-γε-dione, but formed long, pale yellow needles, m. p. 88—89°, and gave a dark brown coloration with alcoholic ferric chloride, a yellow solution in sulphuric acid, and a pale brown colour to wool mordanted with iron.

<div align="right">J. C. W.</div>

Unsaturated β-Diketones. II. HUGH RYAN and JOSEPH ALGAR (*Proc. Roy. Irish Acad.*, 1913, **32**, 9—16).—Although unsaturated ketones did not yield definite compounds on condensation with acetic or benzoic esters (compare preceding abstract), such a result has been attained with the oxalic esters. *Methyl* αγ-*diketo-*ε-*phenyl-Δ*δ-*hexenoate* (*methyl benzylideneacetoneoxalate*),

<div align="center">$CHPh{:}CH{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}CO_2Me$,</div>
from styryl methyl ketone and methyl oxalate in the presence of sodium, forms pale yellow, acicular prisms, m. p. 70° (compare the ethyl ester, Schiff and Gigli, A., 1898, i, 490). It gives a yellow solution in potassium hydroxide, an orange solution in concentrated sulphuric acid, and a yellow solution with greenish fluorescence in alcohol. Ferric chloride imparts a dark red colour to an alcoholic solution, and the substance dyes wool orange-red or brown, according to the mordant employed. αγ-*Diketo-*ε-*phenyl-Δ*δ-*hexenoic acid*, $CHPh{:}CH{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}CO_2H$, may readily be obtained by hydrolysis of the esters, in pale yellow needles, m. p. 139—140°. When the methyl ester is heated with hydroxylamine hydrochloride in methyl alcohol, *methyl* 3-*styryl*isooxazole-5-*carboxylate*,

<div align="center">$CHPh{:}CH{\cdot}C{<}^{CH{:}C{\cdot}CO_2Me}_{N—O}$,</div>
is formed in long, colourless needles, m. p. 142—143°. When ethyl

alcohol is employed, however, a transformation occurs, and the *ethyl ester* is produced, in colourless crystals, m. p. 111°. The free *acid*, $C_{12}H_9O_3N$, is white, and has m. p. 190—192°. The above methyl ester also absorbs bromine, yielding *methyl δε-dibromo-aγ-diketo-ε-phenylhexoate*, CHPhBr·CHBr·CO·CH$_2$·CO·CO$_2$Me, in almost colourless prisms, m. p. 134°.

Similar compounds were obtained by condensing *p*-methoxystyryl methyl ketone with methyl oxalate. *Methyl aγ-diketo-ε-p-methoxyphenyl-Δδ-hexenoate*, OMe·C$_6$H$_4$·CH:CH·CO·CH$_2$·CO·CO$_2$Me, forms yellow needles, m. p. 127·5°, and with bromine yields *methyl δε-dibromoaγ-diketo-ε-p-methoxyphenylhexoate*, $C_{14}H_{14}O_5Br_2$, in pale yellow needles, m. p. 106—108° (decomp.). The free *acid* crystallises with water in bright yellow, slender needles, whilst the anhydrous substance is deep orange, and has m. p. 150—151°. *Ethyl 3-p-methoxystyryl-isooxazole-5-carboxylate*, $C_{15}H_{15}O_4N$, from the above methyl ester with hydroxylamine hydrochloride in ethyl alcohol, forms long, colourless needles, m. p. 76—77°.   J. C. W.

Alkylation of Ketones by means of β-Ketoneoxalic Esters.
ARTHUR KÖTZ and K. BLENDERMANN (*J. pr. Chem.*, 1913, [ii], 88, 257—260).—The method previously employed (this vol., i, 179) to convert 1-methyl*cyclo*hexan-3-one into 1 : 4-dimethyl*cyclo*hexan-3-one is found to be of general application for alkylating both aliphatic and hydroaromatic ketones. It consists in condensing the ketone with ethyl oxalate by means of sodium methoxide or ethoxide, heating the sodium derivative of the resulting ketonic ester (I) with an alkyl haloid, and hydrolysing the product (II) with aqueous alkali hydroxides :

$$R\underset{CH_2}{\overset{CO}{<}} \longrightarrow (I.)\ R\underset{CH·CO·CO_2Et}{\overset{CO}{<}} \overset{R'I}{\longrightarrow}$$

$$(II.)\ R\underset{CR'·CO·CO_2Et}{\overset{CO}{<}} \longrightarrow R\underset{CHR'}{\overset{CO}{<}} + EtOH + H_2C_2O_4.$$
Thus, acetone can be converted into methyl ethyl ketone by condensing it with ethyl oxalate and alcoholic sodium ethoxide, heating the ethyl sodioacetoneoxalate thus formed with methyl iodide, and hydrolysing the resulting methyl derivative with the calculated amount of 10% aqueous sodium hydroxide.

Ethyl 1 : 3-dimethyl*cyclo*hexan-2-onylglyoxylate,

$$CH_2\underset{CH_2-CH_2}{\overset{CHMe·CO}{<}}>CMe·CO·CO_2Et,$$
obtained from 1-methyl*cyclo*hexan-2-one, ethyl oxalate, and methyl iodide, yields, on hydrolysis, 1 : 3-dimethyl*cyclo*hexan-2-one (Kötz and Schaeffer, A., 1912, i, 603).

On treatment with ethyl iodide and subsequent hydrolysis, the sodium derivative of ethyl 4-methyl*cyclo*hexan-2-onylglyoxylate, obtained from 1-methyl*cyclo*hexan-3-one and ethyl oxalate, yields 1-*methyl-4-ethylcyclohexan-3-one*, a strongly refractive, colourless liquid, b. p. 81—82°/17 mm., having an odour resembling that of menthone.

4-Benzyl-1-methylcyclohexan-3-one, prepared in a similar manner, using benzyl chloride, has b. p. 176°/15 mm.

Ethyl methylisothujoneoxalate (*ethyl* 1 : 3 : 4-*trimethyl-5-isopropyl-Δ³-*

cyclo*hexen-2-onylglyoxylate*), $\begin{matrix} CMe\text{——}CO \\ CMe\cdot CHPr^\beta \end{matrix}\text{>}$CMe·CO·CO$_2$Et, obtained by
heating the product of the condensation of *iso*thujone and ethyl oxalate
with methyl iodide, has b. p. 183°/11 mm., and is hydrolysed by
aqueous sodium hydroxide to *methyliso*thujone (1 : 3 : 4-*trimethyl*-5-
isopropyl-Δ³-cyclo*hexen-2-one*), $\begin{matrix} CMe\text{——}CO \\ CMe\cdot CHPr^\beta \end{matrix}\text{>}$CHMe, which has b. p.
229—231°, and has also been prepared by the reduction of hydroxy-
methyleneisothujone (Schaeffer, *Diss.*, Göttingen, 1903).   F. B.

**Isolation of Lapachol from the Heart-wood of Avicennia
tomentosa.** KONRAD BOURNOT (*Arch. Pharm.*, 1913, 251, 351—354).
—The residue left after the evaporation of the ethereal extract of the
powdered heart-wood of *Avicennia tomentosa* yields to 3% aqueous
sodium carbonate a substance, lapachol, $C_{15}H_{14}O_3$, m. p. 140—141°,
truncated, yellow plates, which is shown by its m. p., crystalline form,
solubilities, and formation of a diacetyl derivative, m. p. 130°, to be
identical with Paternò's and with Hooker's lapachoic acid (2-hydroxy-
3-ωω-dimethylallyl-α-naphthaquinone).   C. S.

**The Anthraquinone Series. I. Halogenated 2-Amino-
anthraquinones.** WALTER JUNGHANS (*Annalen*, 1913, 399, 316—330).
—1-*Chloro*-2-*acetylaminoanthraquinone*, m. p. 241—242° (corr.), faintly
yellow needles, obtained by the chlorination of 2-acetylaminoanthra-
quinone in acetic acid containing sodium acetate on the water-bath,
yields, by hydrolysis by acids or alkalis, 1-*chloro*-2-*aminoanthraquinone*,
m. p. 237°, orange needles or reddish-brown leaflets. The latter reacts
with *p*-toluenesulphonamide, potassium acetate, and a trace of copper
acetate in boiling amyl alcohol to form 1-*p*-*toluenesulphonylamino*-
2-*aminoanthraquinone*, m. p. 239° (corr.), yellowish-red leaflets. In a
similar manner, 1-chloro-2-acetylaminoanthraquinone yields 1-*p*-*toluene-
sulphonylamino*-2-*acetylaminoanthraquinone*, m. p. 207° (corr.), long
needles. Both of these substances yield 1 : 2-diaminoanthraquinone by
hydrolysis, whereby the constitution of the chloroaminoanthraquinone
is determined.
By treatment with chlorine in warm glacial acetic acid or with
potassium chlorate and concentrated hydrochloric acid in glacial acetic
acid at the ordinary temperature, 2-aminoanthraquinone yields 1 : 3-*di-
chloro*-2-*aminoanthraquinone*, m. p. 231° (corr.), yellowish-brown needles,
which is converted by boiling acetic anhydride into 1 : 3-*dichloro*-
2-*diacetylaminoanthraquinone*, m. p. 199° (corr.), silvery leaflets, and
into 1 : 3-*dichloro*-2-*benzoylaminoanthraquinone*, m. p. 227° (corr.),
faintly yellow needles, by benzoyl chloride in boiling nitrobenzene.
The constitution of 1 : 3-dichloro-2-aminoanthraquinone is proved by
eliminating the amino-group in the usual manner, whereby is obtained
the 1 : 3-*dichloroanthraquinone*, m. p. 203° (corr.), which is produced
from 1 : 3-dichloro-4-aminoanthraquinone by the same method.
Contrary to statements in the literature, the interaction of equal
molecular quantities of 2-aminoanthraquinone and bromine in glacial
acetic acid at the ordinary temperature produces 3-*bromo*-2-*amino*-

anthraquinone hydrobromide, from which the *base,* m. p. 311° (corr.), yellow leaflets, is obtained by boiling with water. 3-Bromo-2-amino-anthraquinone forms an *acetyl* derivative, m. p. 217° (corr.), colourless needles, and a *benzoyl* derivative, m. p. 279° (corr.), colourless needles. Its constitution is proved by deamidation, whereby 2-bromoanthra-quinone is produced, and also by the formation of a thiazole derivative (Ullmann and Junghans, below). By prolonged boiling with glacial acetic and concentrated hydrobromic acids, 1 : 3-dibromo-2-amino-anthraquinone loses the halogen atom in position 1 and yields 3-bromo-2-aminoanthraquinone, m. p. 311° (corr.). C. S.

Preparation of β-Bromoaminoanthraquinones Containing a Bromine Atom in the Next Position to an Amino-group. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 261270 and 261271).— *3-Bromo-2-aminoanthraquinone,* m. p. 305°, as previously obtained (A., 1904, i, 512) had m. p. 267—270°, and the pure substance has now been prepared as follows : 2-aminoanthraquinone (5·8 parts) and 10 parts of 1 : 3-dibromo-2-aminoanthraquinone (A., 1905, i, 797) dissolved in 160 parts of concentrated sulphuric acid are slowly heated with continual stirring to 160°, when a reaction takes place, and after about fifteen minutes at 170° pure 3-bromo-2-aminoanthraquinone sulphate crystallises out ; the same result is obtained if the bases are heated together during ten minutes at 280° in the absence of any solvent.

2-Bromo-1-aminoanthraquinone (A., 1905, i, 910) is obtained in a similar manner from 1-aminoanthraquinone and 2 : 4-dibromo-1-amino-anthraquinone.

1 : 3 : 5 : 7-*Tetrabromo-*2 : 6-*diaminoanthraquinone,* yellowish-brown needles, m. p. above 360°, is prepared by brominating an aqueous suspension of 2 : 6-diaminoanthraquinone, and when molecular proportions of these two bases are heated together at 195° in slightly diluted sulphuric acid during half an hour, they furnish pure 3 : 7-*dibromo-*2 : 6-*diaminoanthraquinone sulphate ;* whilst a mixture of 1 : 5-diamino-and 2 : 4 : 6 : 8-tetrabromo-1 : 5-diamino-anthraquinones gives rise to 2 : 6-dibromo-1 : 5-diaminoanthraquinone (A., 1905, i, 88).

II. States that 3-bromo-2-aminoanthraquinone can be prepared in one operation by dissolving 2-aminoanthraquinone in concentrated sulphuric acid, cooling, and treating with bromine (1 mol.) ; the crude mixture, which contains monobromo-, dibromo-, and unbrominated bases, is then heated at 180—190°, when it furnishes entirely 3-bromo-2-aminoanthraquinone. In a similar manner, 2 : 7-diaminoanthra-quinone when treated with bromine (2 mols.) gives rise to 3 : 6-*dibromo-*2 : 7-*diaminoanthraquinone ;* this compound closely resembles 3 : 7-dibromo-2 : 6-diaminoanthraquinone, but is more readily soluble in organic liquids. F. M. G. M.

The Anthraquinone Series. II. 1 : 3-Dibromo-2-amino-anthraquinone. FRITZ ULLMANN and WALTER JUNGHANS (*Annalen,* 1913, 399, 330—345).—The following reactions illustrate the great mobility, in the presence of a copper salt as catalyst, of the halogen

atom in position 1 in 1 : 3-dibromo-2-aminoanthraquinone (compare Ullmann and Medenwald, this vol., i, 735). By boiling with benzoyl chloride and nitrobenzene, or with benzoic anhydride, 1 : 3-dibromo-2-aminoanthraquinone yields 3-*bromoanthraquinonylphenyloxazole*,

$$C_6H_4 \underset{CO}{\overset{CO}{<}} > C_6HBr \underset{N}{\overset{O}{<}} > CPh,$$
m. p. 325° (corr.), yellow leaflets, which is decomposed by boiling 80% sulphuric acid, forming, after the addition of water, 3-*bromo*-2-*amino*-1-*hydroxyanthraquinone*, m. p. 269°, reddish-brown needles. 1 : 3-*Dibromo*-2-*dibenzoylaminoanthraquinone*, m. p. 233°, yellow needles, is also obtained by the first method of preparing the oxazole derivative.

In a similar manner, 1 : 3 : 5 : 7-tetrabromo-2 : 6-diaminoanthraquinone, by boiling with benzoyl chloride and naphthalene, is converted into the *bisoxazole*,

$$CPh \underset{O}{\overset{N}{<}} > C_6HBr \underset{CO}{\overset{CO}{<}} > C_6HBr \underset{O}{\overset{N}{<}} > CPh,$$
m. p. above 360°, faintly yellow needles.

By boiling with amyl alcohol, anhydrous potassium acetate, a little copper acetate, and *p*-toluenesulphonamide, 1 : 3-dibromo-2-aminoanthraquinone is converted into 3-*bromo*-2-*amino*-1-*p-toluenesulphonylaminoanthraquinone*, $C_{21}H_{15}O_4N_2BrS$, m. p. 237·5° (corr.), yellowish-brown crystals, which yields 3-*bromo*-1 : 2-*diaminoanthraquinone*, m. p. 312° (corr.), dark red crystals, by hydrolysis · with sulphuric acid. By boiling 3-bromo-1 : 2-diaminoanthraquinone with benzaldehyde or 3-bromo-2-amino-1-*p*-toluenesulphonylaminoanthraquinone with benzoyl chloride, the *iminoazole*, $C_6H_4 \underset{CO}{\overset{CO}{<}} > C_6HBr \underset{NH}{\overset{N}{<}} > CPh$, m. p. 292° (corr.),

yellowish-green needles, is obtained, which forms a *hydrochloride*, colourless needles, and a reddish-brown *sodium* salt.

In the presence of anhydrous sodium acetate and a trace of copper acetate, 1 : 3-dibromo-2-aminoanthraquinone is converted by urethane on the water-bath into *bromohydroxyanthriminazole*,

$$C_6H_4 \underset{CO}{\overset{CO}{<}} > C_6HBr \underset{N}{\overset{NH}{<}} > C·OH,$$
m. p. 370°, yellowish-green needles, and by boiling nitrobenzene into 3 : 3'-*dibromoindanthren*,

$$C_6H_4 \underset{CO}{\overset{CO}{<}} > C_6HBr \underset{NH}{\overset{NH}{<}} > C_6HBr \underset{CO}{\overset{CO}{<}} > C_6H_4,$$

m. p. 515°, indigo-blue needles, and 3-bromo-2-aminoanthraquinone ; the dibromoindanthren forms a blue vat which dyes cotton in blue shades.

1 : 3-Dibromo-2-aminoanthraquinone and boiling benzaldehyde yield a *benzylidene* derivative, $C_{21}H_{11}O_2NBr_2$, m. p. 195° (corr.), yellowish-green needles, which is converted by naphthalene and copper powder at 240—245° into 3 : 3'-*dibromo*-2 : 2'-*dibenzylideneamino*-1 : 1'-*dianthraquinonyl*, $C_{42}H_{22}O_4N_2Br_2$, m. p. 295·5° (corr.), yellow leaflets. By treating the latter in hot nitrobenzene with a little sulphuric acid, or 3-bromo-2-aminoanthraquinone in boiling nitrobenzene with antimony pentachloride, 3 : 3'-*dibromoflavanthren*, $C_{28}H_{10}O_2N_2Br_2$, m. p. 495°, brown needles, is obtained ; its hyposulphite vat is deep blue and dyes cotton in the same shades, changing to orange in air.　　C. S.

[Preparation of a Bromo-derivative of 4-Chloro-1-methyl-anthraquinone.]—FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R.-P. 259881).—When a boiling nitrobenzene solution of 4-chloro-1-methylanthraquinone (15 parts) is treated with a similar solution of bromine (8·5 vols.) it furnishes a *compound* which separates in orange crystals as the solution cools; the m. p. is above 300°.

<div align="right">F. M. G. M.</div>

Preparation of Condensation Products in the Anthra-quinone Series. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 261737). —The *compound* (annexed formula) is obtained when 1 : 2-diaminoanthraquinone and an-thraquinone - 2 - aldehyde are heated together in pyridine solution at 120°; the aldehyde can be replaced in this reaction by ω-chloro- or ω-dichloro-methylanthraquinones, and the diamine by 2 : 3-diaminoanthraquinone.
<div align="right">F. M. G. M.</div>

[Preparation of Anthraquinone Derivatives.] FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R.-P. 262252).—4-a-*Anthra-quinonylaminoanthraquinone*-1 : 2-*acridone* is obtained by condensing 4-aminoanthraquinoneacridone with a-chloroanthraquinone in the presence of aluminium chloride, zinc chloride, or sulphuric acid.

<div align="right">F. M. G. M.</div>

Preparation of Condensation Products in the Anthracene Series. FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R.-P. 260662). —The removal of chlorine or bromine by means of potassium iodide and acetone has previously been described (A., 1911, i, 432), and it is now found that when ω-dibromo-2-methylanthraquinone is heated with potassium iodide (2 parts) and acetone (10 parts) at 100° during twelve to fourteen hours, it yields the previously-described compound, $C_{30}H_{14}O_4$ (A., 1908, i, 999).

When ωω'-tetrabromo-2 : 2'-dimethyl-1 : 1'-dianthraquinonyl (A., 1912, i, 361) is treated in a similar manner, it gives rise to a *di-phthaloylphenanthren*, an orange-brown powder; the preparation of other derivatives by this reaction is discussed.

<div align="right">F. M. G. M.</div>

Synthesis of the Higher Indandiones. II. MARTIN FREUND and KARL FLEISCHER (*Annalen*, 1913, 399, 182—241).—The reaction whereby diethylmalonyl chloride and benzene or its homologues yield diethylindandiones (A., 1910, i, 490) has been examined in the cases where dimethylmalonyl chloride or dipropylmalonyl chloride is used.

[With MARGARETE DECKERT.]—Dimethylmalonyl chloride, which is identified in small quantities best by conversion into *dimethylmalon-anilide*, $CMe_2(CO \cdot NHPh)_2$, m. p. 202·5—203°, reacts abnormally with benzene in the presence of aluminium chloride, yielding ultimately phenyl *iso*propyl ketone and two *substances*, $C_{17}H_{16}O_2$, m. p. 193—194°

and 125° respectively, which are probably $\beta\beta$-dibenzoylpropane and the lactone of β-hydroxy-$\beta\beta$-diphenyl-$\alpha\alpha$-dimethylpropionic acid; the two substances have not been further examined on account of the difficulty of separating them.

Dimethylmalonyl chloride condenses normally with other aromatic hydrocarbons, yielding substituted indandiones. Thus its reaction with *p*-cymene in carbon disulphide in the presence of aluminium chloride leads to the formation of 2 : 2 : 4-*trimethyl*-7-*isopropylindandione*,

$$C_6H_2MePr^{\beta}\underset{CO}{\overset{CO}{<}}>CMe_2,$$
b. p. 168—169°/14 mm., D^{15} 1·634, which is oxidised to an *acid*, probably $C_6H_2(CO_2H)_2\underset{CO}{\overset{CO}{<}}>CMe_2$, m. p. 179—180°, by nitric acid at 115—140°.

Under conditions similar to the preceding, dimethylmalonyl chloride and naphthalene ultimately yield three *substances*, $C_{15}H_{12}O_2$, m. p. 101°, 121°, and 137° respectively, which can only be separated by the mechanical sorting of their well-defined crystals. The constitutions of the three substances have been determined by oxidising the products of their decomposition by alkalis. The substance, m. p. 101°, is 2 : 2-*dimethyl*-1 : 8-*naphthindandione*, $C_{10}H_6\underset{CO}{\overset{CO}{<}}>CMe_2$, since it is converted by boiling 50% potassium hydroxide into 1-*isobutyrylnaphthalene*-8-*carboxylic acid*, $CHMe_2\cdot CO\cdot C_{10}H_6\cdot CO_2H$, m. p. 158·5—159·5°, hexagonal plates and prisms, which is oxidised to naphthalic anhydride by nitric acid at 125°. The substance, m. p. 121°, is 2 : 2-*dimethyl*-1 : 2-*naphthindandione*, $C_{10}H_6\underset{CO}{\overset{CO}{<}}>CMe_2$; it is converted by 50% potassium hydroxide into 1(or 2)-*isobutyrylnaphthalene*-2(or 1)-*carboxylic acid*, m. p. 153—154°, which is oxidised to naphthalene-1 : 2-dicarboxylic acid and its anhydride by boiling glacial acetic acid and nitric acid, D 1·4. The third substance, m. p. 137°, must be 2 : 2-*dimethyl*-2 : 3-*naphthindandione* by exclusion; it is converted by alkali into 2-*isobutyrylnaphthalene*-3-*carboxylic acid*, m. p. 164—165·5°, which is oxidised to *naphthalene*-2 : 3-*dicarboxylic acid*, m. p. 241° (decomp.), by nitric acid at 120°, or by boiling nitric and glacial acetic acids. Naphthalene-2 : 3-dicarboxylic acid forms an anhydride, m. p. 245°, by heating, and yields a fluorescein by the usual method.

By direct treatment with nitric acid at 120—140°, 2 : 2-dimethyl-1 : 8-naphthindandione yields a *nitro*-derivative, $C_{15}H_{11}O_4N$, m. p. 162°, yellow needles; a *dinitro*-derivative, $C_{15}H_{10}O_6N_2$, m. p. 245—248° (decomp.), microscopic, hexagonal plates or prisms, and a colourless *acid*, m. p. 237—239° (decomp.); 2 : 2-dimethyl-1 : 2-naphthindandione yields a yellow *substance* containing nitrogen, and an *acid*, $C_{13}H_{10}O_6$, m. p. 229—233° (decomp.), which is probably 2 : 2-*dimethylindandione*-4 : 5-*dicarboxylic acid*, $CMe_2\underset{CO}{\overset{CO}{<}}>C_6H_2(CO_2H)_2$, whilst 2 : 2-dimethyl-2 : 3-naphthindandione yields nitrogenous products and a *substance*, m. p. 186—187° (decomp.), colourless needles.

When heated above their m. p.'s, 1-*iso*butyrylnaphthalene-8-carboxylic acid and 2-*iso*butyrylnaphthalene-3-carboxylic acid are converted

into *lactones*, $C_{10}H_6\begin{smallmatrix}CO\underline{\hspace{1em}}\\C(:CMe_2)\end{smallmatrix}\rangle O$, m. p. 117·5—118·5° and 174—175°
respectively, which are isomeric with the original indandiones; the
former lactone is re-converted into 1-*iso*butyrylnaphthalene-8-carboxylic
acid by boiling 50% potassium hydroxide, is oxidised to naphthalic
anhydride by boiling nitric and glacial acetic acids, and yields a *bromo*-
derivative, m. p. 141°, microscopic prisms, by bromination in chloro-
form. 1(or 2)-*iso*Butyrylnaphthalene-2(or 1)-carboxylic acid remains
unchanged by heating above its m. p.

Assuming that the $-CH_2 \cdot CH_2-$ group is unattacked, acenaphthene
could yield three indandiones by reaction with dimethylmalonyl chloride
and aluminium chloride in carbon disulphide. Actually only two are
obtained, having m. p. 127·5—129° and 176·5—177·5° respectively.
The former crystallises in colourless needles, and is 2 : 2-*dimethyl*-
3 : 4-*acenaphthindandione*, $CMe_2\begin{smallmatrix}CO\\CO\end{smallmatrix}\rangle C_{10}H_4\langle\begin{smallmatrix}CH_2\\CH_2\end{smallmatrix}$, since it is con-
verted by boiling 50% potassium hydroxide into 3-iso*butyrylacenaph*-
thene-4-carboxylic acid, $\begin{smallmatrix}CO_2H\underline{\hspace{1em}}\\CHMe_2 \cdot CO\end{smallmatrix}\rangle C_{10}H_4\langle\begin{smallmatrix}CH_2\\CH_2\end{smallmatrix}$, m. p. 176° (decomp.),
colourless, microscopic plates, which is oxidised to naphthalene-
1 : 4 : 5 : 8-tetracarboxylic acid by alkaline potassium permanganate.
The isomeride, m. p. 176·5—177·5°, crystallises in pale yellow needles,
and is named *dimethylisoacenaphthindandione* ; its formula has not
been definitely determined.

The oxidation of 2 : 2-dimethyl-3 : 4-acenaphthindandione by sodium
dichromate and boiling glacial acetic acid yields 2 : 2-*dimethyl*-1 : 8-
naphthindandione-4 : 5-*dicarboxylic acid*, $CMe_2\begin{smallmatrix}CO\\CO\end{smallmatrix}\rangle C_{10}H_4(CO_2H)_2$,
m. p. 208—209° (*anhydride*, m. p. 207—208°).

When heated above its m. p., 3-*iso*butyrylacenaphthene-4-carboxylic
acid is converted into a *lactone*, $\begin{smallmatrix}CH_2\\CH_2\end{smallmatrix}\rangle C_{10}H_4\begin{smallmatrix}CO\underline{\hspace{1em}}\\C(:CMe_2)\end{smallmatrix}\rangle O$, m. p.
175—176°, orange needles, which is oxidised by boiling acetic and
nitric acids to *acenaphthalic anhydride* (anhydride of *acenaphthene*-
3 : 4-*dicarboxylic acid*), $\begin{smallmatrix}CH_2\\CH_2\end{smallmatrix}\rangle C_{10}H_4\langle\begin{smallmatrix}CO\\CO\end{smallmatrix}\rangle O$, m. p. 293—294°, pale
brown leaflets. *Acenaphthalic acid* forms an *ammonium* salt, m. p. 283°,
yields its anhydride by heating, does not form a fluorescein, and
dissolves in concentrated sulphuric acid, yielding a pale yellow solution
with a splendid sky-blue fluorescence.

The reaction between anthracene and an excess of dimethylmalonyl
chloride in the presence of aluminium chloride leads to the formation
of 2 : 2-*dimethylanthraceneindandione*, $C_6H_4\langle\begin{smallmatrix}CH\\CH\end{smallmatrix}\rangle C_6H_2\langle\begin{smallmatrix}CO\\CO\end{smallmatrix}\rangle CMe_2$,
m. p. 148·5—149·5°, brownish-red needles or plates, which is oxidised
by chromic and acetic acids to 2 : 2-*dimethylanthraquinoneindandione*,
$C_6H_4\langle\begin{smallmatrix}CO\\CO\end{smallmatrix}\rangle C_6H_2\langle\begin{smallmatrix}CO\\CO\end{smallmatrix}\rangle CMe_2$, m. p. 231—232°, pale yellow prisms,
and is converted by boiling 50% potassium hydroxide into an *isobutyryl*-

anthracene-o-carboxylic acid, $C_6H_4 \!\!<^{CH}_{CH}\!\!> C_6H_2(CO_2H)\cdot COPr^\beta$, m. p. 203—205°, dark brown prisms; the latter, heated above its m. p., is converted into a *lactone,* $C_6H_4 \!\!<^{CH}_{CH}\!\!> C_6H_2 \!\!<^{CO-----}_{C(:CMe_2)}\!\!> O$, m. p. 141—142·5°.

Dimethylmalonyl chloride and phenanthrene in carbon disulphide in the presence of aluminium chloride yield ultimately a *dimethylphenanthreneindandione,* m. p. 207—208°, pale yellow needles, which is converted into *dimethylphenanthraquinoneindandione,* $C_{19}H_{12}O_4$, m. p. 246—247°, orange needles, by oxidation, and into a mixture of two isomeric acids by concentrated potassium hydroxide.

[With MAX ROTHSCHILD.]—Dipropylmalonyl chloride is characterised by conversion into the *dianilide,* $CPr_2^\cdot(CO\cdot NHPh)_2$, m. p. 168—168·5°, colourless prisms, and the *bisphenylhydrazide,* $C_{21}H_{28}O_2N_4$, m. p. 216—217°; by warming with carbonyl chloride in toluene at 100°, the latter is converted into the *diazolone,* $^{CO---O}_{NPh\cdot N}\!\!> C\cdot CPr_2^\cdot\cdot C \!\!<^{O-CO}_{N\cdot NPh}$, m. p. 157—158·5°.

Dipropylmalonyl chloride condenses normally with benzene or other aromatic hydrocarbons in the presence of aluminium chloride. Thus benzene yields, in addition to a small quantity of δδ-*dibenzoylheptane,* m. p. 106—107°, 2 : 2-*dipropylindandione,* $C_6H_4 \!\!<^{CO}_{CO}\!\!> CPr_2^\cdot$, b. p. 168—172°/14 mm., D 1·0390, which is converted into phthalic acid by oxidation. *p*-Cymene yields 4-*methyl*-2 : 2-*dipropyl*-7-*isopropylindandione,* $C_6H_2MePr^\beta \!\!<^{CO}_{CO}\!\!> CPr_2^\cdot$, m. p. 94·5°, colourless needles. Diphenyl yields a *phenyldipropylindandione,* $C_{21}H_{22}O_2$, m. p. 221·5°, colourless needles, the constitution of which has not been definitely determined. Naphthalene does not yield definite condensation products, but acenaphthene yields two *isomerides,* m. p. 154—154·5° and 126° respectively. The former crystallises in yellow needles, and is converted by boiling concentrated aqueous alkalis, or, better, by sodium and boiling alcohol into α-*propylvalerylacenaphthenecarboxylic acid,* $^{CH_2}_{CH_2}\!\!> C_{10}H_4(CO_2H)\cdot CO\cdot CHPr_2^\cdot$, m. p. 166—167°, yellowish-brown leaflets. The isomeride, m. p. 126°, crystallises in yellow leaflets, and does not yield definite products by decomposition by alkalis.

Dipropylmalonyl chloride yields oily or amorphous products with anthracene, phenanthrene, and retene, but condenses with thiophen in the presence of aluminium chloride and carbon disulphide to form ultimately *dithiophenoyldipropylmethane,* $CPr_2^\cdot(CO\cdot C_4SH_3)_2$ or $CPr_2 \!\!<^{C(C_4SH_3)_2}_{CO}\!\!> O$, m. p. 192·5°, yellow needles, and *thiophenoyldipropylmethane,* $C_{12}H_{18}OS$, b. p. 158—163°/25 mm.
A table is given of the colours of the fluorescent solutions of the preceding substances in concentrated sulphuric acid.   C. S.

Action of Nitrogen Trioxide on Camphene. Nitrocamphene and Dinitrohydroxycamphane. PETER LIPP (*Annalen*, 1913, **399**, 241—260).—By the oxidation of *iso*camphane by nitric acid the author obtained (A., 1911, i, 731), amongst other products, a substance, $C_{10}H_{15}O_2N$, m. p. 64°, which is identical with so-called camphenile nitrite obtained by Jagelki by the action of nitrogen trioxide on camphene. The author's opinion that the substance is a nitro-compound (*loc. cit.*) has now been confirmed. He has, therefore, re-examined the action of nitrogen trioxide on camphene.

l-Camphene in petroleum (b. p. 30—40°) at −16° is treated with nitrogen trioxide (from arsenious oxide and nitric acid, not from sodium nitrite), whereby a faintly olive-green oil is produced, which decomposes at the ordinary temperature. The solvent is removed and the oily residue, after distillation with steam, is treated with aqueous potassium hydroxide. The deep red alkaline solution is treated as described below, whilst the residue is the desired substance, l-*nitro-camphene* (annexed formula), m. p. 84—85°
(corr.), $[\alpha]_D^{20} - 146\cdot4°$ in 20% benzene solution, which only differs from *dl*-nitrocamphene, m. p. 64°, in its m. p. and optical activity. The evidence for the presence of a nitro-group is the following: (i) The faintly yellow colour of the substance may be due to the presence of the nitro-group in the neighbourhood of the double linking. (ii) By treatment with alcoholic ammonia at 110—120°, the substance is converted into *l*-camphenilone and nitromethane (identified in the form of methylamine); by the action of boiling, aqueous alcoholic potassium hydroxide, the substance yields *l*-camphenilone and potassium nitroacetate. The nitro-group, therefore, is attached directly to a carbon atom. (iii) By reduction in ethereal solution by aluminium amalgam and water, the substance is converted into, not only ammonia and camphenilanaldehyde (which are the products of reduction in acid or in alkaline solution), but also into *camphenilanaldoxime*,

$$C_8H_{14}:CH\cdot CH:N\cdot OH,$$
b. p. 134—135°/12 mm., a colourless, viscous liquid (*hydrochloride*,

$$C_{10}H_{18}ONCl,$$
m. p. 90—92°, white, crystalline powder). The formation of camphenil-analdoxime is quite analogous to the production of aldoximes by the reduction of nitro-olefines in neutral solution. (iv) The conversion of nitrocamphene into tricyclenic acid by concentrated sulphuric acid is to be described fully in a future communication. The first product is a *sulphate* of camphenylhydroxamic acid, $C_{10}H_{15}O_5NS$, decomp. 127°; this is decomposed by warm water into sulphuric acid and *camphenyl-hydroxamic acid*, $C_{10}H_{17}O_3N$, decomp. 163°. The latter is decomposed by sulphuric acid into hydroxylamine and camphenylic acid, and from the latter, by loss of water, tricyclenic acid is produced. The whole change is analogous to the conversion of a primary nitro-compound into a carboxylic acid containing the same number of carbon atoms.

A second product of the action of nitrogen trioxide on camphene is the oily substance, $C_{10}H_{16}O_8N_2$, described by Jagelki as camphene

nitrosite. However, the substance, the *potassium* salt, $C_{10}H_{15}O_4N_2K$, garnet prisms or bronze leaflets, decomp. 207—209°, of which is contained in the deep red alkaline solution mentioned above, is, when pure, crystalline, m. p. 158·5° (corr.), and has the formula $C_{10}H_{16}O_5N_2$.

The substance is regarded as *ωω-dinitro-2-hydroxycamphane*,

$$CH(NO_2)_2 \cdot C \underset{CH(OH) \cdot CH_2}{\overset{CH_2---CH_2}{<}} \overset{}{>} CH,$$
for the following reasons: The presence of the hydroxyl group is shown by the formation of an *acetyl* derivative, $C_{12}H_{18}O_6N_2$, m. p. 74—75° (corr.), stout plates. The substance, as a secondary alcohol, is oxidised to ketopinic acid by alkaline potassium permanganate at 50—60°. The presence of a *gem*-dinitro-group is suggested by the intense red colour of the potassium salt and by its reconversion into the colourless parent substance by carbon dioxide, and is confirmed by the reduction of an ethereal solution of the substance by aluminium amalgam and water, whereby hydroxylamine and an *oxime*, $C_{10}H_{17}O_2N$, m. p. 127—128·5°, colourless needles, are produced; the oxime is probably 2-*hydroxycamphan-ω-aldoxime*, $C_8H_{15}O \cdot C \cdot CH \cdot NOH$, but the aldehyde obtained from it has not been thoroughly examined owing to lack of material.

The formation of a camphane derivative, ωω-dinitro-2-hydroxy-camphane, from camphene by the action of nitrogen trioxide is effected possibly by the intermediate production of nitrocamphene. This view, however, is not altogether supported by the fact that nitrocamphene and nitric acid, D 1·514, after being kept for four days yield a substance which dissolves in alkalis with a deep red colour, but cannot be isolated, the chief product of the reaction being ketopinic acid, (p-*bromophenylhydrazone*, $C_{16}H_{19}O_2N_2Br$, m. p. 165—166° (corr.), straw-yellow leaflets). Possibly the nitrocamphene and the nitrous acid in the nitric acid form a nitrolic acid, the camphene ring changing at the same time to the camphane ring; the nitrolic acid is then oxidised to ketopinic acid. Attempts to unite nitrocamphene and nitrous acid directly have been unsuccessful. C. S.

Action of Methyl Iodide and Magnesium on Menthone. ALEXANDER E. ARBUZOV (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 700).— The author claims priority for Zelinsky (A., 1901, i, 660) and himself (A., 1908, i, 555) over Vanin (A., 1912, i, 788). T. H. P.

Oil of Adansonia Grandidieri. VICTOR THOMAS and F. BOIRY (*Bull. Soc. chim.*, 1913, [iv], **13**, 827—832).—On extraction with ether, the entire seeds of *Adansonia Grandidieri* yield 43% of oil, whilst the decorticated seeds give 64·5%. The oil obtained from the former has m. p. 20—21°; temperature of solidification, 13°; D^{20} 0·9190; n^{40} 1·4585; saponification number, 192·4; iodine number, 65·4—66·1; Reichert-Meissl number, 0·77; Hehner number, 95·5, whilst that obtained from the latter has m. p. 39—40°; temperature of solidification, 33°; D^{40} 0·9135; n^{40} 1·4521; saponification number, 196; iodine number, 36·9. After removal of the fatty acids, the oils from the entire (i) and decorticated seeds (ii) have the following constants:

m. p. (i) 51—52°; (ii) 45—46°; temperature of solidification, (i) 44·5°; acid number, (i) 179; (ii) 204·5; saponification number, (i) 202·5; (ii) 207·6; iodine number, (i) 66·3—66·9; (ii) 34·5—35; iodine number after acetylation, (i) 25·7; (ii) 26·8.

The oil consists of a mixture of esters of solid and unsaturated liquid acids in the proportion of 42% of the former and 58% of the latter. It is further characterised by the presence of a considerable quantity of a lactone, the precise nature of which has not been determined owing to lack of material. It has an iodine number 67·2, and when treated with bromine yields a liquid bromo-derivative.

The mixture of acids contains myristic acid, 7·6%; palmitic acid, 32·5%; oleic acid, 36·5%; linoleic acid, 8·7%, and lactone, 11·41%.

H. W.

Essential Oils. V. Essence of Cypress. GUSTAVE LALOUE (*Bull. Soc. chim.*, 1913, [iv], 13, 752—754. Compare A., 1911, i, 138; 1912, i, 574, 636).—The author has studied the oils obtained from the branches of *Cupressus sempervirens fastigiata*, L., and *Cupressus lusitanica*, Mill. The latter species yields rather more oil than the former. The oil from the former is brownish, and has D^{15} 0·8744; $a_D +12°6'$; acid number, 0·7; saponification number, 4·9; it dissolves in 3·5 vols. of alcohol (90%). The acetylated oil has $a_D +14°16'$; saponification number, 14·7. The oil from the latter is yellow. Its constants are D^{15} 0·8723; $a_D +9°10'$; soluble in 3 vols. of 90% alcohol; acid number, 1·05; saponification number, 9·8; saponification number after acetylation, 26·6; a_D of acetylated oil, $+8°36'$.

Practically no oil could be extracted from the seeds of *C. sempervirens*. The strobiles, freed from seeds, yielded 0·415% of an amber-coloured oil, D^{15} 0·8739; $a_D +29°52'$; soluble in 4 vols. of 90% alcohol; acid number, 1·0; saponification number, 9·8; saponification number after acetylation, 21·0; a_D of acetylated oil, $+29°48'$. H. W.

Components of the Essence of Seseli bocconi. LUIGI FRANCESCONI and E. SERNAGIOTTO (*Atti R. Accad. Lincei*, 1913, [v], 22, ii, 116—121. Compare A., 1912, i, 123).—In addition to *l*-pinene and β-phellandrene, previously recorded, this oil contains a dicyclic aldehyde, a second carbonyl compound accompanying the aldehyde, a dicyclic primary alcohol, an unsaturated secondary alcohol, and *d-a*-methylbutyric, formic and acetic acids.

Oxidation of the primary alcohol with potassium dichromate and sulphuric acid yields an aldehyde, the *semicarbazone* of which,

$$C_{11}H_{19}ON_3,$$

has m. p. 148—158°. This aldehyde appears to be identical with that of the essential oil mentioned above, so that the aldehyde of the oil probably has the formula $C_{10}H_{16}O$, and the alcohol the composition $C_{10}H_{18}O$. R. V. S.

New Biochemical Syntheses of Glucosides of Alcohols. ÉMILE BOURQUELOT and MARC BRIDEL (*J. Pharm. Chim.*, 1913, [vii], 8, 109—112).—Positive results indicating the formation of β-glucosides have been obtained with the following alcohols. In all cases 100 c.c.

of acetone, containing 20 grams of water per 100 grams of acetone, and 2 grams of dextrose were used, and varying quantities of alcohol and emulsin added. The isolation and characterisation of the glucosides has not yet been effected. The alcohols used were octyl, hexadecyl, benzaldehydecyanohydrin, *cyclo*hexanol, 2-methyl*cyclo*hexanol, α-naphthyl, borneol, morphine, also *tert.*-amyl alcohol and ethylphenylglycollyl ether.

Evidence is also quoted for the synthesis of α-glycerolglucoside. The action of dried yeast on a solution containing 4 grams of salicin and 5 grams of dextrose per 100 c.c. caused an increased dextrorotation. This is considered to indicate the attachment of the alcoholic hydroxyl in salicin to dextrose in the α-position. E. F. A.

Biochemical Synthesis of Glucosides of Multivalent Alcohols: α-Glucosides of Glycerol and Glycol. ÉMILE BOURQUELOT and MARC BRIDEL (*Compt. rend.*, 1913, **157**, 405—408). —α-Glucosidase is capable of exerting a synthesising effect on solutions of glycerol and dextrose in water, the optimum effect being obtained with solutions containing 60 grams of glycerol in 100 c.c. The product is hydrolysed on the addition of water and maceration with more of the α-glucosidase (compare Bayliss, this vol., i, 919). Mixtures of glycol and dextrose are similarly synthesised, the reaction being more rapid than with glycerol. W. G.

Cymarin, the Active Principle of Apocynum cannabinum and Apocynum androsœmifolium. E. IMPENS (*Pflüger's Archiv,* 1913, **153**, 239—275).—Finnemore (P., 1909, **25**, 77) obtained as the active principle of the roots and rhizomes of *A. cannabinum,* "cynotoxin," whilst Moore (T., 1909, **95**, 734) prepared from *A. androsœmifolium,* "apocynamarin." It is now shown that these plants really contain the same bitter principle, *cymarin,* which is so susceptible to the influence even of weak organic acids that the two substances mentioned above may well be decomposition products. Taub and Fickewirth have isolated it by extracting the drug with carbon tetrachloride, dissolving the extract with alcohol, precipitating resins by means of warm water, clarifying the filtrate with basic lead acetate, and, after removing the lead and concentrating under reduced pressure, extracting the residue with chloroform. The cymarin was then precipitated by light petroleum and recrystallised from methyl alcohol. It forms colourless, glistening prisms, m. p. 135—140°, $C = 63.6\%$, $H = 8.4\%$. It is not a glucoside. A series of pharmacological experiments is described which shows that it corresponds in activity with digitalis, being slightly more potent as a diuretic and slightly less so as a cardiac stimulant. J. C. W.

Action of Alkyloxides on Hæmin and its Derivatives. I. Simplification of Hæmin by Potassium Alkoxides and a New Formation of Mesoporphyrin. HANS FISCHER and HEINRICH RÖSE (*Zeitsch. physiol. Chem.*, 1913, **87**, 38—50).—On heating hæmin in an autoclave with potassium methoxide at 220° a considerable quantity of phyllopyrrole is obtained, together with a little trimethylpyrrolepropionic acid.

With potassium ethoxide a mixture of the two dimethyldiethyl-pyrroles is formed :

I. NH$\diagdown\begin{smallmatrix}\text{CMe:CMe}\\\text{CEt=CEt}\end{smallmatrix}$,   II. NH$\diagdown\begin{smallmatrix}\text{CMe:CEt}\\\text{CEt=CMe}\end{smallmatrix}$
in which (I) predominates.

The reaction with alkyloxides is accordingly similar to the reduction effected by hydrogen iodide in the α-position; alkylation follows the simplification of the molecule by reduction.

The hæmin complex remains intact when it is heated with sodium methoxide at 200°. On treatment of the reaction product with hydrogen bromide in acetic acid, the iron is eliminated and meso-porphyrin obtained.   E. F. A.

The Difference between the Hæmocyanins according to their Zoological Origin. CHARLES DHÉRÉ (*Compt. rend.*, 1913, **157**, 309—312).—The preliminary results of an investigation into the differences in composition, constitution, and properties of hæmo-cyanins derived from the blood of different classes of invertebrates. The specimens examined were precipitated more or less completely on dialysis, the oxyhæmocyanin from the snail being obtained in a crystalline form, whilst the others were all amorphous. The behaviour was also varied on applying the biuret test for copper by addition of aqueous sodium hydroxide. Variations were found in the colour of solutions of different samples in N/10-acetic acid, but they all exhibited similar ultra-violet absorption spectra.   W. G.

Studies on Melanin. V. A Comparison of Certain Nitrogen Ratios in Black and in White Wool from the Same Animal. ROSS AIKEN GORTNER (*J. Amer. Chem. Soc.*, 1913, **35**, 1262—1268. Compare A., 1910, i, 760; 1911, ii, 908; 1912, i, 290). —In order to determine if possible whether the chromogen utilised in the formation of melanin is part of the normal structure of keratin or whether it is secreted solely for pigment formation, the author has made comparative analyses of black and white wool from the same animal. No definite conclusion can be drawn, although the evidence seems somewhat in favour of the latter view.

The distribution of nitrogen in the two wools is very similar, with the exception that the presence of the pigment in black wool causes an excess of 3·54% in the humin nitrogen with a corresponding deficiency of 2·50% in the amino-nitrogen in the filtrate from the bases. The total nitrogen content of the white wool was 16·27%, whilst that of the black wool was 15·11%.   D. F. T.

[**Carminic Acid.**]   OTTO DIMROTH (*Annalen*, 1913, **399**, 378).— The author has received information that cochineal, contrary to his recent statement (this vol., i, 977), has been used in dyeing cotton.
                                                                           C. S.

Green Animal Colouring Matters. HANS PRZIBRAM (*Pflüger's Archiv*, 1913, **153**, 385—400).—The green colouring matters in *Bacillus Rossii*, *Dixippus morosus*, grasshoppers, locusts, Egyptian

praying-crickets, the Spanish fly, the skin of frogs, *Bonellia viridis*, and the leaves of the sea-lettuce, fir, syringa, maize, and blackberry have been compared. Ethereal or sometimes alcoholic extracts of equal colour intensity were heated for some time with saturated alcoholic potassium hydroxide, treated with a few drops of concentrated sulphuric or nitric acid, and also examined in the spectroscope. Many authors have doubted that the pigment in these animals is essentially different from chlorophyll, but the present investigations confirm the author in his view that animals develop a different colouring matter. Only in the case of the plant-eating insects could there be any suspicion, from the spectroscopic examination, that a little genuine plant chlorophyll was also present in the extract. In the flesh-eating insects, even in the wing cases of the praying-cricket, there is a different pigment, "animal green." The sea-worm, *Bonellia viridis*, contains a pigment of its own, "bonellein."

The author reviews the literature on the absorption spectra of chlorophyll and animal colouring matters, and finally tabulates the following characteristics. I. Chlorophyll.—Becomes turbid and precipitates black, flocculent masses on heating with alcoholic potassium hydroxide for some time; is only slightly bleached by strong acids, and shows a strong absorption band between 544 and 537 $\mu\mu$. II. Animal green.—Deposits coloured masses and clarifies with alcoholic potassium hydroxide; almost bleached by fuming nitric acid; rendered turbid and brown by sulphuric acid; shows no distinct band between 544 and 537 $\mu\mu$, and no shadow near 630 $\mu\mu$. III. Bonellein.—Coloured violet or blue by strong acids; shows a number of weak bands, and a strong one between 651 and 623 $\mu\mu$.   J. C. W.

Azomethine Dyes from β-Furylacraldehyde. WILHELM KÖNIG (*J. pr. Chem.*, 1913, [ii], **88**, 193—226).—In the presence of perchloric and hydrobromic acids, β-furylacraldehyde readily reacts with primary aromatic amines and with secondary amines of the tetrahydroquinoline and dihydroindole series in alcoholic solution, yielding blue dyes, related to the furfuraldehyde dyes already described by the author (A., 1906, i, 109) and having the following constitution (X = Br or ClO₄):

(I.) NRR'·CH:CH·CH:C(OH)·CH:CH·CH:NRR'X.

The dyes give violet-blue or greenish-blue alcoholic solutions, which rapidly lose their colour when kept. This disappearance of the blue colour is due to the removal of one of the amine residues and the formation of furfuraldehyde derivatives of the formula :

(II.) $\begin{matrix} \text{CH·CH} \\ \| \quad\quad \\ \text{CH——O} \end{matrix}$ >C·CH:CH·CH:NRR'X.
The latter compounds have been isolated in the form of their perchlorates, (i) by heating the perchlorates of the blue dyes, derived from cyclic secondary amines, in glacial acetic acid solution, and (ii) by the direct interaction of molecular amounts of the amines and β-furylacraldehyde in an alcoholic solution of perchloric acid.

That these compounds have the above constitution (II) and not the open-chain formula, NRR'·CH:CH·CH:C(OH)·CH:CH·CHO, has been

established (i) by the action of phenylhydrazine, which results in the removal of the amino-group and the formation of β-furylacraldehyde-phenylhydrazone (V below), and (ii) by the great similarity in the absorption spectra of the perchlorates of the condensation products, formed by cinnamaldehyde and β-furylacraldehyde with 6-methoxy-tetrahydroquinoline (thalline); the condensation product from cinnamaldehyde undoubtedly has the constitution represented in formula III, and hence the analogous product from β-furylacraldehyde must be represented by a similar formula (IV).

$$(\text{III.}) \quad CH_2 {<}^{C_6H_3(OMe)}_{CH_2-CH_2} {>}N{<}^{ClO_4}_{CH\cdot CH:CHPh}$$

$$(\text{IV.}) \quad CH_2 {<}^{C_6H_3(OMe)}_{CH_2-CH_2} {>}N{<}^{ClO_4}_{CH\cdot CH:CH\cdot C}{-}^{CH\cdot CH}_{O}{>}CH.$$
The author discusses both the mechanism of the formation of the dyes and also the relationship between their absorptive power and constitution from the point of view of Kauffmann's theory of partial valency, and, using Gebhard's method of representing the distribution of the partial valencies, assigns to the dyes the following constitution :
$$CH{\cdot\cdot}CH{\cdot\cdot}CH{\cdot\cdot}C(OH){\cdot\cdot}CH{\cdot\cdot}CH{\cdot\cdot}CH$$

NRR'⸺⸺⸺⸺X⸺⸺⸺⸺NRR'

β-Furylacraldehydephenylhydrazone,

$$C_4H_3O\cdot CH:CH\cdot CH:N\cdot NHPh \text{ (V)},$$

prepared from its components in alcoholic solution, is precipitated from the latter solution in citron-yellow needles, which are transformed by crystallisation from light petroleum into colourless crystals, m. p. 132°.

β-Furylacraldehyde condenses with m-nitroaniline in boiling alcoholic solution, yielding the *anil*, $C_4H_3O\cdot CH:CH\cdot CH:N\cdot C_6H_4\cdot NO_2$. This forms citron-yellow needles, m. p. 105°, and yields a *perchlorate*, which crystallises in orange prisms, and is converted by contact with primary or secondary aromatic amines into blue dyes.

The dyes described below were all prepared by the addition of the requisite amine (2 mols.) to a well cooled solution of β-furylacraldehyde (1 mol.) in a small quantity of alcohol, containing either hydrogen bromide (1 mol.) or perchloric acid (1 mol.). They all crystallise with $1H_2O$.

The *bromide* of the dye from the aniline (formula I, R = H, R' = Ph, X = Br) crystallises in dark bluish-green, microscopic needles, m. p. about 102°; the *perchlorate* in blue needles, m. p. 90°.

The *perchlorate* of the dye from m-toluidine forms blue needles, m. p. 108°; that from p-anisidine has m. p. about 115°.

The *bromide* of the dye from methylaniline (I, R = Me, R' = Ph) has m. p. 103°, and on treatment with aniline is converted into the

corresponding dye derived from aniline ; the perchlorate forms lustrous, blue needles, m. p. 110°.

Tetrahydroquinoline yields a dye which forms a *bromide*, m. p. about 125°,

$$\begin{matrix} CH_2 \cdot C_6H_4 \\ CH_2-CH_2 \end{matrix} > N \cdot CH:CH \cdot CH:C(OH) \cdot CH:CH \cdot CH:NBr < \begin{matrix} C_6H_4 \cdot CH_2 \\ CH_2-CH_2 \end{matrix},$$
and a *perchlorate*, m. p. 118°.

The *perchlorates* of the dyes from 6-methyl- and 5-methyl-tetrahydroquinolines have m. p. 132° and 126° respectively.

The dye from 6-methoxytetrahydroquinoline forms a *bromide*, m. p. 129°, and a *perchlorate*, m. p. 121°.

2-Methyldihydroindole yields a dye, of which the *bromide* has m. p. 138°, and the *perchlorate*, m. p. 131°.

The *bromide* of the dye from a-methylphenomorpholine,

$$\begin{matrix} O-\!\!-C_6H_4 \\ CH_2 \cdot CHMe \end{matrix} > N \cdot CH:CH \cdot CH:C(OH) \cdot CH:CH \cdot CH:NBr < \begin{matrix} C_6H_4-O \\ CHMe \cdot CH_2 \end{matrix},$$
has m. p. 121°.

When heated in acetic acid solution the perchlorate of the dye from methylaniline yields the *compound*,

$$C_4H_3O \cdot CH:CH \cdot CH:NMePh \cdot ClO_4,$$
which forms citron-yellow crystals, m. p. 176°, and is transformed into the original perchlorate on treatment with methylaniline.

In a similar manner the perchlorate of the dye from 6-methyltetrahydroquinoline yields the *compound*

$$C_4H_3O \cdot CH:CH \cdot CH:N(ClO_4) < \begin{matrix} C_6H_3Me \\ CH_2 \cdot CH_2 \end{matrix} > CH_2.$$
On crystallisation from glacial acetic acid this separates in long red and yellow needles, m. p. 204°, which have the same composition and cannot be separated by crystallisation from solvents ; the yellow modification passes into the red form on continued heating at 140—150°.

The *perchlorate* of the condensation product from 6-methoxytetrahydroquinoline and β-furylacraldehyde (formula IV), prepared by mixing the components in molecular proportions in alcoholic solution, forms red crystals, m. p. 188°, resembling chromium trioxide.

The corresponding *perchlorate* from cinnamaldehyde (III) forms orange crystals, m. p. 204° ; the *bromide* crystallises in long, orange-red needles, m. p. 185°, containing $1H_2O$.

By the interaction of furfuraldehyde and *m*-nitroaniline in alcoholic solution, Schiff (A., 1880, 391) obtained a substance, which he considered to have the formula : $C_4H_3O \cdot CH(OH) \cdot NH \cdot C_6H_4 \cdot NO_2$. The author finds, however, that the substance is not a furfuraldehyde derivative, but a pyrrole derivative of the following

constitution : $CH < \begin{matrix} CH-\!\!-CH \\ N(C_6H_4 \cdot NO_2) \end{matrix} > C \cdot CH:N \cdot C_6H_4 \cdot NO_2$. It separates

from ethyl alcohol in orange-yellow crystals, containing the solvent (1 mol.), m. p. 167—168°, and forms a *perchlorate*,

$$C_{17}H_{12}O_4N_4, HClO_4, C_2H_6O,$$
which crystallises in microscopic, brownish-red needles, m. p. 173° (decomp.).

Details of the methods employed in the spectrographic examination of the compounds described in the paper are also given. F. B.

Derivatives of Tetronic Acid. LUDWIG WOLFF (*Annalen*, 1913, **399**, 309—316).—[With H. JUNKER.]—*Bistetronic acid*,

$$\overset{CH_2 \cdot C(OH)}{\underset{O \longrightarrow CO}{}} > C \cdot C < \overset{C(OH) \cdot CH_2}{\underset{CO \longrightarrow O}{}},$$
m. p. 235°, colourless, crystalline powder, is obtained by heating *ethyl dibromodiacetylsuccinate* (prepared by the bromination of ethyl diacetyl-succinate in chloroform) at 150—160°, or by treating a boiling aqueous solution of bromotetronic acid with propylidenebistetronic acid and sodium carbonate and subsequently acidifying the solution. Bistetronic acid and ferric chloride develop a blue coloration in aqueous solution and a green in alcohol. The *anilide*, $C_{14}H_{11}O_5N$, m. p. 216°, crystallises in leaflets, and the *dibenzoyl* derivative, $C_{22}H_{14}O_8$, m. p. 215°, in needles.

[With W. HEROLD.]—In general, a-alkyltetronic acids are converted by nitrogen trioxide into nitroso-compounds, $O < \overset{CH_2 \cdot CO}{\underset{CO \longrightarrow CR \cdot NO}{}}$, in the absence of water, and into oximes, $CO_2H \cdot CH_2 \cdot O \cdot CO \cdot CR:NOH$, in the presence of water; in the latter case, when the alkyl group R contains more than one carbon atom, it is eliminated in the form of an aldehyde and a-oximinotetronic acid is obtained. Thus 2-ethyltetronic acid and hot aqueous sodium nitrite, in the presence of a little hydrochloric acid, yield acetaldehyde, a-oximinotetronic acid, and *a'-oximinobutyryl-glycollic acid*, $CO_2H \cdot CH_2 \cdot O \cdot CO \cdot CEt:NOH$, m. p. 171°, colourless needles. In a similar manner, 2-benzyltetronic acid yields benzaldehyde, 2-oximinotetronic acid, and *a'-oximino-β'-phenylpropionylglycollic acid*, $CO_2H \cdot CH_2 \cdot O \cdot CO \cdot C(:NOH) \cdot CH_2Ph$, m. p. 146°, which dissolves in concentrated nitric acid with a blue colour, and is converted into a-oximino-β-phenylpropionic acid by hot aqueous sodium hydroxide, and into the corresponding *amide*, $C_9H_{10}O_2N_2$, m. p. 147°, needles, by aqueous ammonia.

By treatment with 100% nitric acid at 0°, 2-methyltetronic acid or 2-nitroso-2-methyltetronic acid is converted into a neutral *substance*, $C_5H_5O_6N$, m. p. 68°, colourless plates, which probably has the formula
$$O < \overset{CH_2 \cdot C}{\underset{CO \longrightarrow CMe \cdot NO_2}{}} < \overset{O}{\underset{O}{}} .$$ It does not react with ferric chloride or respond to Liebermann's nitroso-reaction, exhibits powerful oxidising properties, and is decomposed by boiling water into dimethyl diketone, hydrogen cyanide, carbon dioxide, and nitric acid. In a similar manner, 2-nitroso-2-ethyltetronic acid is converted into a *substance*, $C_6H_7O_6N$, m. p. 43°, colourless needles. C. S.

Structural Formula of the Polymeride of the Anhydride of Anethole Glycol. LUIGI BALBIANO (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 93—94. Compare A., 1908, i, 901).—The author now assigns to this polymeride a formula of the type

$$R \cdot C_9H_2Me < \overset{O}{\underset{O}{}} > C_9H_2Me \cdot R.$$
R. V. S.

Reactions of the Formamidines. III. Synthesis of *iso*-Oxazolone, *iso*Oxazole, Cyanoacetic and Benzoylacetic Acid Derivatives. FRANK BURNETT DAINS and E. L. GRIFFIN (*J. Amer. Chem. Soc.*, 1913, **35**, 959—970).—In extension of the earlier work (compare A., 1902, i, 602; A., 1909, i, 781) it is found that the methylene group of the *iso*oxazolones of the general formula $\begin{smallmatrix} CH_2 \cdot CO \\ | \quad\quad > O \\ CR = N \end{smallmatrix}$, like that of phenylmethylpyrazolone is capable of reacting with the arylformamidines.

Diphenylformamidine reacts with an equimolecular quantity of phenyl*iso*oxazolone at 120°, yielding aniline and 3-*phenyl-4-anilino-methylene-5-isooxazolone*, $\begin{smallmatrix} O-CO \\ \quad\quad > C:CH \cdot NHPh \\ N:CPh \end{smallmatrix}$, yellow, rhombic crystals, m. p. 145°; in a similar manner, di-*o*-tolylformamidine gives 3-*phenyl-4-o-toluidinomethylene-5-isooxazolone*, yellow crystals, m. p. 170°; 3-*phenyl-4-m-toluidinomethylene-5-isooxazolone*, yellow crystals, m. p. 158°; 3-*phenyl-4-p-toluidinomethylene-5-isooxazolone*, slightly red crystals, m. p. 190°; 3-*phenyl-4-o-anisidinomethylene-5-isooxazolone*, yellow needles, m. p. 138°; 3-*phenyl-4-p-anisidinomethylene-5-isooxazolone*, m. p. 168°; 3-*phenyl-4-p-phenetidinomethylene-5-isooxazolone*, m. p. 174°; 3 - *phenyl-4-ψ-cumidinomethylene-5-isooxazolone*, yellow needles, m. p. 180°; 3-*phenyl-4-m-nitroanilinomethylene-5*-isooxazolone yellow needles, m. p. 206°, and 3-*phenyl-4-p-bromoanilinomethylene-5-isooxazolone*, a pale yellow substance, m. p. 198°, are all obtainable similarly by applying the suitably substituted formamidine. The last-named product can also be obtained by the action of bromine on an acetic acid solution of phenylanilinomethylene*iso*oxazolone, when an intermediate red mono*bromo-compound*, m. p. 148°, is produced, which undergoes rearrangement in solution in pyridine or alcohol with formation of the phenylbromoanilinomethylene*iso*oxazolone.

No derivatives could be obtained from 3-methyl*iso*oxazolone by heating with formamidines as the temperature necessary to induce interaction caused decomposition of the products. Benzylidenemethyl-*iso*oxazolone, however, if heated with an equimolecular proportion of diphenylformamidine at 115—120°, yielded a mixture of benzylidene-aniline with 4-*anilinomethylene-3-methyl-5-isooxazolone*, pale yellow crystals, m. p. 158°, which dissolves unchanged in cold dilute alkalis, but with a warm solution of potassium hydroxide undergoes decomposition with deposition of aniline and needles of a potassium salt, decomp. 265—270°, of an unidentified *substance*; the above condensation product also reacts with bromine in acetic acid solution with precipitation of a yellow *substance*, which loses hydrogen bromide on drying, and when dissolved in alcohol or boiled with water or pyridine undergoes rearrangement into p-*bromoanilinomethylenemethylisooxazolone*, yellow needles, m. p. 204°, also obtainable from benzylidene-methyl*iso*oxazolone and di-*p*-bromodiphenylformamidine. A similar rearrangement has been previously noted (A., 1902, i, 602), the substance m. p. 148° having been since recognised as ethyl α-cyano-β-*p*-bromoanilinoacrylate, $C_6H_4Br \cdot NH \cdot CH:C(CN) \cdot CO_2Et$, and the explanation of this change appears to be expressed by the following

series of equations: $CHR_2 \cdot CH \vdots NPh + Br_2 = CHR_2 \cdot CHBr \cdot NBrPh = CR_2 \vdots CH \cdot NBrPh + HBr \longrightarrow CR_2 \vdots CH \cdot NH \cdot C_6H_4Br$, in the first stage of which the tautomeric form of the anilinomethylene derivative is involved. Diphenylformamidine also combines with bromine, giving a yellow additive *product*, m. p. 262°, which on treatment with potassium hydroxide solution decomposes into *p*-bromoaniline, *p*-bromoformanilide, and aniline.

That the reaction between benzylidenemethyl*iso*oxazolone and formamidines is a general one is evidenced by the following compounds which were also prepared : 4-*o-toluidinomethylene-3-methyl-5-isooxazolone*, pale red needles, m. p. 206° ; 4-m-*toluidinomethylene-3-methyl-5-isooxazolone*, brownish-white needles, m. p. 168° ; 4-p-*toluidinomethylene-3-methyl-5-isooxazolone*, yellow needles, m. p. 204°, which is decomposed by an alcoholic solution of hydrogen chloride with formation of ammonium chloride and *p*-toluidine hydrochloride, and on treatment with bromine in acetic acid solution gives a yellow additive *product*, m. p. 161—163° ; this regenerates the original substance when acted on by alcohol or potassium hydroxide ; 4-p-*anisidinomethylene-3-methyl-5-isooxazolone*, yellow needles, m. p. 190° ; 4-p-*phenetidinomethylene-3-methyl-5-isooxazolone*, yellow needles, m. p. 169° ; 4-m-*xylidinomethylene-3-methyl-5-isooxazolone*, colourless crystals, m. p. 166° ; 4-o-*anisidinomethylene-3-methyl-5-isooxazolone*, yellow crystals, m. p. 169°.

p-*Methoxybenzylidenemethyl*isooxazolone, deep yellow crystals, m. p. 178°, was prepared by a similar method to the corresponding benzylidene compound, namely, by the action of anisaldehyde and hydrochloric acid on the reaction mixture obtained from ethyl acetoacetate and hydroxylamine hydrochloride in aqueous alcohol containing some pyridine. It reacts with the formamidines in a similar manner to the benzylidene derivative, and on heating with di-ψ-cumylformamidine gave 4-*ψ-cumidinomethylene-3-methyl-5-isooxazolone*, a yellow, crystalline substance, m. p. 192°, together with anisylidene-ψ-cumidine, colourless crystals, m. p. 71°.

When a suspension of benzoylanilinomethyleneacetanilide,

$$NHPh \cdot CH \vdots CBz \cdot CO \cdot NHPh,$$

in alcohol is warmed for several hours with rather more than an equimolecular proportion of hydroxylamine hydrochloride and pyridine, there is produced 5-*phenyl*isooxazole-4-carboxyanilide,

$$\begin{matrix} N \!=\! CH \\ O \cdot CPh \end{matrix} \!\!> \!\! C \cdot CO \cdot NHPh,$$
colourless needles, m. p. 135°, from the solutions of which in alkali acids precipitate benzoylcyanoacetanilide, $CN \cdot CHBz \cdot CO \cdot NHPh$, m. p. 203°. In a similar manner, 5-*phenyl*isooxazole-4-carboxy-o-*toluidide*, colourless needles, m. p. 114°, can be obtained from o-toluidino-methylenebenzoylaceto-o-toluidide, and by solution in alkali and reprecipitation by acid is converted into *benzoylcyanoaceto-o-toluidide*, colourless needles, m. p. 132° ; also 5-*phenyl*isooxazole-4-carboxy-p-*toluidide*, colourless needles, m. p. 158°, was prepared, which by successive treatment with alkali and acid yielded *benzoylcyanoaceto-p-toluidide*, colourless needles, m. p. 180° ; in the preparation of the

p-toluidinomethylenebenzoylaceto-*p*-toluidide required for the last synthesis, a quantity of *ethyl α-benzoyl-p-toluidinoacrylate*,

$$C_6H_4Me·NH·CH:CBz·CO_2Et,$$
yellow flakes, m. p. 98°, was obtained. In an analogous manner, p-*anisidinomethylenebenzoylaceto-p-anisidide*, yellow crystals, m. p. 196°, obtainable by heating a mixture of ethyl benzoylacetate and di-*p*-anisylformamidine at 140°, could be converted into 5-*phenylisooxazole-4-carboxy-p-anisylamide*, colourless needles, m. p. 142°, which under the influence of alkali rearranges to *benzoylcyanoaceto-p-anisidide*, colourless needles, m. p. 194°.

Derivatives of 5-methyl*isooxazole*-4-carboxylic acid can be obtained by taking arylaminomethyleneacetoaceto-arylamides in place of the analogous derivatives of benzoylacetic acid in the immediately pre-ceding general synthetic reaction, and the products under the influence of alkali readily pass into the corresponding amides of cyanoacetoacetic acid; 5-*methylisooxazole-4-carboxy-o-toluidide*, colourless needles, m. p. 112°, is converted by alkali into *cyanoacetoaceto-o-toluidide*,

$$CN·CHAc·CO·NH·C_6H_4Me,$$
colourless needles, m. p. 110°; 5-*methylisooxazole-4-carboxy-p-toluidide*, colourless needles, m. p. 140°, is converted by alkali into *cyanoaceto-aceto-p-toluidide*, colourless needles, m. p. 176°. 5-*Methylisooxazole-4-carboxyanilide*, a colourless substance, m. p. 136°, which rearranges to cyanoacetoacetanilide, is difficult to isolate on account of its considerable solubility.

During the course of the investigation the following substances were also obtained apparently for the first time: *ethyl* m-*xylidino-methyleneacetoacetate*, $C_6H_3Me_2·NH·CH:CAc·CO_2Et$, colourless crystals, m. p. 122°, by heating ethyl acetoacetate with di-*m*-xylylformamidine at 120°; *cyanoaceto-m-toluidide*, colourless crystals, m. p. 138°, by heating together ethyl cyanoacetate and *m*-toluidine for several hours at 160°; *cyanoaceto-p-anisidide*, colourless crystals, m. p. 138°, by heating the two components at 160—170°.   D. F. T.

Oxindole and Thio-oxindole. CHARLES MARSCHALK (*J. pr. Chem.*, 1913, [ii], **88**, 227—250).—A recapitulation and extension of previous work (A., 1912, i, 303, 575).—Thionaphthenquinone reacts with hydrazine hydrate in boiling alcoholic solution, yielding a *substance* (probably a *hydrazone*), which crystallises in yellow leaflets, m. p. 128°, and when heated above its m. p. decomposes into nitrogen and thio-oxindole (2-keto-2 : 3-dihydro-1-thionaphthen). The latter com-pound is best prepared by heating o-thiolphenylacetic acid with phosphoric oxide in benzene solution. When prepared by this method and submitted to steam distillation, it is generally obtained in stout prisms, m. p. 44—45°, which on distillation under ordinary pressure are transformed into slender needles, m. p. 33—34°. The more fusible modification is also formed by distilling o-thiolphenylacetic acid alone, or heating it with acetic anhydride and distilling the product in steam. It differs from the modification of higher m. p. in giving at once a deep-blue coloration with ferric chloride. Only in one instance has it been found possible to transform the modification of m. p. 33—34° into the

less fusible variety, a specimen of the former substance, obtained by heating o-thiolphenylacetic acid with phosphoric oxide in benzene solution, being converted into the modification of higher m. p. by acidifying its solution in cold aqueous sodium hydroxide.

On treatment with nitrous acid, thio-oxindole yields thionaphthenquinone-3-oxime, m. p. 181° (Friedländer, A., 1908, i, 200, gives m. p. 186°). It couples with benzenediazonium chloride, yielding a substance, $C_{14}H_{10}ON_2S$, which crystallises in intensely red, lustrous needles, m. p. 159—160°, and is possibly identical with the phenylhydrazone of thionaphthenquinone (m. p. 165—166°) described by Friedländer (*loc. cit.*). With p-nitrobenzenediazonium chloride it forms a red *azo-dye*,

$$C_{14}H_9O_3N_3S,$$
m. p. 271—272°.

The *azo-dyes* from a- and β-naphthalenediazonium chlorides crystallise in stout, brown needles, m. p. 192—193° and 154—156° respectively.

When heated with o-methoxybenzaldehyde in alcoholic solution in the presence of piperidine, thio-oxindole yields 2-*keto*-3-*o-methoxybenzylidene*-2 : 3-*dihydro*-1-*thionaphthen*,

$$OMe \cdot C_6H_4 \cdot CH:C \underset{C_6H_4}{\overset{CO}{<}} \!\!\! > S,$$
which forms yellow needles, m. p. 96—98°, and is hydrolysed by alcoholic potassium hydroxide to a-*thiolphenyl-o-methoxycinnamic acid*, $OMe \cdot C_6H_4 \cdot CH:C(C_6H_4 \cdot SH) \cdot CO_2H$, crystallising in stout, colourless needles, m. p. 134—136°.

It condenses with thionaphthenquinone-2-p-dimethylanil and acenaphthene in hot glacial acetic acid solution containing a little sulphuric acid, yielding 2 : 3'-bisoxythionaphthen (Friedländer, A., 1908, i, 673) and 8-oxy-6-oxythionaphthenylacenaphthene (Bezdzik and Friedländer, *loc. cit.*) respectively.

When heated with isatin in alcoholic solution, thio-oxindole forms an additive *compound*, $S \underset{CO}{\overset{C_6H_4}{<}} \!\!\! > CH \cdot C(OH) \underset{CO}{\overset{C_6H_4}{<}} \!\!\! > NH$, crystallising in colourless needles, which gradually become red at 135°, m. p. 155—160°. The additive compound gives a brown coloration with sulphuric acid, and when heated for a short time with glacial acetic acid containing a few drops of strong hydrochloric acid, is converted into 3'-*indoxyl*-3-*thionaphthen*-2'-*one*, $S \underset{CO}{\overset{C_6H_4}{<}} \!\!\! > C:C \underset{CO}{\overset{C_6H_4}{<}} \!\!\! > NH$, which crystallises in lustrous, silky, brown needles, m. p. 230°, and may also be obtained by the interaction of thio-oxindole or o-thiolphenylacetic acid and isatin in the presence of a mixture of glacial acetic and sulphuric acids (1 : 2) at the ordinary temperature.

(3')-5' : 7'-*Dichloroindoxyl*-3-*thionaphthen*-2'-*one*,

$$S \underset{CO}{\overset{C_6H_4}{<}} \!\!\! > C:C \underset{CO}{\overset{C_6H_2Cl_2}{<}} \!\!\! > NH,$$
prepared by maintaining a solution of 5 : 7-dichloroisatin and thio-oxindole in the above acid mixture for three hours at the ordinary temperature, crystallises in dark brown needles, m. p. 330°.

The corresponding *dibromo*-derivative, from 5 : 7-dibromoisatin, forms brown needles, m. p. 331°. F. B.

The Anthraquinone Series. III. Anthraquinonethiazoles. FRITZ ULLMANN and WALTHER JUNGHANS (*Annalen*, 1913, **399**, 345—352).—*2-Phenyl-*4 : 5-(2' : 1')-*anthraquinonethiazole* (formula I), m. p. 291° (corr.), yellowish-green needles, is obtained by boiling 2-benzylideneamino-anthraquinone with sulphur and naphthalene, or, better, by heating 1-chloro-2-aminoanthra-quinone with potassium thiobenzoate and naphthalene at about 225°.
2-*Phenyl*-4 : 5-(1' : 2')-*anthraquinonethiazole* (formula II), m. p. 260° (corr.), brown needles, and 2-*phenyl*-4 : 5-(2' : 3')-*anthraquinonethiazole*, $C_6H_4\langle\begin{smallmatrix}CO\cdot C:CH\cdot C\cdot N\\CO\cdot C:CH\cdot C\cdot S\end{smallmatrix}\rangle OPh$, m. p. 336—337° (corr.), faintly yellow crystals, are prepared by the latter method from 2-bromo-1-aminoanthraquinone and 3-bromo-2-amino-anthraquinone respectively. The last-mentioned thiazole does not possess dyeing properties.

1 : 3 - Dibromo - 2 - aminoanthraquinone and potassium thiobenzoate react in boiling amyl alcohol, the initially-formed thiazole being converted into a *thiazole*-3 : 3'-*disulphide*, $C_{42}H_{20}O_4N_2S_4$, m. p. about 385°; by a similar method, 1-chloroanthraquinone is converted into the anthraquinonyl-1 : 1'-di-sulphide, m. p. 359°, obtained by Gattermann from anthraquinonyl-1-mercaptan.   C. S.

Selenodiarylamines. WILHELM CORNELIUS (*J. pr. Chem.*, 1913, [ii], **88**, 395—408).—The selenium analogues of thiodiphenylamine and its derivatives are readily obtained by heating diarylamines with selenium dichloride in benzene solution (compare Weizmann and Stephen, P., 1913, **29**, 196).

Selenodiphenylamine, $NH\langle\begin{smallmatrix}C_6H_4\\C_6H_4\end{smallmatrix}\rangle Se$, prepared from diphenylamine, crystallises in small, lustrous, yellow leaflets, m. p. 195°, which become greenish on exposure to air, owing to slight oxidation. Its constitution has been established by the formation of carbazole on distilling the substance with zinc dust or iron filings. With ferric chloride in alcoholic solution, it yields an emerald-green coloration. When heated with methyl iodide in methyl-alcoholic solution, it forms a *methyl* derivative, which crystallises in white needles, m. p. 138—139°, and is freed from the accompanying green oxidation product by reduc-tion with sulphurous acid in alkaline solution. The methyl derivative resembles the parent substance in yielding various characteristic colorations on treatment with oxidising agents. It forms a yellow *nitro*-compound, which is converted by reduction and subsequent oxidation with ferric chloride into a red dye.

When heated with acetic anhydride, selenodiphenylamine forms an *acetyl* derivative, crystallising in white flakes or stout, lustrous, prismatic crystals, m. p. 176°.

On treatment with concentrated nitric acid at 0°, it yields two isomeric *dinitroselenoxydiphenylamines*, $C_{12}H_7O_5N_3Se$, which are readily

separated by taking advantage of the insolubility of the α-isomeride in alcohol. The α-isomeride crystallises in clusters of small, light brown needles, melts with decomposition, and dissolves in aqueous alkalis and ammonia yielding strawberry-red solutions; the white *silver* and *mercuric* salts are mentioned. On reduction and subsequent oxidation, the α-compound gives rise to the selenium analogue of Lauth's violet, and, therefore must have the annexed constitution.
The β-isomeride forms a reddish-brown, crystalline mass, and is converted by successive reduction and oxidation into a reddish-violet *dye*. When treated with dilute nitric acid, selenodiphenylamine yields a *mononitro*-derivative, which, however, could not be separated from the accompanying dinitro-derivatives. On reducing the mixture of nitro-compounds with tin and hydrochloric acid, *aminoselenodiphenyl-amine*, $NH<\frac{C_6H_4}{C_6H_3(NH_2)}>Se$, separates in the form of its *stanni-chloride*. This crystallises in lustrous needles, and, on treatment with zinc and hydrochloric acid, yields the *zincichloride*, crystallising in small, broad, transparent needles. The free *base* is liberated from the latter compound by aqueous sodium hydroxide and crystallises in small, white, pearly, lustrous leaflets; the *hydrochloride* is precipitated in white needles by passing hydrogen chloride into a benzene solution of the base; the *acetyl* derivative has m. p. above 330° (decomp.).

Oxidation of the hydrochloride or zincichloride by means of ferric chloride in aqueous solution results in the formation of a dye, which is precipitated by the addition of sodium and zinc chlorides in the form of its *zincichloride*, $2\begin{vmatrix} N-C_6H_4 \\ NH\cdot C_6H_3 \end{vmatrix}>Se,H_2ZnCl_4$. This crystallises in very slender, bronze needles, dyes silk light blue to bluish-violet, and, on the addition of alkalis to its hot alcoholic solution, yields the free *base*, which forms a crystalline red powder, and is converted by hydrogen chloride in ether solution into the *hydrochloride*.

α-Dinitroselenoxydiphenylamine is reduced by stannous chloride and hydrochloric acid to *diaminoselenodiphenylamine stannichloride*,

$$2NH<\frac{C_6H_3(NH_2)}{C_6H_3(NH_2)}>Se,H_2SnCl_4,H_2O.$$
This crystallises in slender, lustrous, yellowish-brown needles, and is converted by the addition of zinc to its aqueous solution into the *zincichloride*, which is oxidised by ferric chloride to *selenonine*, the selenium analogue of Lauth's violet. The latter compound separates in the form of its *zincichloride*, $2\begin{vmatrix} N-C_6H_3(NH_2) \\ NH\cdot C_6H_3 \end{vmatrix}>Se,H_2ZnCl_4$, in very slender, felted, reddish-brown needles, having a bronze lustre. The dye *base*, obtained from the zincichloride by the action of aqueous sodium hydroxide, crystallises in small bronze needles and forms a *hydrochloride*, which crystallises in long, slender, felted needles, having a bronzy-green lustre, and dyes silk turquoise-blue.

The selenium analogue of methylene-blue has been prepared by the action of hydrogen selenide on p-nitrosodimethylaniline and subsequent oxidation of the resulting compound with ferric chloride in hydrochloric acid solution.

Selenophenyl-β-naphthylamine, $NH<^{C_6H_4}_{C_{10}H_6}>Se$, prepared by heating phenyl-β-naphthylamine with selenium dichloride in benzene solution, crystallises in small, yellow needles, m. p. 176°, and gives a greenish-blue coloration with sulphuric acid.

Seleno-α-dinaphthylamine, $NH<^{C_{10}H_6}_{C_{10}H_6}>Se$, from αα-dinaphthylamine, forms small, yellow needles, m. p. 176—177°.

Seleno-β-dinaphthylamine crystallises from benzene in slender, felted, yellowish-green needles, from nitrobenzene in long, pointed prisms, m. p. 245°, and from alcohol in tabular crystals. On treatment with nitric acid in acetic acid solution, it yields a yellow *nitro*-compound.

Seleno-p-ditolylamine crystallises in yellow, lustrous, broad scales, m. p. 240°. F. B.

New Derivatives of Artemisin and of Santonin. II. ENRICO RIMINI and TEMISTOCLE JONA (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 28—32. Compare this vol., i, 748).—When artemisin is reduced with hydrogen in presence of palladium-black, *α-tetrahydroartemisin*, $C_{15}H_{22}O_4$, is obtained. It crystallises in plates, m. p. 192—193°, $[α]_D^{22} + 49.60°$ (in 2.671% alcoholic solution). From the mother-liquor a second hydro-derivative, *β-tetrahydroartemisin*, $C_{15}H_{22}O_4$, m. p. 165—167°, can be obtained. This substance has $[α]_D^{22} + 65.15°$ (in 2.670% alcoholic solution). Both tetrahydroartemisins are stable towards Baeyer's reagent. *α-Tetrahydroartemisinsemicarbazone*,
$$C_{15}H_{22}O_3:CH_3ON_3,$$
decomposes at 245°. *β-Tetrahydroartemisinsemicarbazone*,
$$C_{15}H_{22}O_3:CH_3ON_3,$$
decomposes at 257—258°. *α-Tetrahydroartemisinoxime*, $C_{15}H_{22}O_3:NOH$, decomposes at 248°. *β-Tetrahydroartemisinoxime*,
$$C_{15}H_{22}O_3:NOH,$$
decomposes at 242°. Artemisinoxime yields α-tetrahydroartemisin when hydrogenated in presence of palladium-black. When α-tetrahydroartemisin is dissolved in sodium hydroxide and the solution acidified with sulphuric acid at a low temperature, *α-tetrahydroartemisinic acid* can be extracted with chloroform; it softens and loses water at 55°, decomposing at 118°. Its *sodium* salt crystallises in needles. *β-Tetrahydroartemisinic acid* is similarly prepared, and is much more stable. It forms needles, m. p. 218—220° (decomp.), and on titration with alkali gives figures agreeing with the composition
$$C_{14}H_{23}O_3·CO_2H.$$
R. V. S.
Action of the Halogens on Artemisin. ENRICO RIMINI and TEMISTOCLE JONA (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 71—74. Compare preceding abstract).—When a solution of artemisin in glacial acetic acid is treated with a solution of hydrogen bromide and bromine in the same solvent, *artemisin dibromide hydrobromide*, $C_{30}H_{37}O_8Br_3$, is

obtained. This unstable oxonium compound, which readily loses bromine, forms lustrous, red crystals which decompose at 94°. Under slightly different experimental conditions, the compound described is accompanied by *monobromoartemisin*, $C_{15}H_{17}O_4Br$, a stable, yellow substance which becomes red at about 70° and decomposes at 95°.

Artemisin di-iodide hydriodide, $C_{30}H_{37}O_8I_3$, similarly prepared, is a brown, crystalline substance, m. p. 118—119° (decomp.).

By the action of chlorine on a chloroform solution of artemisin at 15°, a *chloroartemisin*, $C_{15}H_{15}O_8Cl_3$, is obtained, but the preparation is uncertain; the substance crystallises in needles, which decompose at 212°. When the chlorination is effected at 20°, a crystalline *chloroartemisin*, $|C_{15}H_{20}O_4Cl_2$, is obtained; it decomposes at 133°.

R. V. S.

Identity of Lycorine and Narcissine. YASUHIKO ASAHINA and Y. SUGII (*Arch. Pharm.*, 1913, **251**, 357—360).—The authors have examined the base lycorine, which together with a second base sekisanine was isolated by Morishima (A., 1899, i, 93) from the bulbs of *Lycoris radiata*. They are of opinion that lycorine, $C_{16}H_{17}O_4N$, m. p. 275° (decomp.), darkening at about 240°, $[\alpha]_D^{13}$ – 123·7° in alcohol and pyridine (*hydrochloride*, colourless needles, m. p. 217°; *picrate*, m. p. 195—202° [decomp.], yellow leaflets), is identical with the alkaloid narcissine, $C_{16}H_{17}O_4N$, m. p. 266—267°, $[\alpha]_D$ – 95·8°, colourless prisms (hydrochloride, m. p. 198—199°, colourless needles; picrate, m. p. 196—199°, yellow leaflets), obtained by Ewins (T., 1910, **97**, 2406) from the bulbs of *Narcissus pseudonarcissus*. C. S.

Formula of *apo*Morphine Hydrochloride. VINCENZO PAOLINI (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 121—125).—Estimations of the water of crystallisation in *apo*morphine hydrochloride from various sources all indicate $\frac{3}{4}H_2O$. The amount of chlorine in the salt is that required by the formula $C_{17}H_{17}O_2N,HCl,\frac{3}{4}H_2O$, and the elementary analysis of *apo*morphine gives the composition $C_{17}H_{17}O_2N$. Dibenzoyl-*apo*morphine has, in freezing benzene, the composition required by the formula $C_{17}H_{15}N(OBz)_2$. R. V. S.

Preparation of Hydrogenised Alkaloids of the Morphine Group. HERMANN OLDENBERG and BABETTE OLDENBERG (D.R.-P. 260233).—Alkaloids of the morphine group are readily hydrogenised by the action of hydrogen in the presence of colloidal palladium, or a metal of the platinum group. *Hydromorphine*, $C_{17}H_{21}O_3N,H_2O$, fine needles, m. p. 155—157°, is obtained when morphine hydrochloride (10 parts) in 250 parts of water is shaken with a mixture of colloidal palladium (1 part) in 10 parts of water which has been saturated with hydrogen; the *hydrochloride* forms microscopic prisms; the *sulphate* is less readily obtained in crystalline form; it gives the colour reactions of Fröhde, Husemann, and Marquis.

Hydrocodeine, rhombic crystals, m. p. 62—63°, has also 1 mol. water of crystallisation and gives Fröhde's and Hesse's colour reactions.

Tetrahydrothebaine, $C_{19}H_{25}O_3N$, is prepared from thebaine and responds to Fröhde's and Erdmann's reagents; the *hydrochloride* forms

prisms; the *hydrogen tartrate* is obtained by the reduction of thebaine hydrogen tartrate.

The therapeutic action of these compounds is also discussed.

F. M. G. M

Berberine. II. Berberrubine. GEORG FRERICHS and P. STOEPEL (*Arch. Pharm.*, 1913, **251**, 321—339).—Berberrubine is best obtained by heating well dried berberine chloride at about 190° in a slow current of carbon dioxide. There can be little doubt that anhydrous berberrubine contains the annexed group. Since it is readily converted into berberine iodide by treatment with methyl iodide, other alkyl haloids may be expected to produce homologous berberines. Thus a large excess of ethyl iodide on the water-bath converts berberrubine into *ethylberberrubine iodide (homoberberine iodide)*, $C_{21}H_{20}O_4NI$, yellow or yellowish-brown needles, which reacts with boiling alcoholic $N/2$-potassium hydroxide and acetone to form *ethylberberrubineacetone*, $C_{24}H_{25}O_5N$, m. p. 159°, from which the salts of ethylberberrubine are obtained by heating with dilute acids; the *chloride*, $C_{21}H_{20}O_4NCl,2H_2O$, is described.
By boiling with dilute acetic and sulphuric acids and zinc and a little platinum, ethylberberrubine chloride is reduced and yields, after basification with aqueous ammonia, *ethyltetrahydroberberrubine*, $C_{21}H_{23}O_4N$, m. p. 129°, faintly yellow crystals, which resembles tetrahydroberberine throughout.

Berberrubine reacts additively, not only with alkyl haloids, but also with other organic halogen compounds. Ethyl bromoacetate and alcohol on the water-bath convert it into the *bromide* of *ethyl berberrubineacetate*, $C_{23}H_{22}O_6NBr$, yellow crystals, which is converted by digestion with silver oxide and hot water into *berberrubineacetic acid*, $C_{21}H_{17}O_6N,5H_2O$; a hot aqueous solution of the latter is converted into the *hydrochloride*, $C_{21}H_{17}O_6N,HCl,2H_2O$, yellow crystals, by N-hydrochloric acid.

In a similar manner, berberrubine and ethyl α-bromopropionate yield the *bromide* of *ethyl berberrubinepropionate*, $C_{24}H_{24}O_6NBr$, yellow needles, from which *berberrubinepropionic acid*, $C_{22}H_{19}O_6N,2H_2O$, yellow needles, is obtained; the *hydrochloride* of the latter also crystallises in yellow needles. Berberrubine does not react with ethyl β-iodopropionate.

Berberrubine, unlike berberine, is attacked by oxidising agents most readily in its methoxylated benzene nucleus. By treatment with hot 25% nitric acid it yields two crystalline substances, berberrubinone and berberrubinic acid, both of which are obtained in the form of nitrates. *Berberrubinone nitrate* (annexed formula) forms dark green, almost black, crystals, which are deep red by transmitted light, is converted into a *sulphate* (or mixture of normal and hydrogen sulphates), dark green crystals, by hot dilute sulphuric acid,
and by treatment with boiling dilute sulphuric acid and 30% sodium hydrogen sulphite is reduced to the sulphate of the corresponding quinol, *berberrubinol sulphate*, a yellow substance. From the hot solution of the latter, saturated sodium hydrogen carbonate liberates *berberrubinol*, $C_{18}H_{13}O_4N,3H_2O$, an amorphous, dark red powder.

Anhydrous berberrubinol is a phenol-betaine, and is therefore a completely demethylated berberine; it is not identical with Perkin's berberoline, which has the same composition.
Berberrubinic acid nitrate (annexed formula) and the corresponding *chloride*, $C_{18}H_{14}O_6NCl$, form golden-yellow crystals, and are decomposed by water with the formation of *berberrubinic acid*, an amorphous, yellow substance, which is probably a betaine; it has not been obtained entirely free from the nitrate or chloride.

A hot aqueous solution of berberrubine is converted by sodium hypochlorite into *chloroberberrubine*, $C_{19}H_{14}O_4NCl$, reddish-brown needles, which forms a *chloride*, $C_{19}H_{15}O_4NCl_2,3H_2O$, orange-yellow crystals. Chloroberberrubine certainly contains the chlorine atom in the methoxylated benzene nucleus (probably in the meta-position to the methoxy-group), because by the prolonged action of sodium hypochlorite it is converted into the *lactam chloride*,

$$NCl\cdot CO—C\cdot CH\colon C\cdot O \diagdown CH_2,$$
$$CH_2\cdot CH_2\cdot C\cdot CH\colon C\cdot O \diagup$$
m. p. 114°, colourless needles, of ω-aminoethylpiperonylcarboxylic acid; the lactam-chloride, which can also be obtained by the action of sodium hypochlorite on berberine chloride or bromoberberrubine in hot aqueous solution, is converted into Perkin's lactam, m. p. 181°, by treatment with hot aqueous sodium sulphite.

Chloroberberrubine is reduced to *chlorotetrahydroberberrubine*, $C_{19}H_{18}O_4NCl$, m. p. 142°, colourless crystals (*hydrochloride*, white, crystalline powder), by zinc and platinum and hot dilute acetic and sulphuric acids, and reacts with methyl iodide at 100° to form *chloroberberine iodide*, $C_{20}H_{17}O_4NClI$; the latter, which resembles berberine iodide in its behaviour, reacts with alcoholic $N/2$-potassium hydroxide and acetone to form *chloroberberineacetone*, $C_{23}H_{22}O_5NCl$, m. p. 171°, yellow crystals. The following substances are obtained by methods similar to the preceding: *bromoberberrubine*, $C_{19}H_{14}O_4NBr$, reddish-brown needles, and its *chloride*, $C_{19}H_{15}O_4NClBr,3H_2O$, yellow crystals; *bromotetrahydroberberrubine*, $C_{19}H_{18}O_4NBr$, m. p. 145°, colourless crystals; *bromoberberine iodide*, $C_{20}H_{18}O_4NBrI$, golden-yellow leaflets, and *bromoberberine acetone*, $C_{23}H_{22}O_5NBr$, m. p. 153°, yellow crystals.

C. S.

Preparation of Hydrastinine from Berberine. EMMANUEL MERCK (D.R.-P. 259873. Compare VOSS, A., 1910, i, 415; Freund, A., 1912, i, 383, 487).—Phenyltetrahydroberberine (m. p. 222°) when digested with methyl iodide furnishes a *methiodide*, m. p. 243°.

Phenyldihydroberberine on electrolytic reduction gives rise to two

stereoisomeric phenyltetrahydroberberines with m. p.'s 222° and 202—204°; these can be separated by fractional crystallisation of their sulphates; the *methiodide* of the isomeride (m. p. 202—204°) has m. p. 247°.

When either of the foregoing phenyltetrahydroberberines is digested with silver chloride, and subsequently reduced with sodium amalgam, it yields a *base*, $C_{27}H_{29}O_4N$, m. p. 112—113° (the *hydriodide* has m. p. 218°), which on oxidation gives rise to hydrastinine.   F. M. G. M.

Reactions of the Formamidines. IV. FRANK BURNETT DAINS, O. O. MALLEIS, and J. T. MEYERS (*J. Amer. Chem. Soc.*, 1913, **35**, 970—976. Compare this vol., i, 1086).—The previous investigations have indicated that the general reaction of formamidines with compounds containing methylene hydrogen may be formulated :

$$CH_2XY + NR\!:\!CH\!\cdot\!NHR = CXY\!:\!CH\!\cdot\!NHR + NH_2R.$$
If Y is a carbethoxy-group the amine produced can react with it to give an amide and an alcohol. The occurrence of the second reaction is more marked the higher the temperature.

p-Aminophenylbenzyl ether (hydrochloride, m p. 222—223°; *benzoyl* derivative, m. p. 226—227°; *benzylidene* derivative, colourless leaflets, m. p. 118°; *anisylidene* derivative, m. p. 150°) when warmed with ethyl orthoformate readily enters into reaction, producing *di-p-benzyloxydiphenylformamidine*, $C_7H_7O\cdot C_6H_4N\!:\!CH\cdot NH\cdot C_6H_4\cdot OC_7H_7$, colourless crystals, m. p. 153°; *hydrochloride*, m. p. 261°; *picrate*, m. p. 209°. When heated with ethyl cyanoacetate at 120—130°, the formamidine reacts, producing aminophenylbenzyl ether and *ethyl α-cyano-β-p-benzyloxyanilinoacrylate*, $CH_2Ph\cdot O\cdot C_6H_4\cdot NH\cdot CH\!:\!C(CN)\cdot CO_2Et$, brown crystals, m. p. 120°. The formamidine reacts in the usual manner with ethyl malonate, giving *ethyl p-benzyloxyanilinomethylenemalonate-p-benzyloxyanilide*, colourless crystals, m. p. 131°, as with ethyl malonate the molecule of amine produced in the first stage of the reaction is always found to enter into amide formation. Ethyl acetoacetate with the formamidine yields products of both the first and second stages of the reaction, giving *ethyl p-benzyloxyanilinomethyleneacetoacetate*, $CH_2Ph\cdot O\cdot C_6H_4\cdot NH\cdot CH\!:\!OAc\cdot CO_2Et$, a pale yellow substance, m. p. 95°, together with *p*-benzyloxyanilinomethyleneacetoaceto-*p*-benzyloxyanilide, fine, yellow needles, m. p. 164°.

As was to be expected from experiments with other formamidines, phenylmethylpyrazolone readily reacts with di-*p*-benzyloxydiphenylformamidine, giving *1-phenyl-4-p-benzyloxyanilinomethylene-3-methyl-5-pyrazolone*, red needles, m. p. 181°.

When ethyl orthoformate is heated with *p*-aminodimethylaniline at 125° for two hours, *di-p-dimethylaminodiphenylformamidine*, m. p. 157°, is obtained, which gives a yellow *monohydrochloride*, m. p. 233°, a dihydrochloride and a colourless *trihydrochloride*, m. p. 193°; *picrate*, m. p. 172°. The formamidine reacts with ethyl malonate, yielding *ethyl p-dimethylaminoanilinomethylenemalonate-dimethylaminoanilide*, $NMe_2\cdot C_6H_4\cdot NH\cdot CH\!:\!C(CO_2Et)\cdot CO\cdot NH\cdot C_6H_4\cdot NMe_2$, m. p. 142°, and with ethyl cyanoacetate giving *ethyl α-cyano-β-p-dimethylaminoanilinoacrylate*, $NMe_2\cdot C_6H_4\cdot NH\cdot CH\!:\!C(CN)\cdot CO_2Et$, colourless needles, m. p. 134°. When heated with ethyl acetoacetate the amidine produced phenylene-

dimethyldiamine and *p-dimethylaminoanilinomethyleneacetoaceto-p-dimethylaminoanilide*, NMe$_2$·C$_6$H$_4$·NH·CH:CAc·CO·NH·C$_6$H$_4$·NMe$_2$, m. p. 178°, together with a little *ethyl dimethylaminoanilinomethyleneacetoacetate*, m. p. 88°.

Di-p-iododiphenylformamidine, C$_6$H$_4$I·N:CH·NH·C$_6$H$_4$I, colourless needles, m. p. 175°, is easily obtained by the combination of *p*-iodoaniline and ethyl orthoformate at water-bath temperature; *hydrochloride*, m. p. 249°; picrate, dark yellow crystals, m. p. 226°. With ethyl cyanoacetate at 125°, it produces *ethyl a-cyano-β-p-iodoanilinoacrylate*, brown needles, m. p. 154°, whilst with ethyl malonate *ethyl p-iodoanilinomethylenemalonate-p-iodoanilide*,

C$_6$H$_4$I·NH·CH:C(CO$_2$Et)·CO·NH·C$_6$H$_4$I,
colourless crystals, m. p. 176°, is obtained. With ethyl acetoacetate the products are iodoaniline, *ethyl p-iodoanilinomethyleneacetoacetate,*, C$_6$H$_4$I·NH·CH:CAc·CO$_2$Et, colourless crystals, m. p. 96°, and *p-iodoanilinomethyleneacetoaceto-p-iodoanilide*, m. p. 184°. The formamidine also reacts with acetylacetone, producing *p-iodoanilinomethyleneacetylacetone*, CAc$_2$:CH·NH·C$_6$H$_4$I, pale yellow needles, m. p. 180°, whilst with benzylidenemethylisooxazolone at 140°, *3-methyl-4-p-iodoanilinomethylene-5-isooxazolone*,
$\begin{smallmatrix} N:CMe \\ | \quad\quad \\ O—CO \end{smallmatrix}$ >C:CH·NH·C$_6$H$_4$I, yellow crystals,

m. p. 208°, is obtained. The *benzylidene* derivative, m. p. 85°, and *anisylidene* derivative, colourless needles, m. p. 151°, of *p*-iodoaniline were also prepared.

5-Iodo-*o*-toluidine (acetyl derivative, m. p. 176°, reacts quantitatively with bromine in chloroform solution producing 5-bromoaceto-*o*-toluidide, m. p. 158—159°; *benzylidene* derivative, colourless needles, m. p 55°) also reacts with ethyl orthoformate, giving *di-5-iododi-o-tolylformamidine*, C$_8$H$_8$MeI·N:CH·NH·C$_6$H$_3$MeI, needles, m. p. 169°; *hydrochloride*, m. p. 254°. This formamidine shows the usual behaviour towards compounds containing the methylene group, for example, with ethyl acetoacetate it forms *ethyl 5-iodo-o-toluidinomethyleneacetoacetate*, m. p. 137—138°, and *5-iodo-o-toluidinomethyleneacetoaceto-5-iodo-o-toluidide*, silky needles, m. p. 238°. With ethyl cyanoacetate and malonate the reaction products are *ethyl 5-iodo-a-cyano-o-toluidinoacrylate*, m. p. 207°, and *ethyl 5-iodo-o-toluidinomethylenemalonate-5-iodo-o-toluidide*, m. p. 201°. At 120° with benzylidenemethylisooxazolone the formamidine gives rise to *3-methyl-4-iodotoluidinomethylene-5-isooxazolone*, needles, m. p. 209°. D. F. T.

Preparation of Carbazolemonosulphonic Acids and their 9-Alkyl Derivatives. LEOPOLD CASSELLA & Co. (D.R.-P. 260898. Compare this vol., i, 516).—When carbazole (17 parts) is dissolved in 10—15 parts of hot nitrobenzene and cooled to 0° (when part of the carbazole separates), treated with chlorosulphonic acid (12 parts), and the temperature subsequently allowed to rise to 20°, it furnishes *carbazolesulphonic acid*, which is isolated in the form of its sodium salt, colourless, glistening leaflets; the *barium* salt, glistening scales, is more sparingly soluble. This compound condenses with *p*-nitrosophenol in concentrated sulphuric acid solution to furnish soluble blue dyes containing sulphur.

9-*Ethylcarbazolesulphonic acid* can also be prepared in quantitative yield by this method.   F. M. G. M.

[Preparation of 9-Ethylcarbazole-3:6-diphthaloylic Acid.]
LEOPOLD CASSELLA & Co. (D.R.-P. 261495. Compare A., 1911, i, 567).
—9-Ethylcarbazole reacts with phthalic anhydride and aluminium chloride in nitrobenzene solution, yielding 9-*ethylcarbazole*-3:6-*di-phthaloylic acid*,

$$CO_2H \cdot C_6H_4 \cdot CO \diagdown \diagup CO \cdot C_6H_4 \cdot CO_2H$$
NEt
and this when heated with concentrated sulphuric acid at 100—105° during five hours gives rise to 2:3:6:7-*diphthaloyl-9-ethylcarbazole*,
$$C_6H_4 \vdots C_2O_2 \diagup \diagdown C_2O_2 \vdots C_6H_4.$$

Catalytic Decomposition of Acetonylacetonephenylhydr-azone. ALEXANDER E. ARBUZOV and N. E. CHRUCKI (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 699).—Catalytic decomposition of acetonylacetone-phenylhydrazone at 180—190° in presence of cuprous chloride yields ammonia, dimethylaminophenylpyrrole, benzene and aniline, the last two products probably arising from the decomposition of a little admixed phenylhydrazine.   T. H. P.

Catalytic Decomposition of Methyl Propyl Ketonephenyl-hydrazone. ALEXANDER E. ARBUZOV and A. P. FRIAUF (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 694—696).—Catalytic decomposition of methyl propyl ketonephenylhydrazone at 185—210° in presence of cuprous chloride yields, as principal product, *propylindole*, $C_{11}H_{13}N$, which is an almost odourless, pale yellow liquid, b. p. 155—156°/9 mm., and forms a *picrate*, $C_{17}H_{16}O_7N_4$, m. p. 148—149°. Small proportions of secondary gaseous and liquid products also result from the decomposition.   T. H. P.

Catalytic Decomposition of Dipropyl Ketonephenyl-hydrazone. ALEXANDER E. ARBUZOV and R. E. VAGNER (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 697—699).—Catalytic decomposition of dipropyl ketonephenylhydrazone at 175—235° in presence of cuprous chloride yields principally 3-*ethyl-2-propylindole*, $C_{13}H_{17}N$, which crystallises in unstable, colourless plates, m. p. 45·5°, and forms a *picrate*, $C_{13}H_{17}N, C_6H_3O_7N_3$, m. p. 117·5°. Other products, including aniline, are formed in small proportions.   T. H. P.

Syntheses in the Indole Group. V. Syntheses of *N*- and *C*-Substituted Derivatives of Scatole and Methylketole. BERNARDO ODDO (*Gazzetta*, 1913, **43**, ii, 190—211. Compare A., 1912, i, 649; this vol., i, 755).—3-Acetyl-2-methylindole can be obtained in 86% yield by the action of acetyl chloride on the magnesium derivative of 2-methylindole (*loc. cit.*). Its *hydrochloride*,
$$C_{11}H_{11}ON, HCl,$$

was also prepared. The *aurichloride*, $C_{11}H_{11}ON,HCl,AuCl_3$, becomes brown at about 135°, melting at 158° (decomp.). The *platinichloride*, $(C_{11}H_{11}ON,HCl)_2PtCl_4$, blackens above 170°, melting at 195° (decomp.). The hydrochloric acid solution of the ketone gives precipitates with phosphotungstic acid, potassium cadmium iodide, potassium bismuth iodide, and potassium dichromate.

1-*Acetylscatole*, $C_6H_4\!\!<\!\!\begin{smallmatrix}CMe\\NAc\end{smallmatrix}\!\!>\!\!CH$, is obtained by the action of acetyl chloride on the magnesium derivative of scatole, a low temperature being maintained with ice. It forms colourless needles, m. p. 68°, and has about the normal molecular weight in freezing benzene. Its constitution is shown by its yielding scatole when treated with alcoholic potassium hydroxide, and by the fact that it gives no precipitate with silver nitrate. In the preparation of 1-acetylscatole, a *substance* crystallising in needles of m. p. 146° is also obtained.

2-Acetylscatole is obtained when the above reaction is effected at the temperature of the water-bath. Its *hydrochloride* has the composition $(C_{11}H_{11}ON)_2,HCl$, and its solution gives precipitates with phosphotungstic acid, potassium bismuth iodide, potassium dichromate, and gold chloride. The *platinichloride* has the composition

$$(C_{11}H_{11}ON,HCl)_2PtCl_4,$$
The action of propionyl chloride on the magnesium derivative of scatole yields both propionylmethylindoles, which can be separated by distillation with steam. 1-*Propionylscatole*, $C_{12}H_{13}ON$, has m. p. 45°. 2-*Propionylscatole*, $C_{12}H_{13}ON$, has m. p. 161°, and when fused with potassium hydroxide yields indole-3-carboxylic acid. 3-*Propionyl-2-methylindole*, $C_{12}H_{13}ON$, is obtained from propionyl chloride and the magnesium derivative of methylketole; it forms colourless crystals, m. p. 194°, and has about half the calculated molecular weight in freezing phenylhydrazine (K for phenylhydrazine is 58·59). Oxidation of the substance with potassium permanganate yields acetyl-*o*-aminobenzoic acid.

3-*Butyryl*-2-*methylindole*, $C_{13}H_{15}ON$, is prepared by the action of butyryl chloride on the magnesium derivative of methylketole; it is a white, crystalline substance, m. p. 157—158°, and tends to become yellow when exposed to the air.

3-Benzoyl-2-methylindole, $C_{16}H_{13}ON$ (from benzoyl chloride and the magnesium derivative of methylketole), forms colourless needles, m. p. 181°. When the reaction is effected at a low temperature, traces of a *substance* of m. p. 81° are produced, which is probably the 1-derivative.

R. V. S.

Condensation of Aldehydes with *N*-Mono-substituted *p*-Diamines. RICHARD SCHLÖGL (*J. pr. Chem.*, 1913, [ii], 88, 251—256).—An account of the preparation of a number of anils by the condensation of acetyl-*p*-phenylenediamine, *p*-amino-oxanilic acid, and *p*-aminophenylglycine with aromatic aldehydes.

The *salicylidene, cinnamylidene* (m. p. 120°), 3:4-*dihydroxybenzylidene, vanillidene*, and *furfurylidene* (m. p. 135°) derivatives of *p*-amino-

phenylglycine are prepared by warming the glycine with an alcoholic solution of the corresponding aldehyde.

The *benzylidene* derivative of *p*-aminophenyloxamic acid is obtained in the form of its *hydrochloride*, $C_{15}H_{12}O_3N_2Cl$, m. p. 180°, by heating an alcoholic suspension of the oxamic acid with benzaldehyde and hydrochloric acid.

The following compounds were prepared in a similar manner: the *hydrochlorides* of the *vanillidene* (m. p. 170°), *cinnamylidene* (m. p. 125°), and *furfurylidene* (m. p. 130°) derivatives of *p*-aminophenyl-oxamic acid, and the *hydrochlorides* of the *benzylidene* (m. p. 165°), *vanillidene* (m. p. 208°), and *cinnamylidene* (m. p. 195°) derivatives of acetyl-*p*-phenylenediamine.

The condensation *product* from acetaldehyde and *p*-aminophenyl-glycine forms a dark brown powder (decomp. 280°), insoluble in the ordinary solvents; attempts to effect a condensation of acetyl-*p*-phenylenediamine and *p*-aminophenylglycine with formaldehyde and acetaldehyde were unsuccessful.

All the derivatives mentioned above are readily resolved by boiling with water or alkali hydroxides into their components, and on account of the presence of the azomethine group, are coloured, those of *p*-aminophenylglycine being red.   F. B.

Hydrazones. LUIGI VECCHIOTTI (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 75—76).—Many nitrohydrazones exist in red and in yellow modifications. The present paper gives a list of these compounds and the forms observed in each instance.   R. V. S.

Extractives of Muscle. XIV. - Carnosine and Carnosine Nitrate. WLADIMIR GULEWITSCH (*Zeitsch. physiol. Chem.*, 1913, **87**, 1—11. Compare A., 1900, i, 516; 1905, i, 726; 1906, i, 627; 1907, i, 264, 436).—The purification of carnosine nitrate and carnosine is described. The nitrate crystallises in large, stellate aggregates of needles, m. p. 219° (decomp.), $[a]_D +23\cdot3°$ in 5% solution. The rotatory power increases slightly on dilution; it falls to about half its value in presence of nitric acid.

Carnosine crystallises in large, colourless needles, which unite to rosettes and cauliflower-like aggregates, m. p. 246—250° (decomp.). It has an insipid taste, and is strongly alkaline. It has $[a]_D +21°$, independently of the concentration. No racemisation takes place in preparing it from the nitrate.   E. F. A.

Preparation of Chloro- and Bromo-substitution Products of Indophenols and Indophenolic Substances or their Leuco-derivatives. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 260328 and 260329).—The action of *p*-nitrosophenol on carbazoles has previously been studied (A., 1906, i, 890; 1911, i, 1025), and halogen derivatives of these compounds have now been prepared.

When 4-dimethylamino-4'-hydroxydiphenylamine (230 parts) dissolved in concentrated hydrochloric acid (1700 parts) is treated at 10—15° with 150 parts of chlorine, it furnishes a *dichloro-4-dimethyl-amino-4'-hydroxydiphenylamine hydrochloride* in quantitative yield

which on oxidation gives rise to the corresponding *indophenol.* *Compounds* obtained by the action of chlorine on an *o*-dichlorobenzene solution of the following substances, and their oxidation products are described : from *p*-nitrosophenol with carbazole and the leuco-compound of the same; from *p*-nitrosophenol with *N*-methyl- or *N*-ethyl-carbazole and their leuco-compounds.
II. describes the preparation of the corresponding bromo-derivatives; in this case the reaction is carried out in *o*-dichlorobenzene solution.

F. M. G. M.

Constitution of Anilopyrine. Lino Metello Zampolli (*Boll. chim. farm.*, 1913, **52**, 502—504).—Polemical. A reply to Comanducci (this vol., i, 903). R. V. S.

Preparation of Red Condensation Products from Indigotin, its Homologues, and Substitution Products. Gesellschaft für Chemische Industrie in Basel (D.R.-P. 260243. Compare this vol., i, 763).—The action of phenylacetyl chloride on indigotin yields the red, crystalline *compounds* I or II, according to the conditions of the experiment :

$$C_6H_4\begin{array}{c}CO\cdot CH_2Ph\\<^{N}_{CO}>\end{array}C:C\begin{array}{c}<^{CO}_{N}>\\CH_2Ph\cdot CO\end{array}C_6H_4 \qquad C_6H_4\begin{array}{c}CO———CPh\\<^{N}_{C}>\end{array}C:C\begin{array}{c}<^{C}_{N}>\\CPh———CO\end{array}C_6H_4$$

(I.) (II.)

Analogous *compounds* prepared from tetrabromoindigotin are also described, which are of a somewhat bluer shade. F. M. G. M.

Benzoylation of Benziminazoles. Ludwig Wolff (*Annalen*, 1913, **399**, 297—309).—The reaction described by Bamberger and Berlé, in which secondary benziminazoles yield dibenzoyl-*o*-phenylene-diamine and a fatty acid by treatment with benzoyl chloride and aqueous sodium hydroxide, is explained by the author's experiments on the benzoylation of secondary or tertiary benziminazoles. He finds that secondary benziminazoles yield a benzoyl derivative. This benzoyl derivative or, in the case of a tertiary compound, the benzimin-azole itself forms an additive compound with benzoic acid, which probably has the constitution $C_6H_4\begin{array}{c}<^{NR\cdot COR'}_{NHBz}\end{array}$, and is decomposed by the alkali, yielding benzoylated *o*-phenylenediamines and a fatty acid.

[With R. Grün and F. Kolasius.]—The benziminazoles are treated with benzoyl chloride (2 or 4 mols.) and 10% sodium hydroxide (4 or 6 mols.). The precipitate is treated with ether, whereby the benzoyl derivative and oily products are dissolved; the residue is separated by chloroform into the acylphenylenediamine and dibenzoyl-*o*-phenylenedi-amine.

Benziminazole yields 1-benzoylbenziminazole (in very small amount), dibenzoyl-*o*-phenylenediamine, and *dibenzoylformyl-o-phenylene-diamine*, $NHBz\cdot C_6H_4\cdot NBz\cdot CHO$, m. p. 155—156°, needles, which is converted into formic acid and dibenzoyl-*o*-phenylenediamine by boiling

with alcohol, hydrochloric acid, or sodium hydroxide, and yields, by heating at 180—200°, carbon monoxide, benzoic acid, dibenzoyl-o-phenylenediamine, and 1-benzoylbenziminazole.

2-Methylbenziminazole yields 1-*benzoyl-2-methylbenziminazole*

$$C_6H_4 \left\langle \begin{matrix} NBz \\ N \end{matrix} \right\rangle CMe,$$
m. p. 86°, long needles, dibenzoyl-o-phenylenediamine, and *dibenzoyl-acetyl-o-phenylenediamine*, $NHBz \cdot C_6H_4 \cdot NBzAc$, m. p. 154°, prisms, which is converted into acetic acid and dibenzoyl-o-phenylenediamine by alcoholic hydrochloric acid or sodium hydroxide. 2-Ethylbenz-iminazole yields similar products; 1-*benzoyl-2-ethylbenziminazole*, colourless plates, has m. p. 82°, whilst *dibenzoylpropionyl-o-phenylene-diamine*, m. p. 124°, yields propionic acid and dibenzoyl-o-phenylene-diamine by treatment with sodium hydroxide or hydrochloric acid.

1-*Phenyl-2-ethylbenziminazole*, $C_6H_4 \left\langle \begin{matrix} NPh \\ N \end{matrix} \right\rangle CEt$, m. p. 45°, colour-less plates (*hydrochloride*, $C_{15}H_{14}N_2, HCl, H_2O$, prisms), is prepared by warming o-aminodiphenylamine with propionic anhydride and treating the resulting o-*propionylaminodiphenylamine*, $C_{15}H_{16}ON_2$, m. p. 144°, needles, with 10% hydrochloric acid; by treating the solution with sodium carbonate the benziminazole is precipitated. By the action of benzoyl chloride and 10% sodium hydroxide at 50°, it yields an oil and *propionyl-o-benzoylaminodiphenylamine*, $NHBz \cdot C_6H_4 \cdot NPh \cdot COEt$, m. p. 157°, plates, which is converted by warm alcoholic potassium hydroxide into propionic acid and o-benzoylaminodiphenylamine.

By treatment with benzoyl chloride and 10% sodium hydroxide at 50—60°, 1-phenyl-2-methylbenziminazole yields *acetyl-o-benzoylamino-diphenylamine*, $NHBz \cdot C_6H_4 \cdot NPhAc$, m. p. 122° (which is decomposed into acetic acid and o-benzoylaminodiphenylamine by hot alcoholic sodium hydroxide), a *substance*, $C_{28}H_{20}O_3N_2$, m. p. 165°, needles, and an oil which yields the substance, m. p. 165°, by further benzoylation.

The substance, m. p. 165°, is possibly $C_6H_4 \left\langle \begin{matrix} NPh \\ N \end{matrix} \right\rangle C \cdot CH : OPh \cdot OBz$,

since it does not develop a coloration with ferric chloride, and is con-verted in hot alcoholic solution, by elimination of a benzoyl group, into 1-*phenyl-2-phenacylbenziminazole*,

$$C_6H_4 \left\langle \begin{matrix} NPh \\ N \end{matrix} \right\rangle C \cdot CH_2 \cdot COPh,$$
m. p. 119°, large plates or prisms. The latter develops a green coloration with ferric chloride, yields the substance, m. p. 165°, by benzoylation, and forms a *hydrochloride*, m. p. 240—245° (decomp.), *semicarbazone*, m. p. 202°, colourless prisms, and *phenylhydrazone*, m. p. 164°, colourless prisms.   C. S.

Pyrimidines. LXIII. A New Method of Synthesising Uramils and Thiouramils. TREAT B. JOHNSON and NORMAN A. SHEPHARD (*J. Amer. Chem. Soc.*, 1913, **35**, 994—1007).—Ethyl phthalimidomalonate reacts with thiocarbamide in warm alcoholic solution containing sodium ethoxide, the product being 2-thiouramil, $CS \left\langle \begin{matrix} NH \cdot CO \\ NH \cdot CO \end{matrix} \right\rangle CH \cdot NH_2$, which is probably formed by the hydrolysis of a previous condensation product; thiouramil when warmed with

sodium hydroxide solution undergoes hydrolysis, giving a substance, possibly *aminothiomalonuric acid*, $NH_2 \cdot CS \cdot NH \cdot CO \cdot CH(NH_2) \cdot CO_2H$.

Ethyl β-phthaliminoethylmalonate also condenses with thiocarbamide in the presence of sodium ethoxide in hot alcoholic solution, forming 2-*thio*-5-β-*phthaliminoethylbarbituric acid*,
$$CS \overset{NH \cdot CO}{\underset{NH \cdot CO}{<}} > CH \cdot CH_2 \cdot CH_2 \cdot N \overset{CO}{\underset{CO}{<}} > C_6H_4,$$
prisms, decomp. 265—270° (*sodium* salt, bright yellow), which on hydrolysis yields 2-*thio*-5-β-*aminoethylbarbituric acid*,

$$CS \overset{NH \cdot CO}{\underset{NH \cdot CO}{<}} > CH \cdot CH_2 \cdot CH_2 \cdot NH_2,$$
prisms, decomp. 298—300°, together with phthalic acid. If the condensation is effected with carbamide in place of thiocarbamide, phthalimide and 2 : 4 : 6-triketo-5-β-hydroxyethylpyrimidine (5-hydroxy-ethylbarbituric acid), $CO \overset{NH \cdot CO}{\underset{NH \cdot CO}{<}} > CH \cdot CH_2 \cdot CH_2 \cdot OH$, a pale yellow powder which did not melt below 300°, were obtained.

Ethyl anilinomalonate also readily reacts with thiocarbamide in the presence of sodium ethoxide, giving rise to 2-*thio*-7-*phenyluramil*, $CS \overset{NH \cdot CO}{\underset{NH \cdot CO}{<}} > CH \cdot NHPh$, orange-coloured prisms, decomp. 250—260°. With carbamide, however, a new type of compound was obtained, namely, *anilinomalonuric acid*, $NH_2 \cdot CO \cdot NH \cdot CO \cdot CH(NHPh) \cdot CO_2H$, prismatic crystals, which do not melt below 300°. This substance when digested with acetic acid undergoes dehydration to γ-*phenyluramil*, $CO \overset{NH \cdot CO}{\underset{NH \cdot CO}{<}} > CH \cdot NHPh$, an insoluble, crystalline powder. Allyl-thiocarbamide resembles thiocarbamide in behaving normally with ethyl anilinomalonate, and gives 2-*thio*-7-*phenyl*-1-*allyluramil*,

$$CO \overset{CH(NHPh) \cdot CO}{\underset{NH \underline{\hspace{1.5em}} CS}{<}} > N \cdot CH_2 \cdot CH : CH_2,$$
an insoluble powder, m. p. 185—187° (decomp.); *sodium* salt, brown powder.

When ethyl anilinomalonate is added to an alcoholic solution of sodium ethoxide, it gives a sodium derivative, which on the further addition of *p*-nitrobenzyl chloride reacts with the formation of two substances, one of which is insoluble in ether; the insoluble substance, needles or prisms, m. p. 180—182°, is probably 2-*p*-*nitrobenzylindoxyl*, $C_6H_4 \overset{CO}{\underset{NH}{<}} > CH \cdot CH_2 \cdot C_6H_4 \cdot NO_2$, whilst the soluble substance is *ethyl p*-*nitrobenzylanilinomalonate*, $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot C(NHPh)(CO_2Et)_2$, an oil, which on hydrolysis yields p-*nitrobenzylanilinomalonic acid*, prisms or leaflets, m. p. 205—210° (decomp.).　　　　　D. F. T.
Pyrimidines. LXIV. Synthesis of 4-Methyl-5-ethyl-cytosine. TREAT B. JOHNSON and GEORGE C. BAILEY (*J. Amer. Chem. Soc.*, 1913, **35**, 1007—1014).—The paper commences with a summary of the alkyl derivatives of cytosine, $NH \overset{CO \underline{\hspace{1em}} N}{\underset{CH : CH}{<}} > C \cdot NH_2$, which have been prepared in the same laboratory.

When warmed together in sodium ethoxide solution, ethyl ethyl-acetoacetate and thiocarbamide react normally, giving the colourless

sodium salt of 2-*thio-4-methyl-5-ethyl*-1 : 2 : 3 : 6-*tetrahydro-6-pyrimidone*, $CS \diagdown_{NH \cdot CMe}^{NH-CO} \diagup OEt$, the free substance forming colourless prisms, m. p. 212°; alkylation is effected when the alcoholic solution of the sodium salt is treated with an alkyl haloid, for example, benzyl chloride gives rise to 2-*benzylthiol-4-methyl-5-ethyl*-1 : 6-*dihydro-6-pyrimidone*, blocks, m. p. 160°, whilst ethyl bromide yields 2-*ethylthiol-4-methyl-5-ethyl*-1 : 6-*dihydro-6-pyrimidone*, colourless crystals, m. p. 138°. The last-named derivative is converted by a molecular proportion of phosphorus pentachloride at 100° into 6-*chloro-2-ethylthiol-4-methyl-5-ethylpyrimidine*, b. p. 177—180°/21—23 mm., which is stable in contact with water, but is decomposed by warm alcohol, and also reacts with strong alcoholic ammonia at 140—150°, yielding 6-*amino-2-ethylthiol-4-methyl-5-ethylpyrimidine*, $CEt \diagdown_{CMe---N}^{C(NH_2):N} \diagup C \cdot SEt$, stout blocks, m. p. 89—91°. Both the benzylthiol- and the ethylthiol-substituted pyrimidines described above are converted by hydrolysis with acids into 4-methyl-5-ethyluracil, $CO \diagdown_{NH \cdot CMe}^{NH-CO} \diagup CEt$, the yield being quantitative when the ethylthiol compound is heated with a boiling aqueous solution of chloroacetic acid. The same uracil derivative is obtained in the action of chloroacetic acid on the parent substance, 2-thio-4-methyl-5-ethyl-1 : 2 : 3 : 6-tetrahydro-6-pyrimidone.

2-Ethylthiol-4-methyl-5-ethyl-1 : 6-dihydro-6-pyrimidone, when heated with aniline at 100° and with alcoholic ammonia at 150—160°, eliminates the thiol group with formation respectively of 2-*anilino-4-methyl-5-ethyl* 1 : 6-*dihydro-6-pyrimidone*, $CNHPh \diagdown_{N-CMe}^{NH \cdot CO} \diagup CEt$, m. p. 195°, and 2-*amino-4-methyl-5-ethyl*-1 : 6-*dihydro-6-pyrimidone*, prisms, m. p. 281—282° (decomp.); *hydrobromide*, needles, m. p. 160—175°, according to rate of heating; *hydrochloride*, m. p. 115°, crystallises with one H_2O.

Boiling hydrochloric acid converts 6-amino-2-ethylthiol-4-methyl-5-ethylpyrimidine into 6-*amino-4-methyl-5-ethyl-2* : 3-*dihydro-2-pyrimidone* (*methylethylcytosine*), $CO \diagdown_{NH-CMe}^{N:C(NH_2)} \diagup CEt$, blocks or rectangular prisms, m. p. 295° (decomp.), which is obtained first as the *hydrochloride*, a colourless powder, decomp. at 125°; the *hydrobromide*, blocks, decomp. near 260°; the *picrate*, needles, *mercurichloride*, *phosphotungstate*, and *potassio-bismutho-iodide* were also prepared.

The sodium salt of 2-thio-4-methyluracil reacts with diphenylmethyl bromide in alcoholic solution with formation of 2-*diphenylmethylthiol-4-methyl*-1 : 6-*dihydro-6-pyrimidone*, $CH \diagdown_{CMe-N}^{CO \cdot NH} \diagup C \cdot S \cdot CHPh_2$, m. p. 214°, in small yield.   D. F. T.

Hydantoins. XXIII. Synthesis of 2-Thiohydantoins from Acyl Derivatives of α-Amino-acids. TREAT B. JOHNSON and WALTER M. SCOTT (*J. Amer. Chem. Soc.*, 1913, **35**, 1130—1136. Compare Johnson, A., 1912, i, 390; Johnson and Nicolet, A., 1912, i, 53, etc.). —The reaction between ammonium thiocyanate and an acyl derivative

of an α-amino-acid in acetic anhydride solution appears to be a general one, but the only β-amino-acid examined merely underwent acetylation without any subsequent reaction with the thiocyanate.

o-Carboxybenzoylaminoacetic acid, $CO_2H \cdot C_6H_4 \cdot CO \cdot NH \cdot CH_2 \cdot CO_2H$, obtained by the hydrolysis of ethyl phthalylaminoacetate, when heated by steam for twenty minutes with a $1\frac{1}{4}$ molecular proportion of ammonium thiocyanate in 5—7 parts by weight of acetic anhydride, gave 2-thiohydantoin, m. p. 225—227°, phthalylaminoacetic acid, m. p. 192—193°, and phthalic acid. This was the only case in which the acylhydantoin could not be isolated, although the results indicate that it must have been an intermediate product of the reaction.

p-Methoxyhippuric acid with ammonium thiocyanate in acetic anhydride solution gave 3-p-*methoxybenzoyl-2-thiohydantoin*,

$$\begin{array}{c} CO \cdot CH_2 \\ NH - CS \end{array}\!\!\!\!> N \cdot CO \cdot C_6H_4 \cdot OMe,$$
pale yellow prisms, m. p. 166°, whilst m-nitrohippuric acid yielded 3-m-*nitrobenzoyl-2-thiohydantoin*, m. p. 198—199°.

Benzenesulphonylaminoacetic acid in an analogous manner gave rise to 3-*benzenesulphonyl-2-thiohydantoin*, $\begin{array}{c} CO \cdot CH_2 \\ NH - CS \end{array}\!\!\!\!> N \cdot SO_2Ph$, colourless needles, m. p. 210—211° (decomp.).

The product obtained by a similar process with carbethoxyamino-acetic acid was ethyl 2-thiohydantoin-3-carboxylate, $\begin{array}{c} CO \cdot CH_2 \\ NH - CS \end{array}\!\!\!\!> N \cdot CO_2Et$, plates, m. p. 168°.

The application of dibromophenylalanine and benzoylalanine to this reaction resulted in the formation of 2-*thio-3-acetyl-4-dibromobenzyl-hydantoin*, $\begin{array}{c} NH - CO \\ CS \cdot NAc \end{array}\!\!\!\!> CH \cdot CH_2 \cdot C_6H_3Br_2$, plates, m. p. 171° (which on hydrolysis gave 2-*thio-4-dibromobenzylhydantoin*, colourless needles, m. p. 243°), and 2-*thio-3-benzoyl-4-methylhydantoin*, m. p. 158° respectively.

Anthranilic acid under similar treatment merely became converted into acetylanthranilic acid. D. F. T.

Hydantoins. XXIV. Action of Ammonium Thiocyanate on Lactone Anhydrides of Acylamino-acids. TREAT B. JOHNSON and WALTER M. SCOTT (*J. Amer. Chem. Soc.*, 1913, **35**, 1136—1143. Compare preceding abstract).—The provisional interpretation of the mechanism of the reaction between thiocyanic acid (as ammonium thiocyanate) and the acyl derivative of a monobasic α-amino-acid in acetic anhydride (Johnson and Nicolet, A., 1912, i, 53) is withdrawn in favour of the scheme :

$$RCO \cdot NH \cdot CH_2 \cdot CO_2H \xrightarrow{Ac_2O} \begin{array}{c} CR:N \\ O \cdot CO \end{array}\!\!\!\!> CH_2 \xrightarrow{HSCN}$$

$$RCO \cdot NH \cdot CH_2 \cdot CO \cdot NCS \rightarrow \begin{array}{c} NH - CS \\ CO \cdot CH_2 \end{array}\!\!\!\!> N \cdot COR.$$
Among the reasons for this new view are the facts that acetic anhydride is the only solvent which has been found suitable, and that

the first ring formation is a normal change when acylamino-acids are heated with acetic anhydride; it has already been shown that the lactonoid anhydrides undergo scission by hydrogen chloride, producing acid chlorides in a manner analogous to the second change above (compare Mohr and Kohler, A., 1910, i, 116).

In agreement with the above explanation it is found that with hippuric acid or benzoylalanine, acylthiohydantoins are not produced in acetic acid with ammonium thiocyanate, although if the amino-acid is previously heated with acetic anhydride the resulting lactonoid anhydride readily gives rise to the corresponding acylthiohydantoin in acetic acid solution.

Acetylphenylglycine and ethyl hippurate are not affected by ammonium thiocyanate in acetic anhydride, thus indicating the necessity for the presence of unsubstituted hydrogen at the nitrogen atom and at the carboxyl group. With benzamide, no evidence of the formation of benzoylthiocarbamide was obtained; this is a further reason for discarding the old theory of formation in favour of that now suggested.

Contrary to expectation, the lactim of a-benzoylamino-β-phenyl-acrylic acid failed to react with thiocyanic acid in acetic anhydride, whilst the free acid under such treatment only yielded the lactim.

<div align="right">D. F. T.</div>

Rings Containing a Triple Linking. II. Optimum Number of Atoms in the Ring. PAUL RUGGLI (*Annalen*, 1913, **399**, 174—182).—The following substances of the type

$$O_6H_4 \underset{\hspace{2.5em}C{:}O}{\overset{NH{\cdot}CO{\cdot}[CH_2]x{\cdot}CO{\cdot}NH}{<\hspace{4em}>}} O_6H_4$$
have been prepared from oo'-diaminotolan and the requisite acid chloride in the same manner as *cyclo*succinyldiaminotolan (A., 1912, i, 914); *cyclo*glutaryldiaminotolan, $C_{19}H_{16}O_2N_2$, m. p. 300—302° (decomp.), colourless crystals, *cyclo*adipyldiaminotolan, $C_{20}H_{18}O_2N_2$, m. p. 252° (decomp.), colourless needles, *cyclo*pimelyldiaminotolan, $C_{21}H_{20}O_2N_2$, m. p. 248° (decomp.), colourless needles, *cyclo*suberyldiaminotolan, $C_{22}H_{22}O_2N_2$, m. p. 223—224·5°, colourless needles, and *cyclo*lepargyldiaminotolan, $C_{23}H_{24}O_2N_2$, m. p. about 240° (decomp.), colourless needles.

A comparison of the yields obtained under similar conditions shows *cyclo*adipyldiaminotolan, containing a 14-membered ring, is obtained in the largest amount, namely, 50% of that theoretically possible. Cyclic compounds containing a nuclear triple linking have not been obtained from pp'-diaminotolan or from *trans*-oo'-diaminostilbene.

pp'-Dinitrotolan, which is best prepared by boiling pp'-dinitrostilbene dibromide with pyridine, is readily reduced to pp'-diaminotolan by stannous chloride and hydrochloric and acetic acids in the cold.

<div align="right">C. S.</div>

Benzylcreatinine. WILLY HENNIG (*Arch. Pharm.*, 1913, **251**, 396—400).—Creatinine and benzyl chloride at 136—140° yield *benzylcreatinine hydrochloride*, $C_{11}H_{13}ON_3,HCl$, faintly yellow needles, blackening at about 230° (*aurichloride*, $C_{11}H_{13}ON_3,HAuCl_4$, m. p. 158°, yellow needles; *platinichloride*, $2C_{11}H_{13}ON_3,H_2PtCl_6$, m. p.

177—178°, red crystals), from an aqueous solution of which lead hydroxide liberates *benzylcreatinine*, m. p. 225°, faintly yellow crystals. The action, therefore, of benzyl chloride, similarly to that of alkyl iodides, on creatinine is substitutive, not additive. The oxidation of benzylcreatinine hydrochloride by alkaline 5% potassium permanganate at 30—40° yields *benzylmethylguanidine* (*platinichloride*,

$$2C_9H_{10}N_3,H_2PtCl_6,$$
m. p. 148°; *aurichloride*, m. p. 190—191°). C. S.

Addition of Phenylazoimide to Quinones. II. LUDWIG WOLFF (*Annalen*, 1913, **399**, 274—297).—[With R. HERCHER.]— a-Naphthaquinone and phenylazoimide react to form a dihydrotriazole derivative, $C_6H_4\big<^{CO\cdot CH\cdot NPh}_{CO\cdot CH-\!-N}\big>N$, which cannot be isolated, but decomposes, yielding mainly 1-*phenylazoimino-a-naphthaquinone* [4 : 9-*diketo-1-phenyldihydro-ββ-naphtha*iso*triazole*],

$$C_6H_4\big<^{CO\cdot C\cdot NPh}_{CO\cdot C-\!-N}\big>N,$$
m. p. 241°, pale yellow leaflets, at 60—65°, and mainly *indandione-2-aldehydeanil*, $C_6H_4\big<^{CO}_{CO}\big>CH\cdot CH:NPh$, m. p. 191°, yellow prisms or plates, on the water-bath.

Phenylazoiminonaphthaquinone forms an *oxime*,

$$C_6H_4\big<^{C(:NOH)\cdot C\cdot NPh}_{CO-\!-\!-C-\!-N}\big>N,$$
m. p. 232° (decomp.), almost colourless needles, which probably contains the oximino-group in the position shown, because, unlike the parent substance, it is not ruptured by sodium hydroxide. Phenylazoiminonaphthaquinone itself is decomposed by boiling aqueous alcoholic sodium hydroxide, yielding after acidification 4-o-*carboxybenzoyl-1-phenyl-1* : 2 : 3-*triazole*, $CO_2H\cdot C_6H_4\cdot CO\cdot C\big<^{CH\cdot NPh}_{N\!=\!N}$, m. p. 177—178° (anhydrous), colourless needles containing $\frac{1}{2}H_2O$. This acid is decomposed into phthalic acid, aniline, and probably acetic acid by aqueous sodium hydroxide at 150°, and in alkaline solution yields with hydroxylamine hydrochloride and subsequent acidification the oxime of the acid, which, however, slowly changes to an *anhydride*, $C_{16}H_{10}O_2N_4$, m. p. 220°, colourless needles, insoluble in sodium carbonate.

Indandione-2-aldehydeanil does not develop a coloration with ferric chloride, forms a *sodium* salt, red needles, with alcoholic sodium hydroxide, and is decomposed by boiling aqueous sodium hydroxide, yielding aniline and indandione-2-aldehyde in the form of its *sodium* salt, $C_{10}H_5O_3Na$, yellow needles. Indandione-2-aldehyde crystallises in colourless needles containing H_2O, m. p. 125° (decomp.) (141°, anhydrous), develops a red coloration with ferric chloride, and behaves like a strong, monobasic acid, decomposing carbonates; the *calcium* salt crystallises in sparingly soluble prisms. The aldehyde or its salt in cold aqueous solution reacts with aniline, phenylhydrazine, hydroxylamine, and semicarbazide to form respectively the preceding anil;

phenylhydrazone, $C_{16}H_{12}O_2N_2$, m. p. 220° (decomp.), yellow prisms; *oxime*, $C_{10}H_7O_8N,H_2O$, m. p. 205° (decomp.), orange needles, and *semicarbazone*, $C_{11}H_9O_2N_3$, m. p. 233° (decomp.), yellow needles.

By boiling with 20% hydrochloric acid, the sodium salt of indandione-2-aldehyde is decomposed into formic acid, bindone, indandione, and a *substance*, $C_{19}H_{10}O_4$, m. p. about 308° (decomp.), red needles, which is probably $C_6H_4\!\!<\!\!^{CO}_{CO}\!\!>\!\!C\!:\!CH\cdot CH\!\!<\!\!^{CO}_{CO}\!\!>\!\!C_6H_4$, since it can also be produced by heating equal molecular quantities of indandione and its aldehyde at 120° or in boiling alcohol, and can be converted into these two substances by aqueous sodium hydroxide.

[With M. Körbs.]—Three of the four substances produced by the interaction of phenylazoimide and *p*-benzoquinone have been previously described (A., 1912, i, 1034). The fourth is a *substance*, $C_{18}H_{14}O_2N_4$, m. p. 157—160° (decomp.), yellow leaflets, the constitution of which has not yet been entirely established. The author recommends the formula $N\!\!<\!\!^{NPh\cdot CH\cdot CO}_{N——CH\cdot CO}\!\!>\!\!CH\cdot CH\!:\!NPh$, according to which the substance is the *anil* of *phenylazoiminopentionaldehyde*. The absence of an imino-group and the presence of a triazole ring are respectively proved by the inactivity of the substance towards phenylcarbimide and by the oxidation of the sodium salt of phenylazoiminopentionaldehyde to 1-phenyl-1 : 2 : 3-triazole-4-carboxylic acid and 1-phenyl-1 : 2 : 3-triazole-5-carboxylic acid by 2% sodium hypobromite at 0°. The presence of the C_6-ring in the anil has not been proved, but is rendered very probable by the great similarity of the substance to the anil of indandione-2-aldehyde in its method of formation and behaviour.

By treatment with 10% potassium hydroxide and a little alcohol at 30—40°, the anil is converted into the *potassium* salt of phenylazo-iminopentionaldehyde, $C_{12}H_8O_2N_3K,\frac{1}{2}H_2O$, colourless prisms which become yellow in light; the *sodium* salt, $C_{12}H_8O_2N_3Na,H_2O$, crystallises in colourless leaflets, and forms a *semicarbazone*, $C_{18}H_{11}O_2N_6Na,2\frac{1}{2}H_2O$, faintly yellow needles. These salts and also the semicarbazone are extensively decomposed by treatment with even weak acids.

By fusion or by boiling with xylene or aniline, the anil of phenyl-azoiminopentionaldehyde loses nitrogen and yields a *substance*,
$$C_{18}H_{14}O_2N_2,$$
m. p. 185°, colourless needles, which behaves very similarly to the original anil and is, therefore, probably the *anil* of *phenyliminopention-aldehyde*, $NPh\!\!<\!\!^{CH\cdot CO}_{CH\cdot CO}\!\!>\!\!CH\cdot CH\!:\!NPh$. It does not react with phenylcarbimide or with ferric chloride, and is converted by boiling sodium hydroxide into aniline and the *sodium* salt of *phenyliminopen-tionaldehyde*, $C_{12}H_8O_2NNa,2H_2O$, white needles.

By keeping phenylazoiminopentionaldehydeanil in glacial acetic acid until the evolution of nitrogen ceases, a *substance*, $C_{18}H_{16}O_2N_2$, m. p. about 186° (decomp.), yellow, crystalline powder, is obtained, which is converted by hot aqueous alcoholic sodium hydroxide into aniline and the *sodium* salt of an *acid*, $C_{12}H_9O_2N$, m. p. 234°, colourless needles.

3 : 6-Diamino-1 : 2 : 4 : 5-tetrazine. I. Giacomo Ponzio and G. Gastaldi (*Gazzetta*, 1913, 43, ii, 129—137).—3 : 6-*Diamino*-1 : 2 : 4 : 5-*tetrazine*, $H_2N \cdot C \underset{N \cdot N}{\overset{N : N}{<}} > C \cdot NH_2, H_2O$, begins to crystallise in a few days when a mixture of concentrated solutions of aminoguanidine hydrochloride and potassium hydroxide are kept over concentrated sulphuric acid and solid potassium hydroxide. The substance crystallises in reddish-violet, monoclinic needles, which have a metallic lustre, or in amethyst-coloured laminæ. On heating, it loses water at about 100°, and melts at 204—205° (decomp.), or 206—207° (decomp.), according to the mode of heating; cyanogen and ammonia are evolved. When boiled with sulphuric acid, it yields nitrogen, carbon dioxide, and hydrazine sulphate, whilst heating with potassium hydroxide furnishes ammonia. It is readily reduced to 3 : 6-diamino-1 : 2-dihydro-1 : 2 : 4 : 5-tetrazine. 3 : 6-*Diamino*-1 : 2 : 4 : 5 - *tetrazine hydrochloride*, $C_2H_4N_6$,HCl, forms orange-yellow laminæ, and decomposes about 200°; the *nitrate*, $C_2H_4N_6$,HNO_3,$\frac{1}{2}H_2O$, crystallises similarly, and has m. p. 180—182° (decomp.). The *oxalate*,

$$(C_2H_4N_6)_2, H_2C_2O_4,$$

forms orange prisms, which decompose at about 205°. R. V. S.

Action of Dichlorocarbamide on Amines. Synthesis of 3-Hydroxy - 6- keto-3-phenyl - 2 : 4 - dibenzyl - 1 : 2 : 4 : 5 - tetrazine. Rasik Lal Datta and Satyaranjan Das Gupta (*J. Amer. Chem. Soc.*, 1913, 35, 1183—1185).—By modifying the conditions for the interaction of dichlorocarbamide and amines, which has already been shown to yield chloroamines (Datta, T., 1912, 101, 166 ; A., 1912, i, 962), it is found that other substances can be isolated from the reaction product.

When a cooled saturated solution of dichlorocarbamide is added to a cooled fairly strong aqueous solution of allylamine, a small amount of *p*-urazine separates.

On applying benzylamine in a similar reaction the crystalline product which deposits is a mixture of *p*-urazine with 3-hydroxy-6-keto-3-phenyl-2 : 4-dibenzyl-1 : 2 : 4 : 5-tetrazine. The latter, which can be separated by its greater solubility in acetone, probably owes its formation to the primary formation of benzylchloroamine, two molecules of which then condense with one of free benzylamine and one of dichlorocarbamide. D. F. T.

The Solubility of Uric Acid in Acetic Acid. Francesco Rossi (*Biochem. Zeitsch.*, 1913, 54, 297—304).—The solubility of uric acid in varying strengths of acetic acid from $N/100$ to $16N$ (glacial acetic acid) and at temperatures varying from 15° to 100° was determined. Between the concentrations $N/100$ and $N/10$ the solubility is less than in water ; above the latter concentration it increases and reaches a maximum somewhere about the concentration of $4N$ to $6N$; in higher concentrations, the solubility again declines, especially at higher temperatures. The latter phenomenon is probably due to an action of acetic acid on the uric acid. S. B. S.

Some New Derivatives of Azoxybenzene. BRUNO VALORI (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 125—133. Compare Angeli and Valori, A., 1913, i, 533).—When Zinin's *p*-nitroazoxybenzene is treated with nitric acid (D 1·48) on the water-bath, 2 : 4-*dinitroazoxybenzene*, $C_6H_3(NO_2)_2 \cdot N{:}NPh{:}O$, is produced; it forms pale yellow needles, m. p. 141°.

When Zinin's *p*-nitroazoxybenzene is heated with bromine in presence of iron for one hour at 130° in a sealed tube, 2-*bromo*-4-*nitroazoxybenzene*, $NO_2 \cdot C_6H_3Br \cdot N{:}NPh{:}O$, is formed; it is a yellow powder, m. p. 127°.

o-Nitroazoxybenzene is acted on by nitric acid (D 1·48) on the water-bath, yielding 2 : 6-*dinitroazoxybenzene*, $C_{12}H_8O_5N_4$, which forms colourless scales, m. p. 172°.

If *o*-*p*-bromoazoxybenzene is heated with bromine in presence of iron in a sealed tube for two hours at 115—120°, 2 : 4-*dibromoazoxybenzene*, $C_{12}H_8ON_2Br_2$, is formed; it crystallises in yellow needles, m. p. 97°. In its preparation a small quantity of 2 : 4 : 6-tribromoaniline is produced. Reduction of 2 : 4-dibromoazoxybenzene with tin and hydrochloric acid yields aniline and 2 : 4-dibromoaniline. 2 : 4-Dibromoazoxybenzene yields 2 : 4-*dibromoazobenzene*, $C_{12}H_8N_2Br_2$, when treated with concentrated sulphuric acid, or when reduced with aluminium amalgam and subsequently oxidised with yellow mercury oxide. 2 : 4-Dibromoazobenzene forms orange-red prisms, m. p. 96°. It regenerates the azoxy-compound when treated with hydrogen peroxide in glacial acetic acid solution. 2 : 4 : 4'-*Tribromoazobenzene*,
$$C_{12}H_7N_2Br_3,$$
can be obtained by warming dibromoazobenzene with bromine and iron for a few minutes on the water-bath; it is a pale red substance, m. p. 146°. On oxidation with hydrogen peroxide in glacial acetic acid solution, this compound yields the corresponding 2 : 4 : 4'-*tribromoazoxybenzene*, which on reduction with aluminium amalgam and subsequent oxidation with yellow mercury oxide yields the tribromoazo-compound again. 2 : 4 : 4'-Tribromoazoxybenzene, $C_{12}H_7ON_2Br_3$, crystallises in yellow needles, m. p. 154°.

When 4-bromo-2-nitroazoxybenzene (m. p. 99°) is heated on the water-bath with nitric acid (D 1·50) two products are obtained: (1) 4-*bromo*-2 : 6-*dinitroazoxybenzene*, which forms very pale yellow needles, m. p. 163°, and on treatment with concentrated sulphuric acid yields the isomeric *hydroxyazo*-compound,

$$C_6H_2Br(NO_2)_2 \cdot N{:}N \cdot C_6H_4 \cdot OH$$
(m. p. 224°); (2) 4-*bromo*-2 : 6 : 3'-*trinitroazoxybenzene*,

$$C_6H_2Br(NO_2)_2 \cdot N{:}NO \cdot C_6H_4 \cdot NO_2,$$

which is a yellowish-green, crystalline powder, m. p. 209° (decomp.). The latter compound is exclusively formed if stronger acid (D 1·52) is used in the reaction.   R. V. S.

Phthaleïns. II. Some Nitrogenous Derivatives of Phenolphthaleïn and the Constitution of its Salts. BERNARDO ODDO (*Gazzetta*, 1913, **43**, ii, 175—190. Compare Oddo and Vassallo, A., 1912, i, 792).—*Bis*-p-*tolueneazophenolphthaleïn* (formula overleaf) is obtained when a diazotised solution of *p*-toluidine (1 mol.) is poured

into a cold solution of phenolphthalein ($\frac{1}{2}$ mol.) in potassium hydroxide (3 mols.). It is an orange-yellow, crystalline substance, m. p. 249—253°. When the mother-liquor is acidified, a bright red substance, m. p. 207—210°, is precipitated; the *acetyl* derivative of this compound forms pale yellow scales, m. p. 148—150°. The *diacetyl* derivative of bis-*p*-tolueneazophenolphthalein, $C_{38}H_{30}O_6N_4$, has m. p. 125—131°.

$$CO<\overset{C_6H_4}{\underset{O}{}}>C<\overset{C_6H_3(OH)\cdot N\colon N<\text{—}>Me}{\underset{C_6H_3(OH)\cdot N\colon N<\text{—}>Me}{}}$$

Bis-o-nitrobenzeneazophenolphthalein, $C_{32}H_{20}O_8N_6$, is an orange-yellow substance, m. p. 277°. Its *diacetyl* derivative has m. p. 124—129°. In the preparation of bis-*o*-nitrobenzeneazophenolphthalein, a *substance* of similar appearance but different solubility is formed; its *acetyl* derivative has m. p. 169°.

When bis-*p*-tolueneazophenolphthalein is heated to 110° with phenylhydrazine, a reaction occurs, which is accompanied by rise of temperature and yields diaminophenolphthalein,

$$CO<\overset{C_6H_4}{\underset{O}{}}>C\colon[C_6H_3(NH_2)\cdot OH]_2,$$
which forms pale coffee-coloured crystals, m. p. 245° (decomp.). The substance dissolves in alkalis, alkali carbonates and ammonia, giving a Prussian-blue coloration which disappears on acidification. The substance gives the same coloration with aqueous solutions of pyridine, but not with alcoholic solutions. Diaminophenolphthalein can also be obtained by reduction of dinitrophenolphthalein with stannous chloride (compare Errera and Berté, A., 1896, i, 564; Gattermann and Bamberg, A., 1899, i, 514).

Dinitrophenolphthalein yields a *monoacetyl* derivative, $C_{24}H_{16}O_{10}N_2$, which has m. p. 94—100°, and occurs in a white and in a yellow form.

R. V. S.

Mechanism of Formation and Scission of the Hydroxyazo-compounds. G. CHARRIER and G. FERRERI (*Gazzetta*, 1913, 43, ii, 148—162. Compare this vol., i, 535).—When an ethereal solution of nitric acid (prepared by adding about 20% of nitric acid [D 1·48] to ether cooled in ice) is added to an ethereal solution of 1-benzeneazo-2-naphthyl methyl ether, the *nitrate* of the ether, $C_{17}H_{14}ON_2,2HNO_3$, separates in red, silky needles, m. p. 67° (decomposing with evolution of gas at 69—70°). The salt has about the normal molecular weight in boiling chloroform. It is hydrolysed by water. The salt readily decomposes into benzenediazonium nitrate and 1-nitro-2-naphthyl methyl ether.

The *nitrate* of 1-benzeneazo-2-naphthyl ethyl ether,

$$C_{18}H_{16}ON_2,2HNO_3,$$
forms quadrangular tablets, which are green by reflected and red by transmitted light, and have m. p. 80—81° (decomp.). It readily decomposes in an analogous manner to the methyl ether nitrate.

When 1-nitro-2-naphthyl ethyl ether is warmed with nitric acid

(D 1·40), it is converted quantitatively into 1 : 6-dinitro-2-naphthyl ethyl ether.

A dark red, crystalline crust, consisting probably of 1-benzeneazo-2-naphthol nitrate, is obtained after mixing ethereal nitric acid with an ethereal solution of 1-benzeneazo-2-naphthol. The substance is very unstable.

$$C_{10}H_6 \begin{cases} N{:}NHPh{\cdot}ONO_2 \\ ONO_2 \\ O{\Leftarrow}H \\ R \end{cases}$$
The probable structure of these salts is indicated by the annexed formula, and their mode of decomposition mentioned above suggests an analogous mechanism of formation and scission of the hydroxyazo-compounds.

R. V. S.

Etherification of *o*-Hydroxyazo-compounds. III. G. CHARRIER and G. FERRERI (*Gazzetta*, 1913, 43, ii, 211—227. Compare A., 1912, i, 812; this vol., i, 535, and preceding abstract).—In this paper further nitrates of ethers of arylazo-β-naphthols are described. Their chemical and physical properties resemble those of the members already described (*loc. cit.*).

1-*o*-*Tolueneazo-2-naphthyl methyl ether nitrate*, $C_{18}H_{16}ON_2,2HNO_3$, forms cantharides-green, acicular crystals, m. p. 71° (decomp.).

1-*o*-*Tolueneazo-2-naphthyl ethyl ether nitrate*, $C_{19}H_{18}ON_2,2HNO_3$, crystallises in cantharides-green leaflets, m. p. 62—63° (decomp.).

1-*m*-*Tolueneazo-2-naphthyl methyl ether nitrate*, $C_{18}H_{16}ON_2,2HNO_3$, crystallises similarly, and has m. p. 72° (decomp.).

1-*m*-*Tolueneazo-2-naphthyl ethyl ether nitrate*, $C_{19}H_{18}ON_2,2HNO_3$, forms cantharides-green leaflets, m. p. 84° (decomp.).

1-*p*-*Tolueneazo-2-naphthyl methyl ether hydrochloride* forms red needles which have a golden lustre. The *hydrobromide* crystallises in metallic-looking, green leaflets. The *nitrate*, $C_{18}H_{16}ON_2,2HNO_3$, forms dark red needles with a green lustre, and has m. p. 77° (decomp.).

1-*p*-*Tolueneazo-2-naphthyl ethyl ether nitrate*, $C_{19}H_{18}ON_2,2HNO_3$, crystallises in garnet-red leaflets of golden lustre, and has m. p. 94° (decomp.).

1-*o*-4-*Xyleneazo-2-naphthol*, $C_{18}H_{16}ON_2$, crystallises in cherry-red needles of golden lustre, m. p. 146°; it dissolves in concentrated sulphuric acid, producing an intense red coloration. The *methyl ether*, $C_{19}H_{18}ON_2$, crystallises in red, prismatic leaflets, m. p. 106°. The *methyl ether hydrochloride* forms red needles with golden lustre; the *hydrobromide*, garnet-red needles. The *nitrate*, $C_{19}H_{18}ON_2,2HNO_3$, forms coffee-coloured scales of golden lustre, m. p. 87—88° (decomp.). The *ethyl ether*, $C_{20}H_{20}ON_2$, forms red needles of golden lustre, m. p. 94—95°. The *ethyl ether hydrochloride* forms metallic-looking, coffee-coloured needles; the *hydrobromide*, red needles.

1-*m*-4-*Xyleneazo-2-naphthyl methyl ether*, $C_{19}H_{18}ON_2$, forms garnet-red leaflets of violet lustre, m. p. 72—73°. The *hydrochloride* and *hydrobromide* form garnet-red, acicular crystals. The *nitrate*,

$$C_{19}H_{18}ON_2,2HNO_3,$$
crystallises in cantharides-green needles, m. p. 83° (decomp.).

m-4-Xylenediazonium nitrate and 2-naphthylamine yield 1-*m*-4-*xylene*-

azo-2-naphthylamine, $C_{18}H_{17}N_3$, which crystallises in orange-red leaflets, m. p. 128°. The substance dissolves in concentrated sulphuric acid, producing a reddish-violet coloration.

1-m-4-*Xyleneazo-2-naphthyl ethyl ether*, $C_{20}H_{20}ON_2$, forms garnet-red needles, m. p. 47°. The *hydrochloride* forms coffee-coloured needles, and the hydrobromide, garnet-red needles. The *nitrate*,

$$C_{20}H_{20}ON_2,2HNO_3,$$

crystallises in cantharides-green needles, m. p. 82° (decomp.).

1-p-*Xyleneazo-2-naphthyl methyl ether*, $C_{19}H_{18}ON_2$, forms garnet-red, prismatic tablets, m. p. 91—92°. The *hydrochloride* crystallises in garnet-red needles; the *hydrobromide* in coffee-coloured needles. The *nitrate*, $C_{19}H_{18}ON_2,2HNO_3$, crystallises in cantharides-green laminæ, m. p. 75° (decomp.). The *ethyl ether*, $C_{20}H_{20}ON_2$, crystallises in tufts of red needles or laminæ, m. p. 61—62°. The *hydrochloride* forms a crust of copper-coloured needles, and the *hydrobromide* crystallises similarly. The *nitrate*, $C_{20}H_{20}ON_2,2HNO_3$, forms dark copper-coloured laminæ of golden lustre, m. p. 71° (decomp.).

1-*a-Naphthaleneazo-2-naphthyl methyl ether hydrobromide* crystallises in iridescent, brownish-green needles. R. V. S.

Etherification of *o*-Hydroxyazo-compounds. IV. G. CHARRIER and G. FERRERI (*Gazzetta*, 1913, **43**, ii, 227—244. Compare preceding abstracts).—1-*Anisoleazo-2-naphthyl methyl ether hydrobromide* forms reddish-brown needles. The *nitrate*, $C_{18}H_{16}O_2N_2.2HNO_3$, forms dark green needles, m. p. 90—91° (decomp.). 1-*Anisoleazo-2-naphthylamine*, $C_{17}H_{15}ON_3$, crystallises in garnet-red prisms, m. p. 133—134°; it is soluble in concentrated sulphuric acid with production of a reddish-violet coloration.

1-*Anisoleazo-2-naphthyl ethyl ether hydrobromide* forms brownish-red needles. The *nitrate*, $C_{19}H_{18}O_2N_2,2HNO_3$, is a dark green, crystalline substance, m. p. 85° (decomposing at 86—87°).

1-p-*Methoxybenzeneazo-2-naphthyl methyl ether hydrobromide* forms cantharides-green needles. The *nitrate*, $C_{18}H_{16}O_2N_2,2HNO_3$, forms green, acicular crystals, m. p. 55—56° (decomp.). 1-p-*Methoxybenzeneazo-2-naphthylamine*, $C_{17}H_{15}ON_3$, crystallises in garnet-red leaflets, m. p. 127°. It dissolves in concentrated sulphuric acid, giving a violet-red coloration.

1-p-*Methoxybenzeneazo-2-naphthyl ethyl ether hydrobromide* forms coffee-coloured needles. The *nitrate*, $C_{19}H_{18}O_2N_2,2HNO_3$, crystallises in cantharides-green leaflets, m. p. 67° (decomp.).

1-o-*Ethoxybenzeneazo-2-naphthyl methyl ether hydrochloride* forms garnet-red crystals; the *hydrobromide*, coffee-coloured needles. The *nitrate*, $C_{19}H_{18}O_2N_2,2HNO_3$, crystallises in dark red leaflets of metallic lustre.

1-o-*Ethoxybenzeneazo-2-naphthyl ethyl ether hydrobromide* forms brown needles; the *nitrate*, $C_{20}H_{20}O_2N_2,2HNO_3$, crystallises in green needles, m. p. 86° (decomp.). 1-o-*Ethoxybenzeneazo-2-naphthylamine*, $C_{18}H_{17}ON_3$, forms bright red leaflets, m. p. 117°. It dissolves in concentrated sulphuric acid, giving a reddish-violet coloration.

1-p-*Ethoxybenzeneazo-2-naphthyl methyl ether hydrobromide* forms

coffee-coloured needles. The *nitrate*, $C_{10}H_{18}O_2N_2,2HNO_3$, forms green needles, m. p. 71° (decomp.). 1-p-*Ethoxybenzeneazo-2-naphthylamine*, $C_{18}H_{17}ON_3$, crystallises in orange-yellow laminæ of golden lustre, m. p. 133—134°.

1-p-*Ethoxybenzeneazo-2-naphthyl ethyl ether hydrobromide* forms golden leaflets. The *nitrate*, $C_{20}H_{20}O_2N_2,2HNO_3$, forms orange-yellow plates of golden lustre, m. p. 73—74° (decomp.).

1-o-*Nitrobenzeneazo-2-naphthyl methyl ether*, $C_{17}H_{13}O_3N_3$, crystallises in garnet-red leaflets, m. p. 136—137°. It dissolves in concentrated sulphuric acid, giving an intense red coloration. The *hydrochloride* forms coffee-coloured needles, and the *hydrobromide* is a pale coffee-coloured, crystalline substance. The *nitrate*, $C_{17}H_{13}O_3N_3,2HNO_3$, forms red crystals, m. p. 103°.

1-o-*Nitrobenzeneazo-2-naphthyl ethyl ether*, $C_{18}H_{15}O_3N_3$, crystallises in thin, dark red tablets, m. p. 111°. The *hydrochloride* and the *hydrobromide* are red, crystalline substances. The *nitrate*,

$$C_{18}H_{15}O_3N_3.2HNO_3,$$

forms dark red leaflets of metallic lustre, m. p. 105° (decomp.).

1-m-*Nitrobenzeneazo-2-naphthyl methyl ether nitrate*,

$$C_{17}H_{13}O_3N_3,2HNO_3,$$

consists of golden leaflets, m. p. 66—68° (decomp.).

1-m-*Nitrobenzeneazo-2-naphthyl ethyl ether hydrobromide* is a red, crystalline substance. The *nitrate*, $C_{18}H_{15}O_3N_3,2HNO_3$, crystallises in golden leaflets, m. p. 70° (decomp.).

1-p-*Nitrobenzeneazo-2-naphthyl methyl ether*, $C_{17}H_{13}O_3N_3$, forms dark red, iridescent leaflets, m. p. 128—129°. The *hydrochloride* is a red, and the *hydrobromide* a coffee-coloured, crystalline substance. The *nitrate*, $C_{17}H_{13}O_3N_3,2HNO_3$, forms cantharides-green leaflets, m. p. 75° (decomp.).

1-p-*Nitrobenzeneazo-2-naphthyl ethyl ether*, $C_{18}H_{15}O_3N_3$, crystallises in dark red leaflets, m. p. about 186°. The *hydrochloride* and the *hydrobromide* are red, crystalline substances. The *nitrate*,

$$C_{18}H_{15}O_3N_3,2HNO_3,$$

forms cantharides-green leaflets, m. p. 95—97° (decomp.).

1-α-*Naphthaleneazo-2-naphthyl ethyl ether hydrobromide* crystallises in cantharides-green needles. The *nitrate*, $C_{22}H_{18}ON_2,2HNO_3$, crystallises in copper-red, flat needles of metallic lustre, m. p. 62° (decomp.).

1-β-*Naphthaleneazo-2-naphthyl methyl ether hydrobromide* crystallises in coffee-coloured needles. The *nitrate*, $C_{21}H_{16}ON_2,2HNO_3$, forms deep green, lustrous needles, m. p. 80—81° (decomp.).

Diphenyl-4 : 4'-bisazo-2-naphthol,

$$HO\cdot C_{10}H_6\cdot N\dot{:}N\cdot C_6H_4\cdot C_6H_4\cdot N\dot{:}N\cdot C_{10}H_6\cdot OH,$$

is a dark green, microcrystalline powder, m. p. about 275°; it dissolves in concentrated sulphuric acid with production of a violet-blue coloration. Its *diethyl ether*, $C_{36}H_{30}O_2N_4$, is a red, microcrystalline powder, m. p. about 98—100°. It is soluble in concentrated (and to some extent also in dilute) acids with production of a bluish-violet coloration. The *hydrochloride* and the *hydrobromide* are dark green, crystalline substances. The *nitrate*, $C_{36}H_{30}O_2N_4,4HNO_3$, forms dark green needles of metallic lustre, m. p. 60—61°.

R. V. S.

The Conjugation of the Products of Protein Hydrolysis to Colloidal Carbohydrates. H. FRIEDENTHAL (*Biochem. Zeitsch.*, 1913, **54**, 174—181).—Attention is called to the fact that by the condensation of hydroxyl groups in polysaccharides of colloidal character with the amino-groups of amino-acids, it is theoretically possible to obtain derivatives which have the same empirical composition as proteins, and should yield the same reactions. Although it is not claimed that the majority of the proteins is constituted in this way, it is suggested that substances of this character may exist in the organism. S. B. S.

Coagulation of Proteins by Ultra-violet Light. W. T. BOVIE (*Science*, 1913, **37**, 24—25).—Exposure of certain proteins in quartz tubes to the rays of a quartz mercury-vapour lamp causes them to coagulate. Usually no coagulum forms in glass tubes, but dialysed crystallised egg-albumin is sensitive to longer wave-lengths than the fresh egg-white, since it coagulates in a glass tube. The coagulum has the same properties as that produced by heat without exposure to ultra-violet light. E. F. A.

Temperature-coefficient of the Coagulum Caused by Ultra-violet Light. W. T. BOVIE (*Science*, 1913, **37**, 373—375).—Two reactions are involved in the coagulation of proteins by light: the chemical change caused by the light, and the production of a visible coagulum. The light reaction, resembling other photochemical changes, has a very low temperature-coefficient. The chemical change producing the visible coagulum has a temperature-coefficient as high as two. Probably similar relations exist in other physiological processes which result from the action of light. E. F. A.

The Precipitation of Colloids. II. KARL SPIRO (*Biochem. Zeitsch.*, 1913, **54**, 155—158. Compare A., 1904, i, 124).—A table is given showing that salts, of which the hydrogen-ion concentration in solution is highest, have the greatest action in inhibiting the precipitation of proteins. The hydrogen-ion concentration of the mixtures of the salt and protein solutions is not the mean of the two, but in the case of the sodium, potassium, and lithium salts it is nearly the same as that of the original protein solutions, and in the case of the ammonium salts a little greater. The acetates form an exception, in that the hydrogen-ion concentration of the mixture of protein–salt solutions approaches very nearly the [H˙]-concentration of the salt solution. The results seem to indicate the formation of a salt-protein compound, and the influence of salts on the precipitation of proteins is briefly discussed. S. B. S.

The Content of the Blood-Plasma Proteins in Basic Constituents. KARL LOCK and KARL THOMAS (*Zeitsch. physiol. Chem.*, 1913, **87**, 74—81).—The amounts of ammonia, arginine, histidine, and lysine in serum-albumin, serum-globulin, and fibrin were estimated and the table of results shows considerable discrepancies between

different preparations of the same protein, and according to the method used.   W. D. H.

The Soluble Protein Substances of Milk. Léon Lindet (*Compt. rend.*, 1913, **157**, 307—309).—The so-called albumin of milk possesses all the properties of caseinogen itself, with the exception of its rotatory power, where it has $[a]_D$ $-30°$ instead of $-116°$. The author suggests for it the name β-caseinogen, the a-caseinogen being the one, which is the chief constituent of the protein matter of milk. These two substances resemble one another closely in their solubility in milk serum, in their capillary adherence to the casein in suspension, in their precipitation by phenol, and in their partial coagulation at 75°.
                                                                W. G.

Influence of Calcium Chloride on the Curdling of Milk. Léon Lindet (*Compt. rend.*, 1913, **157**, 381—384. Compare preceding abstract).—Boiled milk is not clotted by rennet, but clots if a small amount of calcium chloride is added. This the author suggests is due to the interaction of the calcium chloride with the alkali phosphate and citrate in the milk serum, thus reducing the quantity of these, and rendering the two caseinogens less soluble. Further, the dicalcium phosphate by dissociation gives rise to phosphoric acid, which removes the calcium oxide from the caseinogens, rendering them still further insoluble.   W. G.

The Action of Rennin on Caseinogen. Alfred W. Bosworth (*J. Biol. Chem.*, 1913, **15**, 231—236).—Calcium caseinogenate which is neutral to litmus is not curdled by rennin ; but solutions which are acid and contain two equivalents of base for each molecule of caseinogen are curdled by rennin. Ammonium, sodium and potassium caseinogenates are not curdled by rennin. No other protein is formed except casein (2 molecules to one of caseinogen) during rennin curdling. Coagulation is the result of a change in solubility, and is the first stage in hydrolytic cleavage.   W. D. H.

Nucleohistone. I. Hermann Steudel (*Zeitsch. physiol. Chem.*, 1913, **87**, 207—213).—Nucleohistone prepared by the method given by Lilienfeld (A., 1894, ii, 146) had exactly the composition given previously. The whole of the nucleic acid present is proved to be true nucleic acid, no other substance containing phosphorus being present in nucleohistone.   E. F. A.

Processes Operative in Solutions, XXX, and Enzyme Action, XX. The Nature of Enzymes and of their Action as Hydrolytic Agents. E. Frankland Armstrong and Henry E. Armstrong (*Proc. Roy. Soc.*, 1913, B, **86**, 561—586).—A discussion of the problems of hydrolysis based on the experience gained in the course of two convergent series of enquiries.

The catalyst is defined as the agent which brings about the inclusion of the interacting substance in the circuit within which change takes place as soon as the circuit is established, the electrolyte being the

actual agent by which change is effected. Action between two non-electrolytes is impossible.

Enzymes are regarded as having a double function, namely, that of attracting or holding the hydrolyte and that of determining its hydrolysis. This twofold action is attributed to the presence in the enzyme of an acceptor together with an agent. The acceptor is a radicle very closely allied to a dominant group in the hydrolyte. The agent is an acid radicle in immediate or compatible proximity, so that a conducting path is formed between agent and acceptor by their association with the solvent. The efficiency of an enzyme depends also on its colloidal character. Each enzyme particle tends to absorb the hydrolyte, so that the solution at its surface is relatively concentrated; in addition it is hydrolated, the activity of the water molecules at the surface being greater than the average activity of the water. As a consequence the colloid surface remains highly charged with the hydrolyte probably up to the point at which the supply in the solution is exhausted.

The change is, therefore, not a simple mass action effect; in fact, in each successive interval of time the enzyme determines the hydrolysis of the same amount of hydrolyte. The observed departures from this rule are shown to be due to the influence of the products of change.

The relationship of the acceptor section of the enzyme to the hydrolyte is that of a superposable and, therefore, practically identical radicle.

The enzymes which hydrolyse the glucosides may be compounds of the glucoprotein class containing either α- or β-glucosidic radicles and therefore capable of hydrolysing either α- or β-glucosides, because their configuration harmonises with that of the one or of the other type of compound. Urease is an enzyme in which the urea residue in arginine is in suitable relationship with the carboxyl group. These conceptions are illustrated by photographs of solid models.

The resting enzyme is not an acid proper, but an internal salt of the glycine type. A substance of superior acidic power must be added to render the zymogen active. The action of acids and alkalis is considered from this point of view.

As the products of change accumulate in the solution, they affect the enzyme in various ways. The product immediately allied to the acceptor enters directly into competition with the hydrolyte. Other products act on the enzyme by neutralising it, by converting it into a derivative different in structure and no longer compatible with hydrolyte, or by changing the osmotic conditions in the solution, and altering the state of hydrolation at the colloid surface. These influences have been studied experimentally. E. F. A.

The Velocity of the Appearance of Protective Enzymes after Repeated Introduction of the Foreign Substrate. I. EMIL ABDERHALDEN and ERWIN SCHIFF (*Zeitsch. physiol. Chem.*, 1913, **87**, 225—230).—Whereas it takes some little time for the protective enzymes to appear on the first injection of a foreign peptone into the blood-serum, if a second injection is made, after the serum has become inactive again, the protective enzymes appear in a much

shorter time. The organism reacts much more rapidly to the second invasion. Experiments made on rabbits with silk peptone and gelatin peptone are described. The injection was preferably intravenous.

E. F. A.

Studies on the Specific Nature of the Intracellular Enzymes by means of the Optical Method. I. EMIL ABDERHALDEN and ANDOR FODOR (*Zeitsch. physiol. Chem.*, 1913, **87**, 220—224).—The behaviour of the juices obtained from various macerated tissues after they had been completely deprived of blood was tested towards the peptones from each of the tissues. Whereas liver juice hydrolysed liver peptone, it had no action on kidney or thyroid peptone. Thyroid juice only attacked thyroid peptone. Kidney juice hydrolysed both kidney and liver peptones, and also, in one experiment out of three, it acted on thyroid peptone. The liver and thyroid cells contain enzymes adapted to their specific components only; the kidney cells have a wider function, and their enzymes are adapted to peptones from other sources.

E. F. A.

Enzymes of Fresh Foods. T. TADOKORO (*J. Coll. Agric. Sapporo, Japan*, 1913, **5**, 57—72).—The fresh sap of Udo twigs, yams, cabbage and lettuce leaves, onions, ginger and radish roots of Japanese origin has been investigated for enzymes. Peptolytic action was only found in ginger and the onion. All the juices contained trypsin and a weak diastase, also oxydase and catalase, but they differed greatly in activity. Lipase was present only in the cabbage. E. F. A.

Specific Nature of the Intracellular Enzymes by means of the Optical Method. II. EMIL ABDERHALDEN and ERWIN SCHIFF (*Zeitsch. physiol. Chem.*, 1913, **87**, 231—232).—The enzymes in muscle juice (from the horse) hydrolyse muscle peptone, but not liver or brain peptone.

Testicle peptone is hydrolysed only by the enzymes in testicle and kidney juice. Brain peptone is hydrolysed only by brain and kidney juices. E. F. A.

Some Conditions Affecting the Activity and Stability of Certain Ferments. JOHN H. LONG and WILLIAM A. JOHNSON (*J. Amer. Chem. Soc.*, 1913, **35**, 1188—1201).—An extension of the earlier investigation on amylopsin (this vol., i, 919) to trypsin. Raw egg-albumin is found to be unsuited to the measurement of proteolytic action, and where egg-albumin is necessary, the authors make use of a Chinese dried albumin; but fibrin and casein are the best materials for comparative studies.

It is found that trypsin is not appreciably injured by the action of 0·3% hydrochloric acid for thirty minutes at 40°, for, although no digestion will occur in the presence of the acid, fibrin can be digested in considerable quantity after neutralisation.

Aqueous solutions of trypsin become weaker on long keeping at the ordinary temperature, the deterioration being more rapid the purer the product; in this respect it is more sensitive than pepsin. In the

presence of sodium carbonate between the concentrations 0·2% and 1% at 40°, the activity of trypsin in fibrin digestion is not affected.

<div align="right">D. F. T.</div>

Purification of Invertase Preparations by Treatment with Acids. JAKOB MEISENHEIMER, STEFAN GAMBARJAN, and L. SEMPER (*Biochem. Zeitsch.*, 1913, **54**, 108—121).—It is found that the content of invertase in a preparation can be increased by preliminary treatment of the expressed juices with acids. Not only acetic, but also hydrochloric, and more especially the dibasic sulphuric and oxalic acids effect this purpose. The addition of acids produces a precipitate of proteins, which carries down with it practically none of the ferment. The addition of too much acid acts deleteriously on the ferment, and for every preparation it is necessary, by means of preliminary experiments, to ascertain the amount of acid which yields the optimal result. For this purpose, the ferment is precipitated by means of acetone, and obtained in a dry form, and its reaction constant is determined polarimetrically with the employment of the equation $K = 1/t \log.a/a—x$. The above-stated facts are illustrated by numerous examples.

<div align="right">S. B. S.</div>

Inhibition of Enzyme Action by Lime-softened Waters. OLAF BERGEIM and PHILIP BOUVIER HAWK (*J. Amer. Chem. Soc.*, 1913, **35**, 1049—1056).—It is found that lime-softened waters exert a pronounced inhibitory effect on the action of salivary and pancreatic amylases. Of the mineral constituents of the water, magnesium hydroxide exerts by far the greatest effect, whilst sodium carbonate and calcium carbonate have a less considerable effect. Investigation shows that the influence of the magnesium hydroxide is due to its existence in a colloidal form which adsorbs the enzyme. In contrast to the action of amylolytic ferments, peptic digestion is but little affected by magnesium hydroxide solution or by lime-softened water.

From the difference in effect of calcium carbonate solution on salivary amylase and pancreatic amylase, it appears that these enzymes are not identical.

<div align="right">D. F. T.</div>

Action of Ammonia on Diastase Rendered Inactive by Heating. THEODOR PANZER (*Zeitsch. physiol. Chem.*, 1913, **86**, 401—406).—Ammonia gas has the same effect on diastase whether it has been rendered inactive by heating or not. It cannot therefore have any action on those groupings in the molecule which are altered by heat, that is, on the groupings to which the activity of the enzyme is due.

<div align="right">E. F. A.</div>

Action of Hydrogen Chloride and Ammonia on Diastase Rendered Inactive by Heating. XI. THEODOR PANZER (*Zeitsch. physiol. Chem.*, 1913, **87**, 115—121).—Diastase which has been rendered inactive by heating, regains some feeble activity when treated first with dry hydrogen chloride and then with dry ammonia.

<div align="right">E. F. A.</div>

The Enzymes of the Tobacco Plant. J. DU P. OOSTHUIZEN and OLIVER MARCH SHEDD (*J. Amer. Chem. Soc.*, 1913, **35**, 1289—1309). —An investigation of the enzymes in two types of Kentucky tobacco, the White Burley variety of the Burley region, and the Yellow Pryor variety of Western Kentucky.

The results indicate the presence of appreciable amounts of invertase, diastase, emulsin, and reductases both in the seed and in the leaf at all stages of its growth and after curing. Small amounts of lipase, inulase, and a proteolytic enzyme also appear to be present. Oxydases were present in the green leaf, but the quantity decreased towards maturity, and was too small for definite detection in the cured leaf. Generally enzymes were found to be absent from the soil.

The probable rôles of the various enzymes are discussed.

D. F. T.

Enzymes in the Leaves of Salix caprea. IWAN BOLIN (*Zeitsch. physiol. Chem.*, 1913, **87**, 182—187. Compare Armstrong, A., 1912, i, 816).—The leaves of *Salix caprea* may contain a salicase, an amygdalin-splitting and a glucoside-splitting enzyme. Salicase is specific for salicin, and has no action on β-methylglucoside. The enzyme acting on β-methylglucoside was present in the leaves in 1911, but absent from the leaves of the same tree in 1912.   E. F. A.

Enzyme Action. XXI. Lipase. III. HENRY E. ARMSTRONG and H. W. GOSNEY (*Proc. Roy. Soc.*, 1913, *B*, **86**, 586—600. Compare A., 1906, i, 126; 1907, i, 103; Tanaka, A., 1910, i, 800).—Methods of preparing active lipase preparations from castor oil seeds in the form of a dry powder and of testing their hydrolytic activity are described. Dilute acetic acid is used to activate the zymogen, which is probably a salt. Lipase is very sensitive to the action of acids, and easily rendered inert by excess of acid. The inferiority as a hydrolyst of esters other than fats is due to the fact that the acids liberated from fats are scarcely soluble in water and very weak.

Lipase is specially fitted to hydrolyse the oily glycerides, and is not suited to act in aqueous solutions. Interaction takes place at and between surfaces separated only by a thin film of water. The inter-action of enzyme and oil is inhibited by both the fatty acid and the glycerol, especially the former. As in other cases of enzyme action, the law of mass action does not apply, and the influence of the products of change and the destruction of the enzyme combine to cause departures from the simple law of enzyme action (compare this vol., i, 116).

Lipase is considered to contain a glycerol nucleus attached to a carboxylic centre in proximity to an acidic group, which can determine the hydrolysis of a fatty molecule that becomes attached to the glycerol acceptor.   E. F. A.

Some New Properties of Peroxydase. The Comparison of its Action with that of Nitrites. JULES WOLFF (*Ann. Inst. Pasteur*, 1913, **27**, 554—567. Compare A., 1912, i, 928).—Plant sap is sufficiently acid to liberate nitrous acid from nitrites. The nitrous

acid thus set free is able to bring about oxidation phenomena similar to those caused by the combination of a peroxydase with hydrogen peroxide. Nitrites are decomposed by monopotassium phosphate.

Peroxydase can be kept for some time in contact with ammonia without being changed. At first the oxidising activity diminishes somewhat, but then it increases, reaching the original value in four to five hours and attaining a maximum activity in forty hours, nearly double the original. This high activity persists for a time and then decreases slowly to the original value.

Orcinol absorbs oxygen from the air in presence of alkali hydroxides, carbonates, etc. The rate of absorption is greatly increased on adding a vegetable peroxydase—it may amount to five times the original value.

When the surface exposed to the air is large, orcinol absorbs oxygen, but does not form any quantity of coloured oxidation product (orcein). The addition of peroxydase increases the oxygen absorption, but not the amount of colour formed. On the contrary when the surface exposed to the air is small, only about one-seventh of the amount of oxygen is absorbed, but orcein is formed. Peroxydase accelerates the formation of the orcein and not the absorption of oxygen under these conditions.

E. F. A.

Preparation of a Nitro-3-aminophenyl-1-arsinic Acid. FARB WERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R.-P. 261643. Compare Bertheim, A., 1911, i, 1055).—When *3-oxalylaminophenyl*-1-*arsinic acid*, $C_6H_4(AsO_3H_2)\cdot NH\cdot CO\cdot CO_2H$, needles, is dissolved in sulphuric acid, treated at 0—5° with 26% nitric acid, and the oxalyl group subsequently eliminated, it gives rise to the hitherto undescribed 6-*nitro-3-aminophenyl-*1-*arsinic acid*, pale yellow needles; this when heated with concentrated alkalis yields 6-nitro-3-hydroxyphenylarsinic acid, whilst the mother liquor furnishes 2-nitro-3-aminophenylarsinic acid; and on reduction with sodium hyposulphite the corresponding diaminodihydroxyarsenobenzenes are obtained.

F. M. G. M.

Preparation of Neutral Derivatives of 3:3'-Diamino-4:4'-dihydroxyarsenobenzene, Soluble in Water. FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R.-P. 260235).—The preparation of compounds by the action of formaldehyde sulphoxylate on 3:3'-diamino-4:4'-dihydroxyarsenobenzene have previously been described (A., 1912, i, 595), and the reaction has now been modified by dissolving the hydroxy-base in ethylene glycol before treating with formaldehyde sulphoxylate and subsequently isolating the product by the addition of alcohol and ether.
F. M. G. M.

Preparation of Aromatic Stibinic Acids. CHEMISCHE FABRIK VON F. HEYDEN (D.R.-P. 261825. Compare this vol., i, 416).—p-*Chlorophenylstibinic acid*, a colourless powder, is obtained when a solution of *p*-chlorobenzenediazonium chloride is treated with antimony trichloride and the yellow precipitate of the additive compound (compare
May, T., 1912, **101**, 1037) collected and decomposed with warm sodium hydroxide; it is purified by methods previously described (*loc. cit.*).

Phenylstibinic acid can also be obtained when aniline is diazotised in the presence of a mixture of antimony trichloride and hydrochloric acid, and the cooled solution slowly added to a solution of sodium hydroxide, when elimination of nitrogen occurs with the formation of the required product.   F. M. G. M.

Preparation of an Aromatic Nitrohydroxystibinic Acid.
CHEMISCHE FABRIK VON F. HEYDEN (D.R.-P. 259875. Compare A. 1886, 884; 1899, i, 209; 1910, i, 803; 1911, i, 594, 1056).—*3-Nitro-4-hydroxyphenylstibinic acid* (annexed formula) is prepared by the following series of reactions. Anhydrous sodium *p*-acetylaminophenylstibinic acid (this vol., i, 416) dissolved in acetic acid (3 parts) is added drop by drop to 8 parts of concentrated sulphuric acid at a temperature below −2°; above this, elimination of the acetyl group occurs; nitric acid (D 1·51) mixed with concentrated sulphuric acid at 0° is then added, and the mixture maintained at this temperature for several hours with continual agitation; on dilution, *3-nitro-4-acetylaminophenyl-1-stibinic* acid is obtained as a yellowish-brown powder; this when heated with a solution of potassium hydroxide (D 1·30) loses ammonia and gives rise to the foregoing 3-nitro-4-hydroxyphenyl-1-stibinic acid, a brown powder, which when heated decomposes without fusion.

                                                                F. M. G. M.

Physiological Chemistry.

A Respiration Apparatus for Small Animals in which the Oxygen Consumption is Automatically Registered. L. S. FRIDERICIA (*Biochem. Zeitsch.*, 1913, **54**, 92—167).—This apparatus combines the Haldane principle, according to which the animal with all excreta are weighed before and after the experiment, the water and carbon dioxide given out by the animal being collected in the ordinary absorption apparatus, with the Regnault-Reiset principle, modified more or less according to Benedict, in which the oxygen which is used up in respiration is automatically replaced from a gasometer, the amount added to the respiration apparatus being automatically registered. For these purposes a circulation is kept up through a closed system by means of a specially designed rotatory blower, which is figured in the text, and the air after leaving the cage containing the animal passes over weighed sulphuric acid and soda-lime tubes. In conjunction with this system is the oxygen holder, the lid of which is counterpoised by a

weight over a pulley, and the whole circuit is so arranged, by the interposition of wash-bottles serving as manometers, that it is constantly under atmospheric pressure. There is a double check, therefore, on the oxygen consumption, namely, the diminution of the oxygen in the gasometer, which is automatically registered, and the gain of weight in the animal holder and absorption apparatus. Both determinations yielded results concordant with one another.

S. B. S.

The Part Played by the Lungs in the Oxidative Processes of the Body. C. LOVATT EVANS and ERNEST H. STARLING (*J. Physiol.*, 1913, **46**, 413—434).—The gaseous metabolism of the lung in the perfused heart-lung preparation is best measured in reference to the heart-weight as the lungs soon become œdematous. It is 1 c.c. of oxygen and 0·94 c.c. carbon dioxide per gram of heart per hour. The lungs do not exercise any general or specific activity in completing oxidations partly carried out in other tissues. W. D. H.

The Influence of the Carbon Dioxide Tension of the Blood on the Ventilation by the Lungs. OTTO PORGES and A. L. SAMPLE (*Biochem. Zeitsch.*, 1913, **54**, 182—185).—In investigations on the influence of the acidity of the blood on the respiration, many authors have attempted to ascertain the stimulability of the breathing centre. Lindhard, more especially, has determined this factor, by allowing the subject of the research to inhale ordinary atmospheric air, and estimating the alveolar ventilation and carbon dioxide tension, and then determining the same factors after inhalation of air to which has been added varying amounts of carbon dioxide. Attention is now called to the fact that in these and similar experiments no account is taken of the fact that the effect on inhaling increased amounts of carbon dioxide will vary according to the pre-existing stimulus. As this pre-existing stimulus depends on the acidity of the blood, it is necessary to take into account, not only the carbon dioxide tension, but also the amount of non-volatile acids, which, according to Porges and his co-workers, are present accompanied by a diminished carbon dioxide tension in acidosis. The influence of the amounts of acid on the action of lungs is illustrated by some experiments on a pregnant patient, and patients with diabetes, and the conclusion is drawn that the method employed by Lindhard and others is not adapted to the determination of the true stimulability of the respiratory centre. S. B. S.

Influence of Alcohol on the Respiratory Exchange During Rest and During Muscular Exercise. C. J. C. VAN HOOGENHUYZE and J. NIEUWENHUYSE (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **16**, 164—172).—The authors have subjected themselves to experiments on the influence of alcohol on the respiratory exchange. While resting, they measured the oxygen-intake and carbon dioxide-output by means of the Zuntz-Geppert apparatus, and found that the respiratory quotient, CO_2/O_2, remained lower for a few hours after

the consumption of alcohol. The experiments involving muscular exercise were performed on a bicycle with adjustable and registrable resistance. The brake-band was tightened until the subject was fatigued, and then, whilst he was pedalling against a constant resistance, without or after a dose of 60 c.c. of 96% alcohol, the respiratory exchange was examined as above. The experiments were performed at 8—15° and at 28°. The respiratory quotient was again found to be lowered for a time after the consumption of alcohol, even at the higher temperature, at which muscular work was less economically performed. Alcohol, therefore, can produce energy for muscular exercise, and this is more economically performed for an hour or two after taking the stimulant. This favourable influence, however, gradually decreases, and tends towards the opposite in time.   J. C. W.

The Influence of Muscular Rigidity on the Oxygen-intake in Decerebrate Cats. HERBERT E. ROAF (*Quart. J. expt. Physiol.*, 1913, **6**, 393—402).—During decerebrate rigidity the oxygen intake is only slightly greater than when the muscles are flaccid.
                                                                    W. D. H.

Rate of Reproduction of the Blood Constituents in an Immunised Horse After a Large Bleeding. R. A. O'BRIEN (*J. Path. Bact.*, 1913, **18**, 89—98).—After the withdrawal of ten litres of blood from an immunised horse, the fluid first appearing in the circulatory system contains an amount of protein far above the normal; hæmolysin and diphtheria antitoxin are reproduced at different rates, and the rate of reproduction of the various blood-proteins is probably associated therewith. Details regarding salts and corpuscles are also given.   W. D. H.

The Effect of Certain Drugs, Toxic Substances, and Micro-organisms on the Fragility of the Red Corpuscles of Man and Animals. W. W. C. TOPLEY (*J. Hygiene*, 1913, **13**, 191—236).—Arsenious acid and atoxyl in toxic doses increase the fragility of red corpuscles *in vivo*. Bile and bile salts cause no change. Various pathogenic hæmolytic micro-organisms cause a rise in fragility, so also do specific hæmolytic sera; the amboceptor alone does not. Experiments *in vitro* were not satisfactory, but, so far as they went, the results confirmed the findings *in vivo*.   W. D. H.

The Formation of Indophenol at the Nuclear and Plasma Membranes of Frog's Blood Corpuscles, and its Acceleration by Induction Shocks. RALPH S. LILLIE (*J. Biol. Chem.*, 1913, **15**, 237—247).—The formation of indophenol by the intracellular oxidation of α-naphthol and dimethyl-p-phenylenediamine takes place most rapidly in the neighbourhood of the nuclear and plasma membranes. This is accelerated by passing induction shocks through the suspension of blood corpuscles.   W. D. H.

Rapid Method of Preparing Thrombin. WILLIAM H. HOWELL (*Amer. J. Physiol.*, 1913, **32**, 264—265).—Pig's fibrin is well washed,

and then extracted with 8% solution of sodium chloride; the extract is heated with an equal volume of acetone; the bulky precipitate of protein contains thrombin; this is filtered off and rapidly dried, then extracted with water, and filtered; the filtrate contains the thrombin, traces of salt, and a heat-coagulable protein; the latter is removed by shaking with chloroform, and the final fluid is evaporated to dryness in a current of cold air. The dried material can be left indefinitely in a desiccator. It is easily and completely soluble in water. W. D. H.

The Relation of Metathrombin to Thrombin. F. W. WEYMOUTH (*Amer. J. Physiol.*, 1913, **32**, 266—285).—The thrombin content of serum is determined by its clotting power on solutions of fibrinogen, and the metathrombin content by the clotting power after activation by alkali and subsequent neutralisation. In dog's serum the activity of both disappears after three to four days; five to eighteen days later there is almost complete return, and then it disappears completely. If kept sterile the initial loss of power is slower, and there is no reappearance of activity. Bacterial growth is responsible for both phases. Thrombin prepared by Howell's method retains its power for long periods (at least eighteen days); its power is destroyed by a substance in serum and in oxalate plasma, which is antithrombin. After the action of antithrombin the presence of metathrombin can still be shown in certain cases. Metathrombin is regarded as a thrombin-antithrombin compound; it is absent in oxalate and fluoride plasma. W. D. H.

The Nitrogen of Blood-serum Freed from Protein. RUDOLF PHILIPP (*Zeitsch. physiol. Chem.*, 1913, **86**, 494—502).—The residual nitrogen after serum has been freed from protein by heat-coagulation is about twice as great as when phosphotungstic acid, uranyl acetate, or ferrum oxydatum dialysatum are employed. The two last-named reagents entirely free the serum from protein. In cases of uræmia the residual nitrogen is increased. W. D. H.

Alterations Produced in Complement-containing Sera by the Introduction of "Lecithin." JOHN CRUICKSHANK and THOMAS J. MACKIE (*J. Path. Bact.*, 1913, **18**, 99—113).—"Lecithins" differ markedly with regard to their power to produce the alterations in complement activity, hæmolysis, etc., with which the paper deals. A large number of preparations are quite inefficient. W. D. H.

Fibrin in Sol and Gel State. The Blood-coagulation Problem. EBEL HEKMA (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **16**, 172—185).—The author has investigated the relation between fibrinogen and fibrin. Pure fibrin, free from blood corpuscles, was found to dissolve quite readily in very dilute sodium hydroxide or sodium carbonate, but a fibrous coagulum could be reproduced by the cautious addition of dilute acids, such as phosphoric or carbonic, or by sodium dihydrogen phosphate or calcium chloride.

Fibrin also dissolved in a slight excess of acid, but could be repre-
cipitated on neutralisation. Coagulation was also effected. in
solutions which had been boiled, from which the conclusion is
drawn that ferments play no part in the process. Fibrin is there-
fore a reversible gel.

Further experiments showed that centrifugated, fluid plasma, or
ascites fluid (that is, a natural fibrinogen solution), like alkaline
fibrin solutions, could be coagulated by traces of acids. Moreover,
alkaline fibrin solutions could be coagulated by serums or organic
extracts which are known to coagulate fibrinogen, and also, like
fluid plasma or ascites fluid, by means of saturated solutions of
sodium chloride or fluoride. A great similarity was thus estab-
lished between fibrinogen as found in blood and body fluids, and a
solution of fibrin in very dilute alkali.

Dried fibrils, the single threads of fibrin, swell out again very
quickly in alkaline solutions, and, if the volume of liquid is small,
raw fibrin will imbibe the whole of it and become jelly-like. A
swollen fibril, however, contracts to its original size in dilute acids,
1% calcium chloride or any saturated salt solution, or even in
excess of water. The swelling process is therefore of a superficial
kind, and it is assumed that it consists in the formation of an
alkali adsorption-compound, which eventually, by the continuation
of the imbibition, passes into colloidal solution. Fibrinogen is thus
considered to be an alkali-hydrosol of fibrin, and its conversion into
the gel, fibrin, and therefore the coagulation of blood, is merely due
to the withdrawal of hydroxyl ions from the adsorption compound
by means of one or other of the factors mentioned above.

<div style="text-align:right">J. C. W.</div>

The Inhibition of Hæmolysis by Cholesterol and Oxy-
cholesterol. E. SCHREIBER and LÉNARD (*Biochem. Zeitsch.*, 1913,
54, 291—296).—A method is described for preparing oxychole-
sterol from cholesterol, and of obtaining emulsions of the same.
Although, by itself, the former substance has a much weaker
power of inhibiting hæmolysis than cholesterol, it increases this
power of the latter substance when added to it in quite small
quantities. Oxycholesterol acts also more weakly than cholesterol
in inhibiting hæmolysis by cobra poison. S. B. S.

· The Influence of Nutrition on the Gaseous Metabolism of
Cold-blooded Animals. BERNHARD ELSAS (*Zeitsch. Biol.*, 1913, **62**,
1—31).—The experiments were made on groups of frogs in a
modified Regnault-Reiset apparatus. The inanition metabolism is
first found; but as this is influenced by the temperature, all the
observations must be carried out at a constant temperature. Food
may then be given in amounts equivalent to the inanition meta-
bolism (isopeinic), or the quantities may be below or above this
(hypo- and hyper-peinic respectively). Iso- and hyper-peinic
administration of dextrose increases the metabolism by from 6 to
20%. Isopeinic feeding with fat does not raise the metabolism.
The increase of metabolism after isopeinic feeding on protein is

very pronounced, 17—40%. These results are compared with some previously published by Weiss. The observations lend no support to the view that the increase of activity is due to alimentary work, but confirm Rubner's views on the specific dynamic values of foods.

W. D. H.

Metabolism of Ammonium Salts. I. The Estimation of Ingested Ammonium Salts in the Dog on an Adequate Mixed Diet. FRANK P. UNDERHILL (*J. Biol. Chem.*, 1913, 15, 321—335).—Ammonium salts of organic acids were given to dogs on a fixed diet, but failed to increase the ammonia nitrogen of the urine. Ammonium salts and inorganic acids caused a varying degree of increase in the ammonia nitrogen of the urine. The experiments afford no adequate explanation for the temporary retention of the ammonium salts. All the inorganic ammonium salts used, and some of the organic salts, cause a distinct excess of total urinary nitrogen, and they apparently stimulate nitrogenous katabolism. Sodium chloride under the same conditions lowers the output of urinary ammonia nitrogen.

W. D. H.

Metabolism of Ammonium Salts. II. Elimination of Ammonium Salts During a Period of Prolonged Inanition. FRANK P. UNDERHILL (*J. Biol. Chem.*, 1913, 15, 337—339).— During inanition in the dog, ingestion of ammonium carbonate fails to produce an increase of urinary ammonia nitrogen. Ammonium chloride causes, however, a marked increase, and also an increase in total nitrogen. At this stage a second ingestion of ammonium carbonate may also bring about an increase of total urinary nitrogen.

W. D. H.

Metabolism of Ammonium Salts. III. The Utilisation of Ammonium Salts with a Non-nitrogenous Diet. FRANK P. UNDERHILL and SAMUEL GOLDSCHMIDT (*J. Biol. Chem.*, 1913, 15, 341—355).—Ammonium chloride added to a non-nitrogenous diet caused no retention of nitrogen, as Grafe states. It exercises a toxic action, and increases the output of urinary ammonia. Ammonium acetate and citrate decrease the nitrogen loss, and lead to retention of nitrogen. The ability of the body to deal with the organic and inorganic salts of ammonium is radically different. W. D. H.

Excretion of Creatine. R. A. KRAUSE (*Quart. J. expt. Physiol.*, 1913, 7, 87—101).—The metabolism of children differs from that of the adult. In boys, creatinuria occurs until the age of five or six; in girls it persists longer, and may last until the intermittent creatinuria occurs which characterises the female sexual cycle. The power to assimilate creatine given with the food is much weaker in children than in the adult. The excretion or non-excretion of creatine depends on the balance between formation and destruction, two processes which are always at work. This view will render it necessary to revise current theories on creatinuria as a pathological condition. W. D. H.

Nitrogen Retention in Feeding on Urea. EDUARD GRAFE (*Zeitsch. physiol. Chem.*, 1913, 86, 347—355).—These experiments are given to support the author's contention (compare A., 1912, ii, 659; 1913, i, 216) that urea in the food leads to retention of nitrogen. The experiments lasted over a long period. W. D. H.

The Relation of Growth to the Chemical Constituents of the Diet. THOMAS B. OSBORNE, LAFAYETTE B. MENDELL, EDNA L. FERRY and ALFRED J. WAKEMANN (*J. Biol. Chem.*, 1913, 15, 311—326).—It has been previously shown that growth and mainten-ance are different things. The best food to promote growth is milk, even if only small quantities are occasionally given, mixed with an artificial diet of protein, fat, carbohydrates, and salts. Protein-free milk is not adequate for growth, but the addition of butter to the protein-free milk restores growth. Evidently some substance is removed from the protein-free milk which is essential, and this is present mixed with the butter-fats. What the substance is, is as yet unknown.   W. D. H.

Sugar Absorption. KORNÉL VON KÖRÖSY (*Zeitsch. physiol. Chem.*, 1913, 86, 356—367).—By interference with the circulation through the intestines, lungs, and heart, absorbed sugar does not occur as such in the blood. The absorption of sugar is not a simple process, and the effect of internal secretions, such as that of the adrenal gland, has to be taken into account. Phosphates may also play an imporant rôle in sugar absorption, as they do in alcoholic fermentation.   W. D. H.

The Distribution of Creatine in the Animal Organism J. C. BEKER (*Zeitsch. physiol. Chem.*, 1913, 87, 21—37).—A large number of organs and tissues in different animals were found to contain creatine in amounts which are greater than that in the blood. These results are given in tables. Experiments are also given which confirm the view that the liver is able to convert creatine into creatinine.   W. D. H.

The Lecithin Content of Different Tissues. JOHN CRUICKSHANK (*J. Path. Bact.*, 1913, 134—136).—The amount of lecithin in various tissues was estimated by the author's method. In 100 grams of moist tissue, ox red corpuscles yielded 2·5, sheep's liver 1·6, human brain 0·6, ox pancreas 0·68, testicles 0·62 gram, and other tissues amounts varying from 0·14 to 0·48 gram.   W. D. H.

Gases Evolved During the Autolysis of Some Organs and Tissues. FILIPPO TRAETTA-MOSCA (*Gazzetta*, 1913, 43, ii, 144—148). —The liver, kidney, brain, and suprarenal capsules yield carbon dioxide, nitrogen, and hydrogen; the intestine evolves carbon monoxide and oxygen in addition to these gases, whilst the pancreas, spleen, lungs, and heart yield only nitrogen. R. V. S.

Calcium and Magnesium in the Brain Under Different Physiological and Pharmacological Conditions. IVO NOVI (*Eighth Inter. Cong. App. Chem.*, 1912, 19, 261).—The proportion of

calcium in the brain of the dog varies from 0·0143 to 0·031, and that of magnesium from 0·0143 to 0·0167% of the fresh material. Age has a marked influence on the calcium-content of the brain. With dogs this content is at its maximum before and just after birth, the minimum is reached prior to weaning, and in old age the initial value is again attained; a similar course is followed in the case of the human brain. With guinea-pigs, the proportion of calcium is minimal in the fœtus, becomes almost doubled a few days after birth, and continues to increase for a month; subsequently it remains constant until old age is reached, when it again increases, sometimes as much as tenfold. Introduction, either subcutaneously or into the stomach, veins, or carotids, of sodium chloride in isotonic or hypertonic solution results in the diminution of the calcium-content of the brain, in some cases by one-half.

The proportion of magnesium in the brain remains constant at all ages and under all the experimental conditions employed.

T. H. P.

Cerebrosides of Brain Tissue. ⁞PHOEBUS A. LEVENE (*J. Biol. Chem.*, 1913, 15, 359—364).—The conclusion that the cerebrosides are optically different isomerides is confirmed by further work, but more data are still wanting to render this certain. W. D. H.

Autolysis of, and Presence of, Proteolytic Ferments in the Brain of the Calf. FILIPPO TRAETTA-MOSCA (*Gazzetta*, 1913, 43, ii, 138—143).—When the brain of the calf is subjected to autolysis (incubation with water in presence of chloroform for a month), lysine, choline, xanthine, and adenine can be subsequently obtained from it. This indicates the presence in the brain of ferments capable of attacking albumin, nucleins, and lecithin. R. V. S.

The Effect of Alcohol on the Excitation, Conduction, and Recovery Processes in Nerves. KEITH LUCAS (*J. Physiol.*, 1913, 46, 470—505).—After exposure to 5% alcohol, a nerve recovers its properties when replaced in Ringer's solution. The impairment of conduction in the nerve produced by alcohol, and the increase in threshold current strength follow a parallel course. The rate of conduction is much slowed, however, at a stage when the rate of recovery is not slowed. This suggests that the recovery process, which is responsible for the refractory period, is a process different from the disturbance which is the basis of propagation of the nervous impulse. W. D. H.

The Influence of Anoxybiosis on the Disappearance of Glycogen from the Autonomous Organs of the Frog. ERNST J. LESSER (*Biochem. Zeitsch.*, 1913, 54, 236—251).—As autonomous organs are designated those tissues, such as liver and muscles, in which action takes place when they are separated from the nervous systems, and the hormones contained in the blood supply. The author has already shown that the rate of glycogen disappearance from the liver after removal from the animal is greater in summer

frogs than in winter frogs, and he now compares this rate when the organs are well supplied with oxygen (oxybiosis) and when they are kept in a current of nitrogen (anoxybiosis). These experiments were of interest, as it has been found that under the influence of anoxybiosis of the whole animal the rate of glycogen disappearance could be increased, and it was thought possible that by this means the behaviour of the livers from winter frogs could be made to approximate to that of summer frogs. It was found that in the months of the year in which the glycogen of the liver is stable, the rate of disappearance is not influenced by anoxybiosis, whereas in the months when the glycogen is labile, anoxybiosis increases the rate. The experiments were carried out at the temperature of 22—24°, and did not extend beyond five hours. Similar results were obtained with muscular tissues.   S. B. S.

Chemical and Bio-chemical Properties of the Lipoids Extracted from Pig's Liver and Egg-yolk. FREDERICK P. WILSON (*J. Path. Bact.*, 1913, **18**, 60—63).—The lipoids extracted from pig's liver and from egg-yolk differ greatly in their chemical (iodine value, etc.) and biochemical (anti-complementary, hæmolytic powers, etc.) properties.   W. D. H.

The Thyroid Gland. XI. WALTER EDMUNDS (*J. Path. Bact.*, 1913, **18**, 52—59).—The thyroid gland in dogs hinders the assimilation of sugar; the parathyroid glands favour it.   W. D. H.

Carbohydrate Metabolism in its Relation to the Thyroid Gland. The Effect of Thyroid Feeding on the Glycogen-content of the Liver and on the Nitrogen Distribution in the Urine. W. CRAMER and R. A. KRAUSE (*Proc. Roy. Soc.*, 1913, *B*, **86**, 550—560).—When rats or cats are fed on a carbohydrate-rich diet plus small amounts of fresh thyroid gland for two or three days, the liver only contains traces of glycogen. This is due to an inhibition of the glycogenic function of the liver, and not to increased utilisation of carbohydrates. There is no glycosuria. The distribution of the nitrogenous constituents in the urine is similar to that observed after withdrawal of carbohydrates from the diet.   W. D. H.

Changes in the Metabolism of Animals After Extirpation of the Thyroids and Parathyroids. J. GREENWALD (*Biochem. Zeitsch.*, 1913, **54**, 159—160).—The author controverts the statement of Paladino (this vol., i, 675) that there is an increased phosphorus output after extirpation of the thyroids. He contends that there is rather a diminution, and the discrepancy between Paladino's results and those of other authors is due to the fact that the former did not investigate the metabolism immediately after the operation, but only after a prolonged period at the onset of tetany, which, it is admitted, may produce increased phosphorus output.   S. B. S.

The Enzymes of the Pituitary Body. LUCIE BUETOW (*Biochem. Zeitsch.*, 1913, **54**, 40—52).—The following ferments were found to be present: Catalase, diastase, pepsin, trypsin, peroxydase, tributyrinase, and urease. The following enzymes could not be detected: Invertase, lactase, a glycolytic ferment, and deamidase. S. B. S.

The Chemistry of the Mammary Gland. J. ARGYLL CAMPBELL (*Quart. J. expt. Physiol.*, 1913, **7**, 53—56).—Considerable differences exist in the mammary gland of different animals, and even between different parts of the gland in the same animal. Lactose is found only when the gland contains milk, and the amount present is thus a measure of the quantity of milk in the gland. The fat, on the other hand, is present, not only in milk, but in the secreting cells, and in the adipose tissue between the alveoli. W. D. H.

The Phosphatides of Human Placenta. III. C. SAKAKI (*Biochem. Zeitsch.*, 1913, **54**, 1—4).—From the alcohol-ether obtained in the purification of the so-called jecorin by Drechsel's method, a precipitate was obtained on addition of alcoholic cadmium chloride, part of which was soluble in ether and the other part insoluble. Both these products were analysed, but the results do not accord with any definite chemical formula. S. B. S.

The Distribution of Phosphorus in the Placenta. C. SAKAKI (*Biochem. Zeitsch.*, 1913, **54**, 5—10).—From the determination of the phosphorus soluble in organic solvents (light petroleum or benzene) the amount of lecithin was calculated as 6·8% of the dried substance. S. B. S.

The Absorption of Water by the Skin of the Frog. S. S. MAXWELL (*Amer. J. Physiol.*, 1913, **32**, 286—294).—An empty frog's skin immersed in water takes up an enormous amount; this depends on the permeability of the skin to water, and its relative impermeability to salts. The assumption of "vital activity" in this process is regarded as unnecessary. W. D. H.

The Absolute Mechanical Efficiency of the Contraction of an Isolated Muscle. ARCHIBALD V. HILL (*J. Physiol.*, 1913, **46**, 435—469).—Fick's results on the mechanical efficiency of muscular contraction are inaccurate; for instance, they do not take into account the heat-production which occurs in the period of recovery. The subject was re-investigated by the author's new methods; his apparatus, however, requires calibration for each experiment and each muscle used. In the sartorius, the initial process of contraction consists mainly of the liberation of free potential energy, which is manifested as tension energy in the excited muscle; this can be used indifferently for the production of work or of heat; the efficiency of the whole process may be almost as high as 50%. The chemical substance possessing the free energy is the lactic acid precursor. W. D. H.

Extractives of Muscle. XV. Presence of Carnosine, Methyl-guanidine, and Carnitine in Horse Flesh. J. SMORODINZEV (*Zeitsch. physiol. Chem.*, 1913, **87**, 12—20).—Horse flesh is shown to contain about 0·58 gram of creatine, 0·08 gram of purine substances, 1·82 gram of carnosine, 0·18 gram of carnitine, and from 0·11 to 0·83 gram of methylguanidine per kilogram of fresh muscle. These proportions are those observed in the muscles of other animals. E. F. A.

The Influence of Starvation on the Creatine Content of Muscle. VICTOR C. MYERS and MORRIS S. FINE (*J. Biol. Chem.*, 1913, **15**, 283—304).—The creatine of rabbit's muscle is relatively increased in the early part of starvation, but decreased at the close, owing to its loss by the urine. That creatine and creatinine are independent in metabolism is dissented from; the old view that the creatinine is derived from muscular creatine is favoured, though the proof is not yet complete. W. D. H.

Influence of Carbohydrate Feeding on the Creatine Content of Muscle. VICTOR C. MYERS and MORRIS S. FINE (*J. Biol. Chem.*, 1913, **15**, 305—310).—The effect of carbohydrate feeding on the creatine of rabbit's muscles is similar to that seen in starvation. The decreased elimination of creatine under these conditions is primarily dependent on the sparing action of carbohydrate on the muscle proteins. W. D. H.

The Derivatives of Ethyl Alcohol Contained in Muscle. ALONZO L. TAYLOR (*J. Biol. Chem.*, 1913, **15**, 217—220).—In dogs which had been without food for one day, and in which the entire alimentary canal had been extirpated, the muscles still yielded alcohol in small amounts. It could not have been derived from food, and the theory is advanced that alcohol is an intermediate stage in the metabolism of dextrose. W. D. H.

Chemical and Physico-chemical Properties of Liquids Expressed from Striated and Plain Muscle. II. Amount of Protein in the Juice and Relations between the Granules (Myosin) Suspended and the Myoprotein Dissolved. FILIPPO BOTTAZZI and G. QUAGLIARIELLO (*Atti R. Accad. Lincei.*, 1913, [v], **22**, ii, 52—59. Compare Bottazzi, A, 1912, ii, 1192).—The granular substance amounts to 33—61% of the total protein of the juice. The total protein amounts to 5·32—9·54%. Data regarding the yield, density, viscosity, total nitrogen, and ash of the juice obtained in different experiments and with muscle from different animals are also recorded. R. V. S.

Presence of Succinic Acid in Meat Extract and in Fresh Meats. HANS EINBECK (*Zeitsch. physiol. Chem.*, 1913, **87**, 145—158).—Succinic acid in some quantity is obtained, both from Liebig's meat extract and from fresh ox and dog flesh. It is present in the carniferrin fraction, and particularly in the mother liquors from

this. It is not derived from the decomposition of Siegfried's phosphorcarnic acid. E. F. A.

Does Milk Contain Phosphatides? VLADIMIR NJEGORAN (*Biochem. Zeitsch.*, 1913, **54**, 78—82).—Milk was treated with anhydrous sodium sulphate, and the mixture was kept in a vacuum until free from water. The residual powder was then extracted with various organic solvents. No phosphorus could be detected in these solutions, and the author draws the conclusion that phosphatides are not present in milk. S. B. S.

The Effect of Pituitary Extract on the Secretion of Milk. JOHN HAMMOND (*Quart. J. expt. Physiol.*, 1913, **6**, 311—338).— Injection of pituitary extract produces an immediate action on the flow of milk, which is followed by a period of decreased flow. The effect, however, is not muscular, nor is it effected through the rise of blood-pressure. . Microscopic evidence points to a direct action on the epithelium cells which set free the milk constituents. The milk formed is rich in fat. The daily yield of milk is only slightly increased as the result of the injection. W. D. H.

Hydrocephalus Fluid. E. SIEBURG (*Zeitsch. physiol. Chem.*, 1913, **86**, 503—510).—An analysis of fluid from a case of hydrocephalus is given. The noteworthy points are: (1) the absence of protein; a faint reaction with Millon's reagent indicates the presence of certain hydrolytic products of protein; and (2) the presence of certain enzymes, namely, diastase, invertase, lipase, and enzymes capable of splitting glucosides and esters. W. D. H.

The Nature of the Depressor Substance in Dog's Urine and Tissues. ALONZO A. TAYLOR and RICHARD M. PEARCE (*J. Biol. Chem.*, 1913, **15**, 213—216).—Attempts to isolate the substance failed. W. D. H.

The Excretion of Formic Acid in Human Urine Under Normal and Pathological Conditions. RUDOLF STEISOWER (*Biochem. Zeitsch.*, 1913, **54**, 189—211).—The formic acid was estimated by distilling urine acidified with phosphoric acid under diminished pressure, collecting the distillate in excess of alkali, and determining the acid in this distillate after concentration by heating with mercuric chloride in the presence of sodium acetate. The mercurous chloride produced by the reduction was weighed. The yield of formic acid thus found is about 90% of the theoretical. Formic acid is found under normal conditions in the urine to the extent of about 13·5 milligrams daily; and the amount is not increased by moderate muscular activity. It does not appear to be influenced by the character of the diet. In many diseases the amount excreted is normal, as in compensated heart affections, carcinoma, gastric ulcer, colelithiasis, constipation, and various febrile conditions. It is increased, however, in uncompensated heart affections, in asphyxia due to work in heart affections in man,

and in animals. It is also increased in diabetes as the result of changes in the fat metabolism. In a single case investigated of muscular dystrophy there was also found an increased output of the acid, due apparently to changes in the muscular metabolism. Reasons are given for supposing that formic acid is a metabolism product of fats, carbohydrates, and proteins.   S. B. S.

Excretion of Formic Acid in Disease. I. GREENWALD and N. W. JANNEY (*Zeitsch. physiol. Chem.*, 1913, **86**, 511—512).—By the use of the method of Dakin, Janney, and Wakeman, it is shown that the excretion of formic acid in the urine is increased in pneumonia, especially during the stage of resolution. Figures are also given in isolated cases of other diseases, but no generalisations are possible from these.   W. D. H.

Substances in Urine Giving Rise to Indigotin. I. ROBERT V. STANFORD (*Zeitsch. physiol. Chem.*, 1913, **87**, 188—206).—The substances in human urine which give rise to indigotin are very unstable. Their amount has greatly diminished in one to three hours, and they have disappeared in three to six hours. The cause of the decomposition is not understood; it is perhaps due to autoxidation. The indigotin-forming substances were obtained by salting-out and extraction with a mixture of ether and alcohol. Even under these conditions they decompose too rapidly for their isolation to be effected. It is considered improbable that they are identical with potassium indoxylsulphate.   E. F. A.

Excretion of Morphine in the Urine. WILHELM RITTER VON KAUFMANN-ASSER (*Biochem. Zeitsch.*, 1913, **54**, 161—173).—The author finds that neither the biological method of Hermann and Straub (action on white mice) nor the chemical method described by van Ryn are suitable for the quantitative estimation of morphine in the urine. He describes a method devised by himself, in which the morphine is finally extracted with chloroform, and estimated by means of iodoeosin. By this method it is found that larger quantities of the alkaloid are excreted by the kidneys than was formerly supposed, the amount eliminated by this channel reaching 39% during a course of constant administration of the drug. Seventy-two hours after the last injection in this series of experiments sufficient alkaloid could be found in the liver, kidneys, and stomach for quantitative estimation.   S. B. S.

The Antagonism Between Adrenaline and Anæsthetics on the Heart. JAMES A. GUNN (*Quart. J. expt. Physiol.*, 1913, **7**, 75—86).—Using the perfusion method on the heart of cat or rabbit it was found that adrenaline can antagonise a concentration of chloroform which enfeebles the beat, but not such a concentration as arrests it. In the case of chloral the antagonism of adrenaline is greater, and the latter drug will set a heart going which is completely arrested by chloral. Adrenaline is also antagonistic to many other substances which weaken cardiac activity. The

rhythmic contractions which adrenaline arouses in a quiescent heart are independent of intrinsic motor ganglia. W. D. H.

Pharmacological Testing of Sulphuric Acid. Esters of Atropine and Scopolamine. PAUL TRENDELENBURG (*Arch. expt. Path. Pharm.*, 1913, **73**, 118—138).—By the esterification of the alcoholic hydroxyl of alkaloids of the atropine group with sulphuric acid, the intramolecular salt formation with the nitrogen of the tropine or scopolamine causes a marked weakening of their affinity for the endings of the vagus nerve. In most cases the stimulating action on the nervous system is increased. The toxicity is not altered as a rule. The esters of the atropine group stimulate the respiratory centre very strongly; this may be useful therapeutically. The scopolamine ester does not possess this property. W. D. H.

Creatine Formation in the Animal Kingdom. Creatine Formation from Betaine and Choline. OTTO RIESER (*Zeitsch. physiol. Chem.*, 1913, **86**, 415—453).—This paper contains a very useful résumé of recent work on the subject. The experiments recorded deal with the effect of the administration of betaine and choline (by mouth or hypodermically) on the amount of creatine in the muscles, and creatinine in the urine. In some cases the material was mixed with surviving muscle. Although in a certain number of cases creatine or creatinine, as the case may be, was increased, the conclusion is drawn that there is no certain proof that betaine or choline leads to creatine formation. W. D. H.

The Fate of Cocaine and Ecgonine in the Organism. SULEIMAN RIFATWACHDANI (*Biochem. Zeitsch.*, 1913, **54**, 83—91).— Cocaine is excreted, after administration to rabbits, in the urine, in amounts which can be quantitatively estimated. For this purpose the urine is extracted by benzene or ether, and the amount of alkaloid thus obtained is estimated by Gordin's method. By long-continued administration of the drug, the amount excreted each day in the urine gradually increases. No destruction of cocaine, when kept in contact with living tissue, could be detected. Ecgonine is also excreted in the urine; for the purposes of detection the urine was evaporated to dryness and treated with methyl alcohol and hydrochloric acid; the alkaloid after conversion into its methyl ester can be extracted by ether. S. B. S.

The Influence of Lecithin on the Action of Drugs. DAVID M. LAVROV (*Biochem. Zeitsch.*, 1913, **54**, 16—26. Compare Hanschmidt, this vol., i, 796).—A summary is given of earlier experiments on the combined action of lecithin and various drugs on frogs, in which it is shown that within certain limits the lecithin diminishes the action of the drug, whereas within higher limits it increases it. In the cases of phosphorus and phenol poisoning, an increase only of the toxic effect was observed. In doses of 0·0015 to 0·003 gram lecithin markedly increases the toxic action of ricin on frogs. Doses of other magnitudes cause a two-fold action. During the first ten

or eleven days they increase the toxic action, but afterwards the ricin effects begin to weaken. The general condition of the animals employed is not without effect.   S. B. S.

Is the Pressor Effect of Pituitrin Due to Adrenal Stimulation ? R. G. HOSKINS and CLAYTON MCPEEK (*Amer. J. Physiol.*, 1913, **32**, 241—244).—The experiments recorded show that the answer to the question is in the negative.   W. D. H.

Pharmacological Notice Concerning Two New Derivatives of Santonin, α- and β-Santonan (α- and β-Tetrahydrosantonin). E. SIEBURG (*Chem. Zeit.*, 1913, **37**, 945—946).—Pharmacological experiments with α- and β-sodium tetrahydrosantonate (Wienhaus and von Oettingen, this vol., i, 474) show that they are not cramp poisons, neither do they act as vermicides. The reduction of the ethylene linking in santonin thus destroys its specific properties.
T. S. P.

p-Hydroxy-β-phenylethylamine, the Poison in the Salivary Gland of Cephalopods. MARTIN HENZE (*Zeitsch. physiol. Chem.*, 1913, **87**, 51—58).—p-Hydroxy-β-phenylethylamine is shown to be the only poisonous constituent of the saliva of the octopus. This base, which had previously been obtained by Barger and Dale from ergot (A., 1909, ii, 689), is thus, like adrenaline, the product of metabolism in a gland.   E. F. A.

Chemistry of Vegetable Physiology and Agriculture.

The Resistance of Spores to Heating in Anhydrous Fluids such as Glycerol and Similar Substances. HOWARD BULLOCK (*J. Hygiene*, 1913, **13**, 168—177).—The method at present in use for the sterilisation of glycerol or oil are quite inadequate; the heating of these fluids has no greater effect than the same temperature in the air. To sterilise these fluids, a temperature of 170° for half an hour or 180° for ten to fifteen minutes is necessary.   W. D. H.

Bacterial Metabolism. XI. Estimation of Urea Nitrogen in Cultures of Certain Bacteria. ARTHUR I. KENDALL and ARTHUR W. WALKER (*J. Biol. Chem.*, 1913, **15**, 277—282).—Urea nitrogen estimated by Folin's method is probably not all due to urea. In bacteria the main nitrogenous end-product of metabolism is ammonia. The urea nitrogen in the culture fluid does not alter.   W. D. H.

Bacterial Metabolism. XIII—XXX. ARTHUR I. KENDALL, ALEXANDER A. DAY, and ARTHUR W. WALKER (*J. Amer. Chem. Soc.*, 1913, **85**, 1201—1249).—An investigation of the effect

of utilisable carbohydrate on the metabolism of protein and protein derivatives by bacteria. The media used consisted of a prepared broth containing meat juice and peptone, and a mixture of the same broth with 1% of dextrose. Four flasks of the sugar-free and of the sugar-containing broths were inoculated with the desired organism and incubated at 37°, the progress of the action being followed by examination of the contents of the flasks over a period of nine days. Determinations were made of the free ammonia, the total nitrogen, the acidity resulting on the addition of formaldehyde, and the acidity or alkalinity of the liquid, using alizarin, neutral red, and phenolphthalein as indicators.

Seventeen groups of bacteria were submitted to examination, and the results are tabulated in the original. D. F. T.

Disinfecting Value of Mercuric Oxycyanide and of Mercuric Oxycyanide Containing Mercuric Cyanide. H. KÜHL (*Arch. Pharm.*, 1913, 251, 340—349).—In general, a solution of a poison at extreme dilution promotes the growth of lower vegetable organisms; at a definite, greater concentration of the poison, the multiplication of the organisms is retarded, whilst at still greater concentrations the poison exerts its lethal action. The author has examined the action on *Bacillus coli* of two samples of mercuric oxycyanide, one practically pure (99%), the other containing 33·3% of oxycyanide and 66·6% of mercuric cyanide. At concentrations of 1 in 200,000 to 1 in 400,000 it is found that solutions of both samples approximately double the rate of growth of the bacilli.

The retarding action of the two disinfectants on the growth of organisms is shown in two ways. Milk coagulates when it contains 0·0005% of either of the two samples, but does not do so when the amount of the poison is increased to 0·005%. In the second set of experiments, urine containing 0·01—0·2% of either of the poisons remains unchanged under the conditions in which the urine alone becomes turbid and evolves ammonia.

Experiments on pure cultures of *Staphylococcus pyogenes*, on raw milk, on tuberculous milk, and on the contents of the stomach and of the intestines and on the brains of a decomposed corpse lead to the astonishing result that there is no appreciable difference in the bactericidal value of the two samples under examination. Another series of comparative experiments shows that the disinfecting value of mercuric oxycyanide is almost equalled by that of a mixture of the oxycyanide and sodium chloride containing 33·3% of the latter. A fuller treatment of the subject is promised; at present the author is of opinion that the sodium chloride, as a disinfectant, slightly active accentuates the bactericidal value of the mercuric oxycyanide by promoting the absorption of the latter substance by the protoplasm. C. S.

Biochemical Reactions of Diphtheria-like Organisms. T. G. M. HINE (*J. Path. Bact.*, 1913, 18, 75—80).—The chief point urged is that the diphtheria-like bacilli, *B. diphtheriae*, alone gives acid with dextrose and dextrin, and not with sucrose. W. D. H

The Inhibition of the Cholera-Red Reaction by Certain Nitrite-destroying Organisms, and on the Mutual Inhibition of B. dysenteriæ (Flexner) and V. choleræ when Grown together. W. J. LOGIE (*J. Hygiene*, 1913, **13**, 162—167).—Certain nitrite-destroying organisms when grown along with *V. cholerae* prevent the appearance of the cholera-red reaction. This is not due to the non-formation of nitrite, but to its rapid destruction by the nitrite-destroying organisms. There are, on the other hand, certain nitrite-destroying organisms which fail to prevent the cholera-red reaction. In the case of *B. dysenteriae* the failure to prevent the cholera-red reaction is due to an inhibition of the growth of both organisms when grown together.   W. D. H.

Spore-producing Bacillus lactis fermentens, a Ferment Producing Butylene Glycol from Lactose. RUOT (*Compt. rend.*, 1913, **157**, 297—299).—*Bacillus lactis fermentens* is a very mobile, anaerobic bacillus, which produces spores after three days on gelose at 30°, which resist a temperature of 90° for five minutes, and can be heated at 100° for half a minute without being killed. It ferments dextrose, sucrose, lactose, mannitol, and glycerol, the products from the sugars being carbon dioxide, hydrogen, alcohol, butylene $\beta\gamma$-glycol, acetylmethylcarbinol, and formic and acetic acids, no lactic or succinic acids being found. The fermentation of milk by this bacillus is very rapid, the products being as above.
                                W. G.

Isolation of B. typhosus from Fæces by means of Brilliant-Green. C. H. BROWNING, W. GILMAN, and T. J. MACKIE (*J. Path. Bact.*, 1913, **18**, 146—148).—The method described is based on the observation that brilliant-green exerts a much more marked inhibitory effect on *B. coli* than on *B. typhosus*.   W. D. H.

Bactericidal Action and Chemical Constitution with Special Reference to Basic Benzene Derivatives. C. H. BROWNING and W. GILMAN (*J. Path. Bact.*, 1913, **18**, 144—146).—*Staphylococcus aureus* and *B. anthracis* are more susceptible to basic benzene derivatives than are organisms of the *Coli* group. It is not possible to differentiate generally that gram-positive organisms are susceptible, and gram-negative organisms are not susceptible to crystal-violet. Salts of the heavy metals do not act less powerfully on the coli-typhoid group than on *S. aureus* and *B. anthracis*. Preliminary details are given of the effects of substituting radicles in benzene derivatives on their bactericidal power; and on the effect of serum on bactericidal action.   W. D. H.

Influence of Ozone on Yeast and Bacteria. CARL A. NOWAK (*J. Ind. Eng. Chem.*, 1913, **5**, 668).—Results of experiments with bottom-fermentation yeast showed that ozonisation is not only of value in freeing the yeast from objectionable organisms which are susceptible to the action of ozone to a larger degree than the yeast itself, but also in eliminating the weakened cells and stimulating the fermentative power of the surviving ones.   W. P. S.

Influence of Mineral Salts on Alcoholic Fermentation. Salts of Tin and Bismuth. MARIUS EMMANUEL POZZI-ESCOT (*Bull. Assoc. chim. Sucr. Dist.*, 1913, **31**, 49—53).—Stannous chloride even in small amounts retards fermentation. Yeast can be acclimatised so as to ferment well in presence of considerably more stannous chloride than will retard fermentation with ordinary yeast; the yeast, however, rapidly degenerates. Stannic chloride is much more toxic than stannous chloride.

With regard to bismuth, the basic nitrate, with which Gimel obtained favourable results, is quite insoluble when washed with hot water. N. H. J. M.

The Enrichment of the Invertase Content of Living Yeasts. JAKOB MEISENHEIMER, STEFAN GAMBARJAN, and L. SEMPER (*Biochem. Zeitsch.*, 1913, **54**, 122—154).—The effect of allowing various yeasts to remain in contact with various sugars on their content in invertase was investigated. It was found that the amount largely increased by this treatment. Large quantities of the organism were allowed to remain for one to two days in sucrose solutions, which were then cooled on ice, and poured off. A portion of the yeast was then removed, the juice expressed and treated with acetone. The invertase reaction constant of this preparation was then determined. The main portion of the yeast was again treated in a similar way, and the reaction constant of a portion also determined; the main bulk was again treated with sugar, and these processes repeated until the yeast was exhausted. During these successive treatments the invertase content increased, although the zymase content diminished. The relative influence of various sugars on the increase of invertase content was also investigated. In the majority of cases, the yeasts were allowed to grow in a Lindner solution, to which was added the various sugars. It was found that in most of the experiments invert sugar and lævulose caused a larger increase in the invertase than dextrose or sucrose. The lævulose was generally more effective than the invert sugar, and the sucrose slightly more effective than dextrose. The results may possibly be explained on the assumption that a lævulose-invertase combination is somewhat more stable than the combination of invertase with other sugars, and the ferment is thereby more efficiently guarded against change during the autolysis of the yeast. S. B. S.

The Dominance of Roquefort Mould in Cheese. CHARLES THOM and JAMES N. CURRIE (*J. Biol. Chem.*, 1913, **15**, 249—258).—The low percentage of oxygen in the open spaces within the cheese accounts for the dominant activity of *Penicillium roqueforte* in Roquefort and similar cheese. Gas analyses from cultures of various kinds of moulds are presented. W. D. H.

Phenomena of Imbibition in the Seeds of Avena sativa. F. PLATE (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 133—140).—From experiments with solutions of potassium, sodium, barium,

and calcium hydroxides, and of hydrochloric, nitric, sulphuric, and phosphoric acids, the author finds that both cation and anion have specific functions in regard to this phenomenon. The solutions accelerate germination, and considerable concentrations do not spoil germination, but even favour it.   R. V. S.

Compounds Obtained from Plant Seeds by the Methods for Extracting Lecithin. IV. Peas, Larch, Rice. , GEORG TRIER (*Zeitsch. physiol. Chem.*, 1913, **86**, 407—414).—Peas contain rather over 1% of lecithin. This yielded galactose on acid hydrolysis and colamine when hydrolysed with barium hydroxide.

The lecithin from larch seeds contained about 3·3% of phosphorus, 0·75% of nitrogen, and 4% of galactose.

Rice which had not been deprived of the husk yielded a lecithin compound having the properties of a cerebroside.   E. F. A.

Distribution of Carboxylase in Plants. W. ZALESKI (*Ber. deut. bot. Ges.*, 1913, **31**, 349—353).—Carboxylase was found in various seeds, such as peas, lupines, *Vicia Faba*, wheat, and maize, in etiolated seedlings, and in moulds.

Although anærobic, carboxylase is active in presence of oxygen; and some of these substances decompose pyruvic acid equally well in air and in hydrogen. Some, however, such as ripening pea seeds, fail to decompose pyruvic acid in presence of air, whilst they are very active in a vacuum. The stem points of *Vicia Faba* decompose pyruvic acid in presence of air if previously extracted with methyl alcohol.   N. H. J. M.

Chemical Composition of Cooked Vegetable Foods. KATHARINE I. WILLIAMS (*J. Ind. Eng. Chem.*, 1913, **5**, 653—656).— Analyses of cooked vegetables, cereals, and leguminous seeds, etc., are recorded (compare P., 1903, **19**, 26).   W. P. S.

Chlorophyll Assimilation. K. VON KŐRÖSY (*Zeitsch. physiol. Chem.*, 1913, **86**, 368—383).—In acacia leaves immersed in nutritive fluids the assimilation of starch and sugar was about 10%, but the fat in the leaves was not increased.   W. D. H.

Composition of the Fruit and Seeds of Adansonia digitata. RUSSELL GEORGE PELLY (*J. Soc. Chem. Ind.*, 1913, **32**, 778—779). —The seeds of the baobab tree (*Adansonia digitata*) consist of a very tough husk enclosing a soft, oily kernel, devoid of starch. Analysis gave, in percentages: moisture, 12·1; ash, 3·5; oil, 11·6; protein (total nitrogen multiplied by 6·25), 11·2; fibre, 22·5; carbohydrates (by difference), 39·1. The ash of the kernels contained: potash, 31·0; soda, 7·2; and phosphoric acid, 34·2%. The oil as extracted by light petroleum had D_{15}^{15} 0·915, saponification value, 190·5—191·7, and iodine value (Hübl, seventeen hours), 76·7—77·8. The seeds are free from alkaloids and cyanogenetic glucosides.

The fruit pulp gave: moisture, 15—16%; ash, 4·76—6·10%;

matter soluble in alcohol, 16·7—18·7%. The ash consisted largely of alkali carbonates, and contained: silica, 4·74; lime, 8·88; potash, 48·90; soda, 4·20; and phosphoric acid, 1·08%. The pulp consisted largely of pectous matter. The free acid extracted by 95% alcohol was found to be citric acid; no indications of tartaric acid were obtained, but small amounts of malic acid may be present. The pulp also contains an acid or acids of the pectic type, possibly present as acid potassium salts and insoluble in alcohol.   T. S. P.

Application of the Biochemical Method to the Detection of Sucrose and Glucosides in Certain Ericaceæ. ÉMILE BOURQUELOT and (Mlle.) A. FICHTENHOLZ (*J. Pharm. Chim.*, 1913, [vii], 8, 158—164).—The presence of sucrose, of a β-glucoside which is hydrolysed by emulsin, and of invertase and emulsin is demonstrated in *Arbutus unedo, Arbutus Menziezii, Azalea mollis, Calluna vulgaris, Kalmia latifolia*, and *Vacinium myrtillus*.   E. F. A.

Plant Chemistry. P. Q. KEEGAN (*Chem. News*, 1913, 108, 61—62. Compare A., 1912, ii, 1085).—A brief résumé and discussion of our present knowledge of the occurrence and composition of the bitter principles, fat-oils, and oxydases in plants, special reference being made to analyses of the bearberry (*Arbutus uva-ursi*).   W. G.

The Nature of the Sugar Found in the Tuber of Arrowhead. K. MITAKE (*J. Biol. Chem.*, 1913, 15, 221—229).—Dextrose, lævulose, and sucrose were found; galactose and raffinose are doubtful; maltose, pentose, and mannose are absent.   W. D. H.

Capoc Seeds and Capoc Oil. HERMANN MATTHES and HEINRICH HOLTZ (*Arch. Pharm.*, 1913, 251, 376—396).—Capoc seeds, obtained from *Eriodendron anfractuosum* and other trees and plants allied to the *gossypium*, contain 7·5% of water, 25·6% of fatty oil, and 5·6% of ash; the last consists essentially of potassium phosphate, and contains also considerable quantities of calcium, magnesium, and sulphuric acid. Capoc oil, which is expressed from the seeds, is a pale yellow, viscous liquid, having a faint, pleasant odour and taste; after long keeping it deposits solid constituents. It resembles cotton-seed oil, with which it is often adulterated. The oil has D^{15} 0·9218, n^{40} 1·4630, and is optically inactive. It has iodine number 88·7 (93·3) [the numbers in brackets are the values given by a capoc oil extracted from the seeds by petroleum], acid number 21·6 (3·4—4·6), saponification number 192·3 (196·3), Reichert-Meissl value 0·8, and Polenske value 0·14—0·34. The m. p. of the fatty acids (Hehner's method) is 34—35° and the solidifying point 28—30°, the values of the m. p. and of the solidifying point being 36° and 31—32° respectively after the acids have been freed from phytosterol. The very high m. p. of the fatty acids serves to identify capoc oil in the presence of other oils, as also do Halphen's reaction Milliau's modification of Becchi's reaction, and the nitric

acid test. The behaviour of the oil with Welman's, Serger's, and Kreis's reagents, and in the elaidic acid test is also described. Capoc oil is a drying oil, but does not become hard even after four months' exposure.

Capoc oil consists essentially of the triglycerides of palmitic, oleic, and linolic acids. The fatty acids are 26—28% palmitic acid and 72—74% liquid acids (40% linolic acid and 60% oleic acid); volatile acids are present only in small quantity. The oil contains 1·04% of unsaponifiable matter.

The crude phytosterol obtained from the oil contains 74% of reddish-brown, slightly dextrorotatory liquid constituents (iodine number 74·7), and 26% of a solid *phytosterol*, m. p. 136°, $[\alpha]_D - 29·97°$ in alcohol and ether (*acetate*, m. p. 126°, needles).

C. S.

Presence of Quinine in the Seed of Cinchona Ledgeriana (Moens). P. VAN LEERSUM (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **16**, 153—155).—In order to investigate the formation of quinine in *Cinchona* the author has examined the seeds of *C. Ledgeriana*. The finely powdered seed was first extracted with light petroleum, which removed a pale green oil, D^{18} 0·930, $[\alpha]_D^{20} - 26°$, which formed 18·6% of the material, and then digested with lime and sodium hydroxide and extracted with benzene. The total alkaloid so obtained (about 0·38% of the dry seed) was purified, and finally concentrated as the hydrochloride on a microscope slide, when quinine was detected by the herapathite reaction (compare A., 1905, ii, 620).   J. C. W.

The Availability of Glucosamine Hydrochloride as a Source of Nitrogen for the Nutrition of Maize (Zea Mays) and Beans (Phaseolus multiflorus). MARSTON LOVELL HAMLIN (*J. Amer. Chem. Soc.*, 1913, **35**, 1046—1049).—When, for the purpose of comparison, the above-named plants were grown in an ordinary culture solution, in a nitrogen-free solution and in a solution containing glucosamine hydrochloride as the sole source of nitrogen, it was invariably found that the glucosamine had a deleterious effect, and caused withering.

It is evident, therefore, that under the conditions of the experiment, glucosamine cannot be utilised as a source of nitrogen for nutrition.   D. F. T.

A New Species of Prostanthera and its Essential Oil. R. T. BAKER and HENRY G. SMITH (*J. Roy. Soc., New South Wales*, 1913, **46**, 103—110).—The stalks and leaves of the new shrub, for which the name *Prostanthera cineolifera* is proposed, yield 0·71% of a yellow oil, which rapidly darkens on exposure to light. The crude oil has D^{15} 0·9204, n^{22} 1·4711, and is soluble in 1·7 volumes of 70% alcohol. After removal of phenols and aldehydes, the cleared oil has D^{15} 0·9199; n^{22} 1·4706, $\alpha_D + 4·1°$. Saponification number of ester + free acid = 9·9 by boiling and 8·5 by cold saponification with two hours' contact; saponification number after acetylation 34·2 by

boiling, 18·3 by cold saponification. It is probable that the principal ester in the oil of this plant is geranyl acetate, constituting 2·9% of the crude oil. The isolation of geraniol was not, however, practicable owing to the small quantity of oil obtainable. The phenols present constitute 0·65% of the oil, and are composed of carvacrol and thymol. Cuminaldehyde is present to the extent of 0·142%.

The main constituents of the oil are cineole (61 per cent.) and cymene. A small quantity of a dextrorotatory terpene, probably pinene, is also present, whilst, by the action of alcoholic potassium hydroxide on the portion of the oil boiling above 224°, a substance is obtained which is possibly a sesquiterpene, but the amount of which is insufficient for identification.   H. W.

Condition of Soil Phosphoric Acid Insoluble in Hydrochloric Acid. WILLIAM H. FRY (*J. Ind. Eng. Chem.*, 1913, 5, 664—665).— Whilst it is probable that soils may contain small quantities of phosphoric acid compounds which are not soluble in hydrochloric acid, mineralogical analyses have shown that a very large number of soils contain apatite (a soluble phosphate) enclosed in quartz grains. The quartz acts as a protective coating, and the phosphate is apparently insoluble in hydrochloric acid.   W. P. S.

Organic Soil Constituents in their Relation to Soil Fertility. OSWALD SCHREINER (*Eighth Inter. Cong. App. Chem.*, 1912, 15, 231—245).—In water-culture experiments with wheat, it was shown that creatinine, creatine, hypoxanthine, arginine, histidine, and nucleic acid are all assimilated, both when supplied as the only source of nitrogen and in presence of nitrate. When nitrates are present in addition to the organic compounds, there is a decrease in the amount of nitrate assimilated as compared with the amount when nitrate alone is supplied. The lowest decrease in nitrate absorbed was 17% with creatine, and the highest, 45%, with hypoxanthine. Further experiments on the effect of histidine, creatinine, and asparagine, used singly and together, showed increased growth with the single substances, in the order as given; and a further increase when all were present simultaneously, although the amount of nitrogen supplied was the same.   N. H. J. M.

Organic Phosphorus in the Soil. JOHN STEWART (*Eighth Inter. Cong. App. Chem.*, 1912, 15, 273—300).—The Grandeau method for estimating organic phosphorus in soils gives somewhat low results, since some of the phosphorus dissolves in the acid, and some remains undissolved after treatment with alkali. The method is, however, one of the best hitherto proposed.

The iron and aluminium of humus are organically combined, except the small amount in colloidal form.

The decaying organic matter of soils interacts with the phosphates present with production of various organic compounds containing phosphoric acid and the different bases. Acid and basic mineral phosphates are probably found as intermediate products.

Barium chloride, magnesia mixture (both in alkaline solutions), phenylhydrazine in faintly acid solution, and ammonium hydroxide in presence of sufficient iron or aluminium, reprecipitate inorganic phosphorus quantitatively in presence of organic matter, in some cases at least. No precipitate is formed in absence of organic matter.   N. H. J. M.

Biochemical Factors in Soils. MICHAEL X. SULLIVAN (*Eighth Inter. Cong. Appl. Chem.*, 1912, 15, 305—312).—The oxidising power of soils, as indicated by aloin, is greater in productive than in less productive soils, and in surface soils as compared with subsoils. The catalytic power of soils shows similar differences.

It is evident from the presence of such compounds as histidine, arginine, and cytosine, that soils contain enzymes, either intra- or extra-cellular. No soil extract has hitherto been found to contain diastatic, inverting, lipolytic, proteolytic, oxidising, or catalysing enzymes; and it has been found that when diastase is added to soil it is either fixed or destroyed in a few days.

The oxidising and catalysing powers of soils are probably due to the inorganic and organic substances rather than to enzymes. Both properties are retained for years by air-dried soils. Many substances present in soils result from the metabolism of micro-organisms. In mould cultures, fatty acids, especially oleic and palmitic acids, purine bases, such as guanine, adenine, and hypo-xanthine, histidine, and probably thymine, are present.
                                                              N. H. J. M.

Increasing the Manurial Action of Cyanamide under the Influence of Ferric Oxide. ALBERT STUTZER (*Eighth Inter. Cong. App. Chem.*, 1912, 15, 301—304).—The results of pot experiments with oats grown in sandy loam showed that the manurial value of cyanamide is increased by addition of molasses, owing to the increased production of carbon dioxide in the soil.

In further experiments, it was found that addition of ferric oxide, in the form of bog ore, greatly increased the yield of oats. It was found that ferric oxide accelerates the production of carbamide from cyanamide, and there may be a stimulating action in addition.

As a rule, 50 kilos. of bog ore per hectare will suffice.
                                                              N. H. J. M.

Boron as Catalytic Manure. HENRI AGULHON (*Eighth Inter. Cong. App. Chem.*, 1912, 15, 9).—In pot experiments with peas, haricots, beet, and radish, the yields were increased by boric acid up to 34%. In field experiments with oats, the yield was increased by 54% when 1·5 kilo. of boric acid per hectare was applied. Applications of 20—50 kilos. were found to be too much for wheat, oats, maize, lucerne, peas, colza, and lupines; the yields, weighed fresh, were frequently increased without any gain in dry matter.
                                                              N. H. J. M.

Organic Chemistry.

Preparation of Hydrocarbons with Two Conjugated Double Linkings. FARBENFABRIKEN VORM. FRIEDR. BAYER & Co. (D.R.-P. 261642).—When $\alpha\gamma$-glycols of the general formula

$$\text{RRC(OH)·CHR·CR(OH)·CHRR}$$
(where R is an alkyl group or hydrogen) are heated with agents that withdraw water, they furnish compounds of the general formula

$$\text{RRC:CR·CR:CRR.}$$

Butane-$\alpha\gamma$-diol when heated with 30% sulphuric acid at 170—180° yields a 10% yield of erythrene; with phosphoric acid at 300° the yield is 60%, and with magnesium sulphate at 300—400° about 50%, whilst β-methylbutane-$\beta\delta$-diol with potassium hydrogen sulphate at 160—170° gives rise to a 20% yield of isoprene.

$\alpha\alpha$-Dimethylerythrene, b. p. 74°, is obtained in 40% yield from β-methylpentane-$\beta\delta$-diol at 160° with aluminium chloride.

<div align="right">F. M. G. M.</div>

Diisobutenyl from Tribromoisobutane. VL. KRESTINSKI and K. KRIVOROTKO (*J. Russ. Phys. Chem. Soc.*, 1913, 45, 946—949).—The action of magnesium on $\alpha\beta\gamma$-tribromoisobutane, $\text{CH}_2\text{Br·CMeBr·CH}_2\text{Br}$ (compare Pogorshelski, A., 1905, i, 315), in presence of ether and treatment of the product obtained with water, yields, as principal product, $\beta\epsilon$-dimethyl-$\Delta^{\alpha\epsilon}$-hexadiene, $\text{CH}_2\text{:CMe·CH}_2\text{·CH}_2\text{·CMe:CH}_2$, D^{20} 0·7512, n_D^{20} 1·4309 (compare Pogorshelski, A., 1899, i, 785). Treatment of the latter with hydrogen bromide yields the $\beta\epsilon$-dibromo-$\beta\epsilon$-dimethylhexane, $\text{CMe}_2\text{Br·CH}_2\text{·CH}_2\text{·CMe}_2\text{Br}$, m. p. 68°.

<div align="right">T. H. P.</div>

Preparation of Halogen Derivatives of the Paraffin Series. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 261677, 263716).—A satisfactory yield of chlorinated or brominated hydrocarbons is obtained by mixing the parent hydrocarbons in a gaseous condition with the vapour of the required halogen. Mixtures of chloro- and dichloro-, and of bromo- and dibromo-hexane were thus obtained; chloroisopentane furnished $\alpha\beta$-dichloro-β-methylbutane, whilst chloropentane gave rise to a *dichloropentane*, b. p. 130—150°. In the second patent it is shown that the halogenation can be effected by means of the silent electric discharge; thus n-pentane furnishes a mixture of α- and γ-chloropentane.

<div align="right">F. M. G. M.</div>

Addition of Bromine to Chlorinated Olefines. WALTHER HERZ and W. RATHMANN (*Ber.*, 1913, 46, 2588—2590. Compare this vol., ii, 26, 765).—The reactions between bromine and di-, tri-, and tetra-chloroethylene have been studied. Known quantities of the two substances, with or without diluents, were sealed up in test-tubes of dark brown glass, and kept at 25° for different intervals, when the tubes were broken under potassium iodide and the unabsorbed bromine

titrated. By employing a large excess of hydrocarbon the reaction could be expressed in the form, $1/t \log a/(a-x)$, where a is the initial concentration of bromine and x the amount absorbed after the time t.

cis-Dichloroethylene was found to absorb bromine nearly twice as fast as the *trans*-modification. No constant values could be obtained in the case of trichloroethylene, but *aaβ-trichloro-aβ-dibromoethane* was isolated as a pale yellow, pungent smelling liquid, b. p. 126°/85 mm. The influence of diluents was studied in the case of tetrachloroethylene.

<div align="right">J. C. W.</div>

The Action of Sodium Ethoxide on Tetranitromethane. A Caution. ALEXANDER K. MACBETH (*Ber.*, 1913, **46**, 2537—2538; *Chem. World*, 1913, **2**, 328).—The addition of sodium ethoxide to tetranitromethane may give rise to serious explosions.

In an experiment in which 30 grams of tetranitromethane were being treated with an alcoholic solution of sodium ethoxide, the formation and separation of the sodium derivative of trinitro-methane appeared to be proceeding in a normal manner when a violent explosion occurred doing serious damage to the experimenter and to the laboratory.

<div align="right">D. F. T.</div>

Mechanism of the Reactions between Alcohols and Mineral Acids. Oxonium Compounds of Hydrogen Haloids. ALEXEI E. FAVORSKI (*J. pr. Chem.*, 1913, [ii], **88**, 480—495. Compare McIntosh, T., 1904, **85**, 919; 1905, **87**, 784; A., 1905, i, 254, 677; 1906, i, 481, and Mokievski, A., 1899, i, 729).—Di*iso*propylcarbinol, ethyl*tert.*-butylcarbinol, and *iso*propyl*tert.*-butylcarbinol (this vol., i, 12) readily form with hydrogen haloids, crystalline oxonium salts of the following types:

$$(\text{I.}) \quad {\substack{R\\H}}{>}O{<}{\substack{H\\X}} \qquad (\text{II.}) \quad {\substack{R\\H}}{>}O{\diagup}^{\!H\ H}\!\!\!\!\diagdown O{<}{\substack{R.\\X}}$$
The compounds of the second type are the more stable, and are obtained by the action of the hydrogen haloid on the alcohols at 0° or the ordinary temperature; at lower temperatures compounds of the first type are produced. The oxonium compounds derived from glycols (Mokievski, *loc. cit.*) and diethylene ether are formulated as follows:

$$\begin{array}{c} CH_2 \cdot O {<}{\substack{H\\H}} \\ | \\ CH_2 \cdot O {<}{\substack{H\\X}} \end{array} \quad \text{and} \quad \begin{array}{c} CH_2 \cdot OH \cdot CH_2 \\ | \qquad | \qquad | \\ CH_2 \cdot OX \cdot CH_2 \end{array}.$$
The author considers that the intermediate formation of oxonium compounds of this kind must be taken into account in explaining the mechanism of all reactions in which alcohol and mineral acids simultaneously take part, and illustrates his views by reference to the formation of ethers and hydrocarbons by the action of acids on alcohols, and the transformation of glycols into ketones and aldehydes under the influence of acids.

[With ANNA I. UMNOVA.]—The *compounds* of di*iso*propylcarbinol with hydrogen iodide and hydrogen bromide, $2C_7H_{15} \cdot OH, HX$,

separate in colourless crystals, m. p. 77—78° and 68—69° respectively, by passing the hydrogen haloids into the carbinol at the ordinary temperature; the corresponding *hydrochloride* is very hydroscopic.

[With P. Aschmarin.]—The following *compounds* of ethyl *tert.*-butylcarbinol are described: $2C_7H_{15}\cdot OH,HI$, m. p. 74—76°; $2C_7H_{15}\cdot OH,HBr$, m. p. 52—54°; $C_7H_{15}\cdot OH,HBr$, m. p. 13—17°; $C_7H_{15}\cdot OH,HCl$, m. p. 23—25°; $2C_7H_{15}\cdot OH,HCl$.

[With Ernst Fritzmann.]—The compounds of *iso*propyl*tert.*-butylcarbinol with hydrogen iodide, $2C_8H_{17}\cdot OH,HI$, and hydrogen bromide, $2C_8H_{17}OH,HBr$, have m. p. 78—80° and 77—78° respectively.

F. B.

The Spacial Arrangement of the Hydroxyl Groups of Polyhydroxy-compounds. The Configuration of the Saturated Glycols and of α- and β-Dextrose. Jacob Böeseken (*Ber.*, 1913, 46, 2612—2627).—The influence of hydroxy-compounds on the conductivity of boric acid solutions is set forth in a series of experiments, most of which have already been described (this vol., ii, 147; i, 742). The main conclusion arrived at by the author, that exaltation of the conductivity is caused by those compounds in which two hydroxyl groups attached to neighbouring carbon atoms are also in the same plane, thus permitting the formation of ring combinations with the boric acid, is further exemplified and extended to the determination of the configuration of saturated glycols and of α- and β-dextrose. Saturated glycols have no positive influence, and therefore the hydroxyl groups are arranged on opposite sides of the neighbouring carbon atoms. Alcohols with more than two hydroxyl groups are likely to have some pair or other in the favourable position, and glycerol, erythritol, β-nitro-αγδ-trihydroxy*iso*butane, pentaerythritol, mannitol, dulcitol, and sorbitol have positive influences in increasing degrees.

α- and β-Methylglucosides, sucrose, and raffinose have no pair of hydroxyl groups in the favourable position, and have only a minimal, negative influence on boric acid. α-Dextrose has a greater influence than β-dextrose, and the sugars are therefore represented by the formulæ I. and II. respectively, α-dextrose possessing one pair of neighbouring hydroxyl groups on the same side of the plane of the ring.

(II.) \quad O\diagdown & HC\cdot OH \\
& OH\cdot CH \\
& HC\cdot OH
\end{array}
$$
The gradual fall in the conductivity of α-dextrose–boric acid and the rise in conductivity of β-dextrose–boric acid coincide with the mutarotation, and the constants for the mutarotation and the alteration in

conductivity are equal. If the mutarotation were accompanied by the opening of the ring, a chain of five labile hydroxyl groups would be formed, and the conductivity of the boric acid solution would be increased. The fact that this does not happen supports E. F. Armstrong's view that mutarotation takes place without disturbing the γ-oxide ring (T., 1903, **83**, 1305).   J. C. W.

Conversion of Cellulose into Dextrose. HERMANN OST (*Ber.*, 1913, **46**, 2995—2998).—In reply to the interpretation placed by Willstätter and Zechmeister (this vol., i, 955) on the optical activity of the dextrose obtained by Ost and Wilkening (A., 1910, i, 364) from the hydrolysis of starch by sulphuric acid, the author maintains that the other experiments of the latter investigators supply final evidence that the yield of dextrose was in reality over 90% of the starch used, and attributes the low optical activity to the well known considerable effect of the presence of traces of impurity.   D. F. T.

Electrical Conductivity of Some Platinum Compounds of Organic Disulphides. LEO A. TSCHUGAEV and A. KOBLJANSKI (*Zeitsch. anorg. Chem.*, 1913, **83**, 8—26).—In order to avoid the complications introduced by water, the author has examined the conductivity of a large number of complex compounds in methyl alcohol. It is found that compounds of the type $[PtS''Cl_2]$, where S'' is a dithioether, are non-conducting, but that further addition of disulphide causes a rapid increase of conductivity. An equilibrium occurs: $[PtS''Cl_2] + S'' \rightleftharpoons [Pt2S'']Cl_2$, the latter compound then becoming ionised.

The compounds of ethylene-dithioglycol ethers have been compared with those from propylene-dithioglycol ethers. The platinum chloride compound of the *diethyl ether*, $[PtCl_2,C_3H_6(SEt)_2]$, crystallises in needles, m. p. 135°, and the *di-n-propyl ether* compound has m. p. 133°. It has not been found possible to prepare sufficiently pure compounds from aa- and $a\epsilon$-dithioglycol ethers, but the conductivity of mixed solutions of these sulphides with stable $a\beta$-compounds has been determined. The aa-dithio-ethers have the least tendency to form complexes.

The conclusions are in accordance with Werner's co-ordination theory.   C. H. D.

Compounds of Platinous Nitrite with Organic Dithio-ethers. LEO A. TSCHUGAEV and WITALIUS G. CHLOPIN (*Zeitsch. anorg. Chem.*, 1913, **82**, 401—419. Compare A., 1910, i, 354; 1912, i, 70).—Like the halogen compounds, platinous nitrite readily forms isomeric compounds with dithio-ethers. The bimolecular compound is the first product, and is more stable than in the case of the halogen compounds, so that the conversion into the unimolecular form takes place much less readily. The latter modifications are most readily obtained from the chlorides and soluble nitrites.

Diethyl ethylene dithioether and platinous nitrite form a *compound*, $[Pt2C_2H_4(SEt)_2]Pt(NO_2)_4$, m. p. 170—170·5°. It reacts with Reiset's chloride to form the yellow compound $[Pt4NH_3]Pt(NO_2)_4$. The former

compound is also obtained from the bimolecular chloride and sodium nitrite. The unimolecular *compound*, $C_2H_4(SEt)_2,Pt(NO_2)_2$, has m. p. 161—161·5°, and does not react with Reiset's chloride. Excess of the ether, together with potassium platinonitrite, convert it into the bimolecular modification.

Dimethyl ethylene dithioether and platinous nitrite yield the bimolecular *compound,* $[Pt2C_2H_4(SMe)_2]Pt(NO_2)_4$, m. p. 214·5—215°, which is slowly converted, even in the cold, into the unimolecular compound, m. p. 210·5—211°, by an excess of the ether.

The dipropyl dithioether also yields two *compounds*, m. p. 184·5—185° and 179—179·5° respectively, and the *compounds* from the di-n-butyl dithioether have m. p. 181—181·5° and 172—172·5° respectively.

Diethyl propylene dithioether yields a *compound* with m. p. 229—229·5°, the constitution of which is uncertain.

Diethyl β-hydroxypropylene $\alpha\gamma$-dithioether yields a sparingly soluble *compound*, m. p. 182—182·5° (decomp.), and probably bimolecular.

Dimethyl sulphide yields only a unimolecular compound with platinous nitrite, all attempts to prepare a bimolecular modification having failed. C. H. D.

Complex Compounds of Organic Sulphides with Quadrivalent Platinum. LEO A. TSCHUGAEV and J. BENEVOLENSKI (*Zeitsch. anorg. Chem.*, 1913, **82**, 420—425).—Isomerism has not hitherto been observed in compounds of quadrivalent platinum with organic sulphides. It is now found that compounds with two complex ions are obtained from hydrogen platinichloride and sulphides, but that their composition does not correspond with the expected formulæ.

Methyl sulphide and platinic chloride yield a precipitate with the empirical composition $Pt,2Me_2SCl_3$, which at 110—115° suddenly changes from red to yellow, yielding a mixture of two substances, which may be separated by means of chloroform. The less soluble compound, $PtCl_4,2Me_2S$, darkens from 150°, whilst the other,

$$PtCl_2,2Me_2S,$$
has m. p. 157°. The original compound is thus $[Pt,4Me_2S]PtCl_6$. A similar compound is obtained from diethyl ethylene dithioether.
C. H. D.

Formic Acid as a Solvent. OSSIAN ASCHAN (*Chem. Zeit.*, 1913, **37**, 1117—1118).—The solubilities of a number of inorganic salts and organic compounds in 95% formic acid are given. A wide range of metallic salts is found to dissolve in this acid, but not so freely as in water. Easily reduced salts are liable to decomposition, but, whereas iodine is liberated from sodium iodide in the cold, potassium iodide is stable. The acid decomposes pinene nitrosochloride and the salts of weak organic acids, and esterifies certain alcohols, such as borneol. With these exceptions, it is a useful solvent for many organic compounds, including in addition to bromo-carboxylic acids, for which it has already received frequent application, polycyclic hydrocarbons, terephthalic acid, uric acid, indigotin, and alizarin.

The acid is easily volatilised on the water-bath, and deposits large

crystals of many substances, as, for example, suberic acid, citric acid, α-bromocamphor, α-nitronaphthalene, and m-dinitrobenzene. It is now cheaper than glacial acetic acid, and usually exhibits a greater difference of solvent power between the hot and cold liquid, and, in spite of its blistering effect, it is deserving of more extensive application.   J. C. W.

Displacement of Acetic Acid from Solutions of its Salts by Carbon Dioxide Under High Pressure. VLADIMIR N. IPATIEV (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 992—994. Compare Ipatiev and Verchovski, A., 1909, ii, 564; 1911, ii, 716).—The author has investigated the action of carbon dioxide under a pressure of 50 atmospheres on aqueous solutions of various acetates, both at the ordinary temperature and at 90°. With 12% calcium acetate solution, crystalline calcium carbonate was precipitated in some cases, but not in others; in one instance, 1 gram of the carbonate was obtained from 50 c.c. of the acetate solution after seven days at 90°. In a similar manner barium acetate yields the carbonate, and copper acetate the basic carbonate, $CuCO_3,Cu(OH)_2,H_2O$, but no precipitate was obtained from nickel acetate, even after several months.   T. H. P.

The Action of Acetic Anhydride on Ferric and Chromic Nitrates. RUDOLF F. WEINLAND and HANS REIHLEN (*Zeitsch. anorg. Chem.*, 1913, **82**, 426—430).—The compounds described by Späth (A., 1912, i, 408) as normal ferric and chromic acetates are really acetates of the triferri-(chromi)hexa-acetato-base, and the method of preparation has no advantage over those usually adopted. Both compounds yield the characteristic platinichlorides.   C. H. D.

Production of Hydrocarbons from a Solution of Sodium Stearate by Electrolysis. H. T. F. RHODES (*Chem. News*, 1913, **108**, 201).—The production of hydrocarbons by the electrolysis of aqueous solutions of the salts of aliphatic acids increases in difficulty with increasing molecular weight of the acid, probably owing to the partial hydrolysis which occurs when the salts are dissolved in water. By employing a small current, however, the author has succeeded in electrolysing an aqueous solution of sodium stearate which had been acidified with acetic acid, and has obtained a hydrocarbon very similar in physical properties to paraffin wax. The substance could only be detected after the solutions had been preserved for some time, and could not be identified owing to the small yield.   H. W.

Oxidising Action of Potassium Permanganate in an Alkaline Medium on Normal, Saturated Fatty Acids. EVGENJI S. PRSHEVALSKI (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 891—905; *J. pr. Chem.*, 1913, [ii], **88**, 495—501. Compare A., 1911, i, 947).—The action of faintly alkaline potassiumpermanganate solution on various acids of the aliphatic series has been investigated.

With 1% permanganate solution, n-heptoic acid gives (1) valeric, butyric, and propionic acids; (2) a ketonic acid, probably
$$CH_3 \cdot [CH_2]_4 \cdot CO \cdot CO_2H,$$

m. p. 51—52°; (3) a dibasic dihydroxy-acid, $C_5H_8(OH)_2(CO_2H)_2$, and (4) adipic, glutaric, succinic, and oxalic acids. Under similar conditions, *n*-hexoic acid yields glutaric acid, in addition to the acids already mentioned (*loc. cit.*). *n*-Valeric acid gives butyric, propionic, oxalic, and succinic acids. At either 37—38° or 100°, *n*-butyric acid yields oxalic and propionic acids, whilst if 5% permanganate is used, β hydroxybutyric and *iso*malic acids are also formed. Propionic acid gives carbon dioxide and oxalic acid, and if the oxidation is carried out in a solution containing 5% of alkaline hydroxide, hydroxypropionic acid.

The results obtained show that the difficulty of oxidising normal fatty acids increases with the shortness of the carbon-atom chain (compare Margulies, A., 1894, i, 491), and that the products obtained vary with the conditions of oxidation. In every case oxidation takes place at two points of the carbon-atom chain: (1) at the carbon atom adjacent to the carboxyl group, the next lower fatty acid being formed, and (2) at the carbon atom next to the methyl group.

Since the dibasic acids obtained never contained the same numbers of carbon atoms as the original acids, but always one less, the methyl group must undergo oxidation to carboxyl and then to carbon dioxide.

That oxidation of two carbon atoms simultaneously in one molecule of an acid may take place is shown by the formation of a dihydroxy-dicarboxylic acid from *n*-heptoic acid. As intermediate products of these oxidations, hydroxy- and keto-acids are formed.

In view of the ready oxidisability of the methyl group, which is adjacent to a partly oxidised carbon atom, the possibility of the formation of acetic acid in these oxidations seems doubtful.

With *n*-butyric acid, oxidation is accompanied by isomerisation of the normal propyl group to the iso-group.   T. H. P.

Lignoceric Acid. HANS MEYER, LEO BROD, and WALTHER SOYKA (*Monatsh.*, 1913, **34**, 1113—1142).—Lignoceric acid is shown to occur in the "solid paraffin" fraction of tar distilled from Bohemian lignite. With a view to ascertaining whether lignoceric acid, $C_{24}H_{48}O_2$, has the normal structure it has been degraded to $C_{22}H_{44}O_2$ (A., 1904, i, 548; 1905, i, 405, 736), and attempts have also been made to synthesise it from normal behenic acid, $C_{22}H_{44}O_2$. The degradation product is not identical with behenic acid, and the synthetic product is not lignoceric acid, so that the latter cannot be the normal 24 carbon saturated fatty acid.

Lignoceric acid, $C_{24}H_{48}O_2$, m. p. 80—80·5°, prepared from ground-nut oil, on treatment with bromine in presence of amorphous phosphorus yields *a-bromolignoceric acid*, m. p. 68·5°, which crystallises in colourless rhombohedra and on treatment with sodium ethoxide in dry alcohol furnishes with some difficulty *a-ethoxylignoceric acid*, m. p. 61—62°, crystallising in slender, colourless needles. *Methyl a-bromo-lignocerate*, m. p. 46—47°, forms small, colourless crystals. The bromo-acid when boiled with potassium iodide in alcohol yields *a-iodolignoceric acid*, m. p. 74°, which forms small, colourless prisms from a mixture of light petroleum and acetic acid, and when treated with potassium

hydroxide furnishes a mixture of *a-hydroxylignoceric acid* (m. p. 92°, small crystals) with the *unsaturated acid*, $C_{24}H_{46}O_2$, m. p. 59°, which forms a crystalline mass. The latter acid on oxidation with permanganate yields oxalic acid and *isobehenic acid*, $C_{22}H_{44}O_2$, m. p. 75°. The latter crystallises in glancing pearly leaflets, and furnishes a *methyl* ester, m. p. 54°, as colourless leaflets, and a crystalline *lithium* salt, m. p. 210° (decomp.). Melting-point curves for mixtures (1) of behenic and *iso*behenic acids, and (2) of the methyl esters of the two acids are given.

Behenic acid, m. p. 82—84°, was prepared by the catalytic reduction of erucic acid, and converted successively into the chloride (leaflets, m. p. 73—75°); methyl ester, m. p. 55°; amide, m. p. 111°, and the latter reduced to docosyl alcohol by means of sodium in amyl alcohol and this was converted into docosyl iodide, m. p. 46°. The latter was condensed with ethyl malonate to *docosylmalonic acid*, and this heated until carbon dioxide was no longer evolved when it yielded a *tetracosanic acid*, $C_{24}H_{48}O_2$, m. p. 85·5—86°, crystallising in pearly leaflets, and furnishing a *methyl* ester (m. p. 59·5—60°, glancing scales), a crystalline *lithium* salt, and an *a-bromo*-derivative, m. p. 73·5°, the *methyl* ester of which has m. p. 57°, and crystallises in glancing leaflets. Melting-point curves and tables for mixtures (1) of synthetic tetracosanic acid and lignoceric acid, and (2) of the methyl esters of these two acids are given.

In the synthesis of the tetracosanic acid the principal product is a *ketone*, $C_{47}H_{94}O$, which was not further characterised.

The synthetic method described was also used in preparing arachidic acid, m. p. 77°, from octadecyl iodide (compare Baczewski, A., 1897, i, 11). Melting-point curves for mixtures of lignoceric acid with (*a*) arachidic acid, (*b*) stearic acid, and (*c*) palmitic acid are given.

T. A. H.

Montanic Acid. HANS MEYER and LEO BROD (*Monatsh.*, 1913, **34**, 1143—1157. Compare Easterfield and Taylor, T., 1911, **99**, 2302).—Montanic acid has been exhaustively examined and purified by methods described in detail in the original, and shown to have the formula, $C_{28}H_{56}O_2$, first suggested by Ryan and Dillon (A., 1909, i, 629). A number of its derivatives are described.

Montanic acid melts at 85° and crystallises from acetic acid in small, pearly leaflets. The *chloride*, m. p. 67·5—68·5°, forms masses of leafy crystals and is readily soluble in benzene or petroleum. The *amide*, m. p. 112°, separates from alcohol as a crystalline powder. *a-Bromomontanic acid*, m. p. 77°, forms colourless scales from a mixture of acetic acid and light petroleum; with sodium ethoxide in alcohol, it yields *a-ethoxymontanic acid*, m. p. 71—72°, crystallising from acetic acid in colourless scales, and with ethyl alcohol in presence of mineral acids, *ethyl bromomontanate*, m. p. 62—63°, which forms colourless leaflets from alcohol. Attempts to eliminate hydrogen bromide and form the corresponding unsaturated acid were successful. T. A. H.

Ground-nut (Earth-nut) Oil. HANS MEYER and ROBERT BEER (*Monatsh*, 1913, **34**, 1195—1208).—The numerous researches already

conducted on the composition of ground-nut oil render it probable that it contains glycerides of arachidic, lignoceric, oleic and linoleic acids, and leave doubtful the presence of glycerides of palmitic, stearic, and hypogaeic acids. The authors confirm the occurrence in the oil of glycerides of the four first-named acids and also of palmitic acid, but they were unable to find any evidence of stearic or hypogaeic acid in the fatty acids prepared from the oil (compare Franz, *Diss.*, München, 1910). The supposed stearic acid obtained by Hehner and Mitchell's method (A., 1897, ii, 289) lowers the melting point of stearic acid and in reality consists of a mixture of arachidic and lignoceric acids. No trace of dihydroxypalmitic acid could be found in the oxidation products from the unsaturated fatty acids of ground-nut oil so that hypogaeic acid cannot be a constituent of these acids. Tables and curves of the melting points of mixtures of arachidic acid with (*a*) stearic acid and (*b*) palmitic acid are given in the original.

<div align="right">T. A. H.</div>

Candelilla Wax. HANS MEYER and WALTHER SOYKA (*Monatsh.*, 1913, **34**, 1159—1172. Compare Olsson-Seffer, *Bull. Imp. Inst.*, 1909, **7**, 411; Hare and Bjerregard, *J. Ind. Eng. Chem.*, 1910, **2**, 203; Deiler, *ibid.*, p. 454; Sanders, P., 1911, **27**, 250, and *Anal. Inst. Nac. Med. Mex.*, 1905, **7**, 498, and Niederstadt, *Chem. Zeit*, 1911, **35**, 1190).—Candelilla wax on extraction with hot alcohol yields 18 to 20% of soluble soft resin, which gives the Liebermann-Storch reaction. The portion of the resin-free wax soluble in hot alcohol, but insoluble in the cold, consists principally of dotriacontane, not hentriacontane as Sanders (*loc. cit.*) supposed, which was isolated by extraction with ether and amounted to 74 to 76% of the crude wax. The remaining constituent not removed by ether is a lactone, $C_{30}H_{58}O_3$, m. p. 88°, which forms a colourless, crystalline mass, is neutral in reaction, but yields a *potassium* salt when boiled with potassium hydroxide in alcohol, and is partly esterified when treated with methyl alcohol and sulphuric acid. This substance appears to be that which Sanders mistook for myricyl alcohol (*loc. cit.*), and which Fraps and Ruther (*J. Ind. Eng. Chem.*, 1910, **2**, 454) described as a hydrocarbon. It is perhaps identical with Darmstädter and Lifschütz's lanoceric acid lactone (A., 1896, i, 522).

The authors doubt whether the hydrocarbon frequently found in plants and described as hentriacontane really consists of the latter.

<div align="right">T. A. H.</div>

Water of Crystallisation of the Calcium Salt of Lauronolic Acid. CHARLES E. BURKE (*J. Amer. Chem. Soc.*, 1913, **35**, 1647—1648).—Although the rapid evaporation of a solution of calcium lauronolate on a water-bath gives surface crystals containing approximately $3H_2O$ (Noyes and Burke, A., 1912, i, 159), yet under the conditions of Bredt's method with slower evaporation (A., 1911, i, 417) the crystals, which separate in this case under the liquid, contain exactly $2H_2O$, as stated by Bredt.

<div align="right">D. F. T.</div>

Preparation of Di-iodotariric Acid. F. HOFFMANN-LA ROCHE & Co. (D.R.-P. 261211. Compare A., 1892, 470).—*Di-iodo-*

tariric acid, colourless needles, m. p. 48·5°, containing 47·5% of iodine and of therapeutic value, is obtained when a boiling aqueous solution of tariric acid containing sodium hydroxide is slowly treated with 9 parts of a mixture of iodine (100 parts), potassium iodide (160 parts), and water (740 parts); the product is separated by the addition of dilute sulphuric acid.   F. M. G. M.

The Ability of Alcoholic Hydroxyl Groups to Form Complexes. II. GENNARO CALCAGNI (*Atti R. Accad. Lincei*, 1913, [v], 22, ii, 157—162. Compare A., 1910, i, 811; Weinland and Herz, A., 1912, i, 854).—The *basic glycollate* of a *hexaglycollatotriferri*-base, $[Fe_3(OH)_2(CO_2 \cdot CH_2 \cdot OH)_6] \cdot CO_2 \cdot CH_2 \cdot OH(FeOH)_3$, prepared by fractional precipitation of an alcoholic solution with ether, is an orange-yellow, amorphous substance which is hygroscopic and readily hydrolyses. The *basic nitrate*, $[Fe_3(OH)_2(CO_2 \cdot CH_2 \cdot OH)_6]NO_3 \cdot Fe(OH)_3$, is similar in properties. The *basic lactate* of a *hexalactatotriferri*-base,

$$[Fe_3(OH)_2(CO_2 \cdot CHMe \cdot OH)_6]CO_2 \cdot CHMe \cdot OH \cdot Fe(OH)_3, 4H_2O,$$
is an orange-yellow, hygroscopic substance which is readily hydrolysed. When solutions of chrome alum and sodium benzoate are mixed, *chromous benzoate*, $Cr(CO_2Ph)_2, H_2O$, is precipitated. *Ferrous salicylate*, $Fe(CO_2 \cdot C_6H_4 \cdot OH)_2$, is a reddish-violet, amorphous substance. *Chromous salicylate* was also prepared.   R. V. S.

Complex Oxalic Derivatives of Iridium. ALEXIS DUFFOUR (*Ann. Chim. Phys.*, 1913, [viii], 30, 169—240).—A detailed, connected account of work already published (Abstr., 1909, i, 762—763; 1910, i, 541; 1911, i, 519; 1912, ii, 849). Apart from slight modifications of some of the views expressed already, the following new results are now recorded. *Thallous iridotetrachloro-oxalate*, $Tl_3IrCl_4C_2O_4$, forms maroon-coloured, microscopic, hexagonal lamellæ, which are pleochroic and faintly birefringent. *Argentous iridotetrachloro-oxalate* resembles the thallous salt, but only assumes a crystalline texture after prolonged contact with water.   T. A. H.

Electrolytic Reduction of Aldehydes. WILHELM SCHEPSS (*Ber.*, 1913, 46, 2564—2574).—An extension of the earlier investigation (Tafel and Schepss, A., 1911, i, 784) in which it was demonstrated that by electrolytic reduction the aldehyde group in anisaldehyde can be directly converted into the methyl group. The reduction of the aldehydes was effected in a mixture of alcohol and sulphuric acid.

Propaldehyde undergoes reduction to propane less readily than does acetone, and it was found that cathodes of lead or cadmium are much more effective than a mercury cathode. No formation of any organic lead or mercury compounds analogous to those observed in the reduction of acetone could be detected.

Reduction of heptaldehyde yielded *n*-heptane, and again the action proceeds less easily than with methyl *iso*amyl ketone (Tafel, A., 1909, i, 766). Benzaldehyde (compare Kauffmann, A., 1899, i, 152; Law, T., 1907, 91, 755) at a cadmium cathode gave as hydrocarbon product a small quantity of toluene; no benzene could be detected (compare

Law, *loc. cit.*). *p*-Hydroxybenzaldehyde could be reduced to *p*-cresol ; salicylaldehyde and *m*-hydroxybenzaldehyde appeared to undergo reduction only as far as the corresponding alcohols, and in attempts to reduce the former more energetically much resinification occurred.

Protocatechualdehyde gave 3 : 4-dihydroxytoluene, whilst vanillin gave the corresponding ether, 4-hydroxy-3-methoxytoluene. The experiments in the latter case were conducted with cadmium electrodes and the result is somewhat at variance with that of Law (*loc. cit.*). Piperonal underwent reduction to hydropiperoin and *methylenedioxytoluene*, an aromatic oil, b. p. 81—83°/11 mm., 197—198° (corr.)/741·5 mm., D_{10}^{16} 1·1353, n_D^{16} 1·53165.

When reduced in solution in the usual mixture of alcohol, and sulphuric acid, *p*-dimethylaminobenzaldehyde was converted into the corresponding alcohol, which immediately condensed with the alcohol of the solvent ; the product was therefore p-*dimethylaminobenzyl ethyl ether*, $NMe_2 \cdot C_6H_4 \cdot CH_2 \cdot OEt$, a liquid of characteristic amine odour, b. p. 269—271°/747 mm. ; *methiodide*, m. p. 141·5—143°. Reduction of the aldehyde in alcohol-free diluted sulphuric acid gave as chief product *p*-dimethylaminobenzyl alcohol, as a viscous oil, b. p. 175—178°/28 mm. (compare Rousset, A., 1895, i, 176).

In the above examples it was generally found that the process of reduction became more speedy and complete with increased temperature and current density. The extent to which reduction was effected varied considerably, however, in different cases.

A repetition of the reduction of citral (Law, T., 1912, 101, 1025, 1544) at a lead cathode certainly yielded a red product at the cathode, but it was of a resinous nature and not an organic lead compound.   D. F. T.

Formation of Methylglyoxal. CARL NEUBERG and W. OERTEL (*Biochem. Zeitsch.*, 1913, 55, 495—503).—The importance of methylglyoxal as an intermediary product of sugar degradation has been often discussed, and the substance has been obtained directly from dextrose by various methods (distillation in presence of weak alkalis, zinc carbonate, etc.). It is now shown that it can be obtained from sugars in larger quantities if solutions of these substances are heated with sodium carbonate or disodium hydrogen phosphate in the presence of phenylhydrazine. Particularly good yields were obtained in this way from lævulose, and moderate yields from dextrose. Mannose also yielded a small quantity. The methylglyoxal was in each case identified in the form of an osazone.   S. B. S.

Plant Colloids. III. Processes of Solution and Removal of the Ash of Starch. MAXIMILIAN SAMEC and F. VON HOEFFT (*Koll. Chem. Beihefte*, 1913, 5, 141—210. Compare A., 1912, ii, 144).—The influence of the removal of the ash from starch on the physicochemical properties of starch solutions has been studied, and the properties of solutions of such starch are compared with those of ordinary starch solutions prepared under identical conditions. It is shown that the three processes, removal of the ash, solution and ageing

occasion the same changes in the properties of starch solutions, namely, decrease of the viscosity, and decrease of the influence of acids and bases on the viscosity. These changes take place more rapidly the higher the temperature. At constant temperature in solutions of different concentrations the viscosity decreases in the same proportion in the same time. Simultaneously with the decrease of viscosity an increase in the electrical conductivity is brought about, and the electric transport and amount precipitated by alcohol decrease. The osmotic pressure is slightly decreased, whilst the optical rotation slightly increases and the quantity of titratable acid increases. Starch granules give practically no free electrolyte to water at ordinary temperatures, but at the swelling temperature this occurs fairly rapidly, and at the same time the power of the granules for taking up water increases in a series of sudden steps. The observations lead to the assumption that the ash of starch is present as an amylphosphoric acid, and this assumption brings observations of other observers into agreement.   J. F. S.

Chemistry of Starch. Schardinger's Crystalline Dextrins. II. Hans Pringsheim and Franz Eissler (*Ber.*, 1913, 46, 2959—2974. Compare A., 1912, i, 832).—Further observations on dextrin-β (hexa-amylose), dextrin-α (tetra-amylose), and their scission products are recorded and the properties of the crystalline "slime" prepared by Schardinger are described. Provisional formulæ for diamylose and *iso*-diamylose are advanced and discussed.

Schardinger's "slime" $[(C_6H_{10}O_5)_2]x, C_2H_5 \cdot OH$, was prepared by dissolving crude dextrin (precipitated by means of chloroform from the liquid produced by the action of *Bacillus macerans* on starch paste) in hot water, heating to remove chloroform and then diluting with water, when the slime was precipitated. It was isolated by means of a centrifuge, and crystallised from water containing 1·5% alcohol, when it formed hexagonal tablets. It has $[\alpha]_D^{20} + 139 \cdot 2°$. On acetylation in presence of zinc chloride, it yields the hexa-acetate of diamylose (*loc. cit.*) and by the Baumann-Schotten method yields the *dibenzoate* of *diamylose*, m. p. 200° (approx.), an amorphous substance also obtained when tetra-amylose is benzoylated by this process, an observation which indicates that the slime belongs to the α-group of dextrins. Triamylose, the scission product of dextrin-β, yields a *tribenzoate*, m. p. 190°, which is also amorphous.

These amyloses (dextrins) all yield additive products with iodine when their aqueous solutions are treated with iodine in potassium iodide. The iodine additive products of the α-group form green-tinted needles, become blue when moistened with water, but form dark red solutions when much water is added ; those of the β-group form dark reddish-brown prisms, and give dark red solutions with water. *Tetra-amylose iodide*, $(C_6H_{10}O_5)_4, 1\frac{1}{2}I$, and *hexa-amylose di-iodide*, $(C_6H_{10}O_5)_6 \cdot 2I$, belonging respectively to these groups, have been prepared ; the slime gives an iodide of the α-type.

When tetra-amylose is dissolved in glycerol by heating, and the liquid is heated at 200° during thirty minutes, a small part of the dextrin is converted into the slime and a little into *isodiamylose*, a new

amorphous amylose of the β-type. The latter is also obtained in the form of its amorphous *hexa-acetate* when tetra-amylose is acetylated with acetic anhydride in presence of sulphuric acid. Similarly, hexa-amylose when heated in water for a long time yields a small amount of the slime, and when acetylated in presence of sulphuric acid yields iso*triamylose-nonoacetate*, from which on hydrolysis iso*triamylose* is obtained; both these products are also amorphous. These new amyloses are hygroscopic, dextrorotatory, decompose without melting when heated, and reduce Fehling's solution. Some preliminary observations on the acetylation of "soluble" starch are also recorded.

Starch was separated by Gatin-Gružewska's method (A., 1911, i, 357) into amylopectin and Maquenne's amylose. These two products on treatment with *Bacillus macerans* fermented less easily than starch, but yielded the same products, viz., tetra-amylose, hexa-amylose, and the slime.

Takadiastase and *Penicillium africanum* hydrolyse hexa-, tetra-, tri-, and di-amyloses, whilst emulsin decomposes *iso*tri- and *iso*di-amyloses, but has no action on the other four. Yeast and diastase do not act on any of the six dextrins.   T. A. H.

Hexabromoplatinates [Platinibromides]. ALEXANDER GUTBIER and A. RAUSCH (*J. pr. Chem.*, 1913, [ii], 88, 409—424. Compare A., 1910, i, 12; 1911, i, 32).—On account of their sparing solubility and superior powers of crystallisation, the platinibromides may be employed with advantage for the characterisation of amines in place of the platinichlorides.

A solution of hydrogen platinibromide, suitable for this purpose, is readily obtained by dissolving platinic chloride in 20—30 times its weight of hydrobromic acid (D 1·49), and evaporating its solution to half its bulk.

The platinibromides have no definite m. p., but become dark and sinter before liquefaction takes place.

The compounds described below form light red to dark red crystals having a magnificent lustre:

Tetramethylammonium platinibromide, $(NMe_4)_2PtBr_6$, lustrous, red crystals of octahedral habit. *Tetraethylammonium platinibromide*, felted crystals.

Tripropylammonium platinibromide, compact clusters of deep red, rhombic, double pyramids.

Diisobutylammonium platinibromide, elongated prisms. *Triisobutylammonium platinibromide*, small, red crystals. iso*Amylammonium platinibromide*, bright red crystals. *Diisoamylammonium platinibromide*, tabular crystals. *Triisoamylammonium platinibromide*, bright red prisms. *Allylammonium platinibromide*. *Guanidine platinibromide*, $C_2H_{12}N_6PtBr_6$, lustrous, red crystals of a complicated structure. *Triphenylguanidine platinibromide*,

$$2NPh\text{:}C(NHPh)_2,H_2PtBr_6,$$
slender, felted, orange-red needles.

Nitrosodimethylammonium platinibromide, $(NO\cdot NHMe_2)_2PtBr_6$, acicular, pleochroic prisms. *Nitrosodiethylammonium platinibromide*, dark red, fibrous crystals. *Nitrosodipropylammonium platinibromide*,

red prisms. *Nitrosodiisobutylammonium platinibromide,* dark red, felted crystals.

m-*Chlorophenylammonium platinibromide,* $(C_6H_4Cl\cdot NH_3)_2PtBr_6$, lustrous, red plates. p-*Chlorophenylammonium platinibromide,* bright red, elongated prisms. 2 : 4-*Dichlorophenylammonium platinibromide,* dark red platelets.

o-*Bromophenylammonium platinibromide,* prisms combined, with pyramids. m-*Bromophenylammonium platinibromide,* small, dark red, felted crystals. p-*Bromophenylammonium platinibromide,* red, fibrous crystals.

m-*Nitrophenylammonium platinibromide,* prisms. p-*Nitrophenyl-ammonium platinibromide,* elongated prisms. p-*Nitrosophenyldi-methylammonium platinibromide,* $(NO\cdot C_6H_4\cdot NHMe_2)_2PtBr_6$, deep red, felted crystals.

o-*Tolyldimethylammonium platinibromide,* $(C_6H_4Me\cdot NHMe_2)_2PtBr_6$, lustrous, red plates.

p-*Tolyldimethylammonium platinibromide,* red plates. 2 : 4-*Tolylene-diammonium platinibromide,* $C_7H_{12}N_2PtBr_6$, deep red prisms. 3 : 4-*Tolylenediammonium platinibromide,* vivid red prisms.

o-*Methoxyphenylammonium platinibromide,* vivid red, monoclinic prisms. p-*Methoxyphenylammonium platinibromide,* long, slender, lustrous, red prisms. o-*Ethoxyphenylammonium platinibromide,* stellar, feebly pleochroic discs, or long prisms. p-*Ethoxyphenylammonium platinibromide,* lustrous, red, fibrous crystals.

Tribenzylammonium platinibromide, dark red crystals. *Benzyl-methylammonium platinibromide,* dark red prisms.

Benzylidenemethylammonium platinibromide,
$$(CHPh\vcentcolon NHMe)_2PtBr_6,$$
red, felted aggregates. *Benzylidene-ethylammonium platinibromide,* leaflets.

Phenylbenzylammonium platinibromide, dark red crystals. *Phenyl-benzylmethylammonium platinibromide,* $(NHMePh\cdot C_7H_7)_2PtBr_6$, red, felted crystals. *Phenylbenzylideneammonium platinibromide,* elongated prisms. 2 : 4 : 5-*Trimethylphenylammonium platinibromide,* light red prisms.

3-*Methylpyridinium platinibromide,* dark red, regular crystals. *Dimethylpyridinium platinibromide,* dark red, felted crystals. *Tri-methylpyridinium platinibromide,* clusters of deep red crystals. *Piperidinium platinibromide,* elongated prisms. iso*Quinolinium platinibromide,* lustrous, red, prismatic crystals.   F. B.

Action of Ammonia on β-Aminocrotonates and β-Carb-ethoxyaminocrotonates. ERNST PHILIPPI (*Monatsh,* 1913, **34**, 1187—1193. Compare this vol., i, 598).—It is argued that the substance which Meister (A., 1888, 675) regarded as having the formula $OEt\cdot C(OH)(NH_2)\cdot CH\vcentcolon CMe\cdot NH\cdot CO\cdot NH_2$, may be equally well represented by the formula
$$CH_3\cdot CH(NH\cdot CO\cdot NH_2)\cdot CH(NH_2)\cdot CO_2Et$$
or $CH_3\cdot C(NH_2)(NH\cdot CO\cdot NH_2)\cdot CH_2\cdot CO_2Et$, so far as the reactions described by Meister are concerned. The author finds that the substance on treatment with hot alkali solution yields ethyl β-amino-.
crotonate, and that the latter condenses with carbamide in dry alcohol to regenerate the parent substance, which must therefore be ethyl β-amino-β-carbamidobutyrate represented by the third formula given above.

It is remarkable that whilst the substance is formed by the action of alcoholic ammonia at 160—170° on ethyl β-aminocrotonate, it is not produced when liquefied ammonia is allowed to react with the ester in the cold even for several days. It is probable that in the former case part of the ester is decomposed with the formation of carbamide, which then condenses with the rest of the ester. **T. A. H.**

The Condensation of Carbamides with Esters. GEORG ROEDER (*Ber.*, 1913, **46**, 2560—2564).—In an attempt to prepare hydurilic acid from ethyl ethanetetracarboxylate and carbamide, Conrad (A., 1907, i, 985) obtained scarcely a trace of the desired substance, although the analogous reaction with guanidine in place of carbamide proved satisfactory. It is now shown that the reaction with carbamide follows a different course from that expected, giving rise to *ethanetetra-carboxydi-imide*, which carbonises at 270ᶜ. The reaction was effected in warm alcoholic solution containing sodium ethoxide, and can be represented as : $CH(CO_2Et)_2 \cdot CH(CO_2Et)_2 + 2CO(NH_2)_2 =$

$$NH\mathopen{<}^{CO \cdot CH \cdot CO}_{CO \cdot CH \cdot CO}\mathclose{>}NH + 2NaOCN + 4EtOH.$$
With thiocarbamide, the ester behaves as ethyl dimalonate, and under similar conditions to the last gives rise to *dithiohydurilic acid*, according to the equation : $CH(CO_2Et)_2 \cdot CH(CO_2Et)_2 + 2CS(NH_2)_2 =$

$$CS\mathopen{<}^{NH \cdot CO}_{NH \cdot CO}\mathclose{>}CH \cdot CH\mathopen{<}^{CO \cdot NH}_{CO \cdot NH}\mathclose{>}CS + 4EtOH ;$$ the product, which is unaltered at 250°, gives a yellow *pyridine* salt, and when suspended in water is coloured green by ferric chloride ; it can be desulphurised to hydurilic acid by heating at 100° with concentrated sulphuric acid.

As might be expected from the above results, ethyl succinate condenses with carbamide under similar conditions to the above with formation of succinimide and sodium cyanate. It is suggested that in this and the analogous case above, the course of the reaction follows the stages : $CH_2(CO_2Et) \cdot CH_2 \cdot CO_2Et \longrightarrow \mathopen{}^{CH_2 \cdot CO}_{CH_2 \cdot CO}\mathclose{>}N \cdot CO \cdot NH_2 \longrightarrow$

$\mathopen{}^{CH_2 \cdot CO}_{CH_2 \cdot CO}\mathclose{>}NH + NH_2 \cdot CO_2Et$; the last substance, the formation of which is attributed to the action of the alcohol on the primary condensation product, then decomposes under the influence of sodium ethoxide into alcohol and sodium cyanate.

When ethyl phthalate is subjected to this reaction, either with carbamide or thiocarbamide, the product is phthalimide. **D. F. T.**

Chloro-glyoxime, Oxime Derivatives of Oxalyl Chloride and Oxalyl Semichloride, and Cyanoformylchloride Oxime. JOSEF HOUBEN and H. KAUFFMANN (*Ber.*, 1913, **46**, 2821—2835).—By careful chlorination in cold hydrochloric acid solution, both chloro-

amphi- and chloro-*anti*-glyoxime are converted into the same dichloro-*anti*-glyoxime. The chloro-*anti*-glyoxime is the more readily chlorinated. It is established that fuming hydrogen chloride converts chloro-*amphi*-glyoxime into the *anti*-modification contrary to the statement of Hantzsch, (A., 1892, 693).

Dichloro*anti*glyoxime, $OH \cdot N{:}CCl \cdot CCl{:}N \cdot OH$, has decomp. 221° when crystallised from water, or 212° when crystallised from toluene. It gives a reddish-brown coloration with ferric chloride.

Dichloroglyoxime diacetate, $OAc \cdot N{:}CCl \cdot CCl{:}N \cdot OAc$, separates in well formed crystals, m. p. 162—163°. Dry ammonia gas converts it into dioximino-ethylenediamine, which differs from the known compound, firstly, in forming a *diacetyl* derivative, m. p. 206° when crystallised from water, or 212° when crystallised from chloroform, and secondly, in not yielding a dibenzoyl derivative. The difference is attributed to a changed configuration.

Thionyl chloride converts chloro*amphi*glyoxime into *chloro-oximino-acetonitrile*, $OH \cdot N{:}CCl \cdot CN$. This is purified by distillation and the crystals formed, which are extremely hygroscopic, filtered and dried in a current of air in a specially constructed apparatus. It has m. p. 55—56°; the vapour has a very irritant action. It crystallises in monoclinic prisms and plates giving no coloration with ferric chloride until it has been warmed with water for a few seconds. The substance is a mixture of the two forms :

$$\begin{array}{ccc} Cl \cdot C \cdot CN & & Cl \cdot C \cdot CN \\ \| & \text{and} & \| \\ HO \cdot N & & N \cdot OH \end{array}$$

, in which one greatly preponderates. The form present in the smaller proportion is much more easily decomposed by water. Probably the conversion of one form into the other takes place during the distillation.

Solution of the nitrile in water yields very soon a voluminous, flocculent precipitate which does not contain halogen. Its investigation is not yet completed, but it is probably *dioximino-oxalonitrile* $NC \cdot C(N \cdot OH) \cdot C(N \cdot OH) \cdot CN$. It explodes violently at 250—260°.

Whereas both chloro-*amphi*- and *anti*-glyoxime diacetate and chloro-*amphi*-glyoxime monoacetate distil unchanged in a vacuum, the *anti*-diacetate at the ordinary pressure is decomposed, losing acetic acid and forming *chloro-oximinoacetonitrile acetate*, $CN \cdot CCl{:}N \cdot OAc$, a clear liquid, b. p. 74—75°/13 mm.

Fuming hydrochloric acid converts it into *chloro-oximinoacetamide*, $OH \cdot N{:}CCl \cdot CO \cdot NH_2$, which crystallises in well-formed, pointed needles, m. p. 162°, crystallised from water, or 166° crystallised from benzene (decomp.).

On acetylation, *acetoximinochloroacetamide*, $OAc \cdot N{:}CCl \cdot CO \cdot NH_2$, m. p. 134°, is formed. This compound serves to distinguish the oximinoacetamide from the chloroglyoximes.

The *hydrochloride* of *chloro-oximinoacetiminomethyl ether*,

$$OH \cdot N{:}CCl \cdot CCl(NH_2) \cdot OMe,$$
forms crystals, m. p. 161°. The analogous *ethyl* ether has m. p. 155—164° according to the rate of heating.

When hydrolysed in fuming hydrochloric acid, *chloro-oximinoacetic acid*, $OH \cdot N{:}CCl \cdot CO_2H$, is formed. This has m. p. 125° (decomp.)

The acid is also obtained from chloro-oximinoacetic ester as prepared by Jovitschitsch (A., 1906, i, 732).

It has a strong acid astringent and yet sweet taste. It gives a deep, dark red coloration with ferric chloride. E. F. A.

Crystals of Diamminedimethylglyoximinecobalt Chloride. D. N. Arteméev (*Zeitsch. Kryst. Min.*, 1913, **52**, 632; from *Ann. Inst. Mines, St. Petersburg*, 1910, 2). Crystals of Chloroammine-dimethylglyoximinecobalt. D. N. Arteméev and D. Th. Muraschev (*ibid.*, 1913, **52**, 627—628; from *ibid.*, 1910, 2, 272—274). Crystals of Nitroaquodimethylglyoximinecobalt. D. N. Arteméev and W. M. Lomberg (*ibid.*, 1913, **52**, 632—633; from *ibid.*, 1910, **2**, 352—356).—Descriptions are given, in Fedorov's nomenclature, of the crystals of these compounds prepared by L. A. Tschugaev (A., 1906, i, 814). Their formulæ are respectively $Co(NH_3)_2D_2H_2Cl,5H_2O$, $CoNH_3ClD_2H_2$, and $CoNO_2D_2H_2,H_2O$, where

$$D = \begin{matrix} CH_3 \cdot C:NO \\ | \\ CH_3 \cdot C:NO \end{matrix}$$

L. J. S.

Complex Compounds of Rhodium. Leo A. Tschugaev and W. Lebedinski (*Zeitsch. anorg. Chem.*, 1913, **83**, 1—7).—Rhodium forms complex compounds with a-dioximes, completely resembling those of tervalent cobalt (A., 1906, i, 814; 1907, i, 904). Two series of compounds are formed, one being salts of a mono-acid base, $[Rh,2NH_3,D_2H_2]X$, and the other salts of a monobasic complex acid, $[RhCl_2D_2H_2]H$ (D = dimethylglyoxime, X = halogen). The complex acid is remarkably stable.

Diamminedimethylglyoximinerhodium chloride,

$$[Rh,2NH_3,D_2H_2]Cl,5H_2O,$$
from dimethylglyoxime and chloropentamminerhodium chloride at 150°, crystallises from hot water. The *iodide* is anhydrous. The *nitrate* is precipitated in microscopic tablets; the *perchlorate*, *platini-chloride*, and *platinibromide* are very insoluble.

Rhodidichlorodimethylglyoximinic acid, $[RhCl_2,D_2H_2]H$, from sodium rhodihexachloride and dimethylglyoxime, boiled with water, crystallises from water containing a little hydrochloric acid. The *ammonium* salt, with $1H_2O$, forms large, brownish-yellow crystals. The *guanidinium* salt is anhydrous and sparingly soluble. C. H. D.

Decomposition of Alkylidenehydrazines. Nicolai M. Kishner (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 973—986).—The action of magnesium methyl iodide on *cyclo*butanecarboxylamide yields acetyl-*cyclo*butane, b. p. 137—139°/761 mm., and the latter, on decomposition of its hydrazone, gives *ethylcyclobutane*, $CH_2 \overset{CH_2}{\underset{CH_2}{<}} > CHEt$, b. p. 70°/754 mm., D_0^0 0·7461, D_0^{20} 0·7284, n_D^{15} 1·4032, n_D^{20} 1·4004, which is extremely stable towards permanganate, towards fuming hydrobromic acid in a sealed tube at 100°, and unlike derivatives of three-membered rings, towards concentrated sulphuric acid at the ordinary temperature. Reduction of ethyl*cyclo*butane by means of fuming hydriodic

acid in a sealed tube at 210° yields γ-methylpentane, but no *n*-hexane ; as would be expected from the presence of a CH-group in the molecule, γ-methylpentane is readily attacked by fuming nitric acid.

1 : 1-Dimethyl*cyclo*pentane (compare A., 1908, i, 864) may be obtained by distilling 1 : 1-dimethyl-2-*cyclo*pentanonehydrazone (A., 1911, i, 42) with potassium hydroxide and platinised porous tile.
Allylacetonehydrazone [Δ^a-*hexylen*-ε-*onehydrazone*],
$$CH_2:CH \cdot CH_2 \cdot CH_2 \cdot CMe:N \cdot NH_2,$$
b. p. 187—188°/757 mm., $D_0^{17\cdot5}$ 0·8990, mixes with water in all proportions and, when distilled with potassium hydroxide and platinised porous tile, yields Δ^a-*hexene*, $CH_2:CH \cdot CH_2Pr$, b. p. 64°/756 mm., D_0^{20} 0·6734, n_D^{20} 1·3870.

Distillation of β-methyl-Δ^β-hepten-ζ-onehydrazone with potassium hydroxide and platinised porous tile yields β-*methyl*-Δ^β-*heptene*, $CMe_2:CH \cdot CH_2Pr$, b. p. 122·4°/756 mm., D_0^{20} 0·7254, n_D^{20} 1·4169, which gives β-methylheptane (compare Clarke, A., 1911, i, 345) on reduction by Sabatier and Senderens' method, and forms the *nitrosochloride*, $CMe_2Cl \cdot C(:NOH) \cdot CH_2Pr$, m. p. 48—51°, this exhibiting normal cryoscopic behaviour in benzene. By removal of hydrogen chloride from the nitrosochloride, conversion of the oxime thus obtained into the corresponding ketone, and distillation of the hydrazone of this ketone with potassium hydroxide and platinised porous tile, β-methyl-Δ^β-heptene is again obtained.

Distillation of pentan-α-ol-δ-onehydrazone gives *n*-amyl alcohol.

βζ-Dimethyl-Δ^β-octene, $CMe_2:CH \cdot CH_2 \cdot CH_2 \cdot CHMeEt$, obtained by distillation of the hydrazone of the keto-alcohol,
$$OH \cdot CMe_2 \cdot CO \cdot CH_2 \cdot CH_2 \cdot CHMeEt$$
(A., 1911, i, 1027), with potassium hydroxide and platinised porous tile, seems to be identical with the hydrocarbon obtained from citronellaldehydehydrazone (A., 1911, i, 1027). T. H. P.
Complex Mercury Compounds from Ethylene and Carbon Monoxide. WALTER SCHOELLER, WALTER SCHRAUTH, and WALTER ESSERS (*Ber.*, 1913, 46, 2864—2876).—Mercury acetate in methyl alcohol reacts with a molecule of ethylene to form *acetatomercuriethyl methyl ether*, $CH_2 \cdot CO \cdot O \cdot Hg \cdot CH_2 \cdot CH_2 \cdot OMe$, crystallising in colourless, slender, pointed needles, m. p. 42°. The *bromide* of the ether forms bunches of needles, m. p. 58°; the *iodide* crystallises in stellate aggregates of needles or platelets.

In presence of ethyl alcohol reaction between the mercury salt and ethylene is slower, and *acetatomercuridiethyl ether*,
$$CH_2 \cdot CO \cdot O \cdot Hg \cdot C_2H_4 \cdot OEt,$$
is formed. This sinters at 33°, m. p. 36°. The *chloride* crystallises in colourless needles, m. p. 92°.
When carbon monoxide is substituted for ethylene, *methyl acetatomercuriformate*, $CH_2 \cdot CO \cdot O \cdot Hg \cdot CO \cdot OMe$, is formed. It crystallises in stellate aggregates of needles, m. p. 110° (corr. decomp.). The *chloride* separates in long needles, m. p. 110° (corr. decomp.); the *bromide* is composed of colourless platelets, decomp. 127—128°, and the *iodide* is similar in appearance.

Treatment with hydrogen sulphide in methyl alcohol gives rise to

the formation of *methyl sulphidomercuriformate*, $S(Hg \cdot CO \cdot OMe)_2$, obtained as a colourless, cheese-like precipitate.

Mercury acetate ethyl formate crystallises in aggregates of needles which sinter at 65°, decomp. 125°. The *chloride* forms plates, m. p. 88° (corr. decomp.); the *bromide* and *iodide* are very similar. The *sulphide* was obtained as a yellowish-white precipitate.　　E. F. A.

Decomposition of Pyrazoline Bases. Conversion of Phorone into 1:1-Dimethyl-2-*iso*butenyl*cyclo*propane. NICOLAI M. KISHNER (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 957—972).—The similarity in structure between mesityl oxide and phorone suggests the possibity of transforming the latter ketone into a pyrazoline base and thence into a hydrocarbon containing a trimethylene ring (compare A., 1912, i, 245). This possibility has been realised by the author.

Phorone and hydrazine react according to the equation:

$$CMe_2 \colon CH \cdot CO \cdot CH \cdot CMe_2 + N_2H_4 \longrightarrow CMe_2 \colon CH \cdot C \underset{N—NH}{\overset{CH_2 \cdot CMe_2}{<}}.$$
When distilled with potassium hydroxide in presence of platinised porous tile, this pyrazoline base decomposes in two ways, giving (1) 1:1-dimethyl-2-*iso*butenyl*cyclo*propane, or (2) the trimethylpyrazoline and acetone, $CMe \underset{N—NH}{\overset{CH_2 \cdot CMe_2}{<}} + COMe_2.$

1:1-*Dimethyl-2-isobutenylcyclopropane*, $CH_2 \underset{CH \cdot CH \colon CHMe_2}{\overset{CMe_2}{<}}$, is a liquid, b. p. 132°/758 mm., D_0^{20} 0·7677—0·7681, n_D 1·4414—1·4420. Although the chemical properties of this hydrocarbon are in complete accord with the structure given above, yet the magnitude of the molecular refraction is virtually identical with that calculated for a compound with two double linkings; this exaltation may depend on the relation of the trimethylene ring to the grouping $\colon CMe_2$, such relation possibly resembling that between two conjugated double linkings.

Oxidation of 1:1-dimethyl-2-*iso*butenyl*cyclo*propane by means of 1% potassium permanganate solution proceeds according to the scheme:

$$CH_2 \underset{CH \cdot CH \colon CMe_2}{\overset{CMe_2}{<}} \longrightarrow CH_2 \underset{CH \cdot CH(OH) \cdot CMe_2 \cdot OH}{\overset{CMe_2}{<}} \longrightarrow$$

$$CH_2 \underset{CH \cdot CO \cdot CMe_2 \cdot OH}{\overset{CMe_2}{<}} \longrightarrow CH_2 \underset{CH \cdot CO_2H}{\overset{CMe_2}{<}} + CH_3 \cdot COMe \ ;$$
the intermediate glycol was not isolated.

The *ketol*, $CH_2 \underset{CH \cdot CO \cdot CMe_2 \cdot OH}{\overset{CMe_2}{<}}$, is a viscous liquid with an odour resembling terpineol, b. p. 200°/758 mm., D_0^{16} 0·9377, D_0^{20} 0·9347, $n_D^{16 \cdot 5}$ 1·4500, n_D^{20} 1·4490; it exhibits an optical exaltation of 1·43, although that due to the trimethylene ring is usually less than 1. Its *semicarbazone*, $C_9H_{16}O \colon N_2H \cdot CO \cdot NH_2$, m. p. 127°, and its *phenylurethane*, $C_9H_{15}O \cdot O \cdot CO \cdot NHPh$, crystallise in needles.

1:1-*Dimethylcyclopropane-2-carboxylic acid*, $CH_2 \underset{CH \cdot CO_2H}{\overset{CMe_2}{<}}$, is an oily liquid, b. p. 198°/751 mm., D_0^{18} 0·8990, n_D 1·4385, optical exaltation 0·83; it is stable towards alkaline permanganate solution.

Reduction of 1 : 1-dimethyl-2-*iso*butenyl*cyclo*propane by the method of Sabatier and Senderens, either at 120—125° or at 170°, yields a mixture of (1) a *cyclo*propane derivative, probably 1:1-dimethyl-2-*iso*butyl*cyclo*propane, and (2) $\beta\beta\epsilon$-*trimethylhexane*,

$$CMe_3 \cdot CH_2 \cdot CH_2 \cdot CHMe_2,$$
b. p. 124—125°/763 mm., D_0^0 0·7082—0·7086, n_D 1·3987—1·3998. Treatment of the 1 : 1-dimethyl-2-*iso*butyl*cyclo*propane with hydrogen bromide and subsequently with 2% potassium hydroxide solution yields $\beta\gamma\epsilon$-*trimethylhexan-β-ol*, OH·CMe$_2$·CHMe·CH$_2$·CHMe$_2$, b. p. 171—172°/755 mm., D_0^{20} 0·8316, n_D 1·4313.

1 : 1-Dimethyl-2-*iso*butenyl*cyclo*propane combines rapidly with 1 mol. of hydrogen bromide, giving the *monobromo*-derivative,

$$CH_2 {<}^{CMe_2}_{CH \cdot CH_2 \cdot CMe_2Br} \text{ or } CH_2 {<}^{CMe_2}_{CH \cdot CHBr \cdot CHMe_2},$$
b. p. 94—96°/31 mm., D_0^{20} 1·1046, whilst the prolonged action of hydrogen bromide yields $\delta\zeta$-*dibromo-$\beta\zeta$-dimethylheptane*,

$$CHMe_2 \cdot CH_2 \cdot CHBr \cdot CH_2 \cdot CMe_2Br,$$
b. p. 134—136°/31 mm., D_0^{20} 1 3846. When distilled with aniline, both the mono- and dibromo-compounds yield $\beta\zeta$-*dimethyl-$\Delta^{\beta\delta}$-heptadiene*, CMe$_2$:CH·CH:CH·CHMe$_2$, which contains a small admixture of another hydrocarbon with different positions of the double linkings and has the following approximate physical constants: b. p. 139—141°/758 mm., D_0^{20} 0·7482—0·7510, n_D 1·4456—1·4470. Reduction of this hydrocarbon by Sabatier and Senderens' method at 170° results in the formation of $\beta\zeta$-dimethylheptane. T. H. P.

Decomposition of Pyrazoline Bases. Conversion of Cinnamaldehyde into Phenyl*cyclo*propane. NICOLAI M. KISHNER (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 949—957).—*Phenylcyclopropane*, CHPh${<}^{CH_2}_{CH_2}$, prepared by distilling phenylpyrazoline (from cinnamaldehyde and hydrazine) in presence of potassium hydroxide and platinised porous tile, is a liquid, b. p. 173·6°/758 mm., D_0^{15} 0·9449, D_0^{20} 0·9401, n_D^{15} 1·5342. Under the influence of moderately dilute sulphuric acid, it is converted into the same dimeride, $C_{18}H_{20}$, of α-phenyl-Δ^α-propylene as is obtained by boiling the latter with sodium.

Phenyl*cyclo*propane combines slowly with hydrogen bromide, yielding *o-bromopropylbenzene*, CHPhBr·CH$_2$Me, b. p. 129—130°, 43 mm., D_0^{15} 1·3124, n_D 1·5528. When boiled with aqueous potassium hydroxide, the latter gives (1) the hydrocarbon, $C_{18}H_{20}$, referred to above; (2) phenylethylcarbinol, and (3) allylbenzene, which is also obtained when α-bromopropylbenzene is distilled in presence of quinoline.

In acetic acid solution, the action of bromine on phenyl*cyclo*propane results mainly in the replacement of the nuclear hydrogen, combination of bromine with the trimethylene ring occurring to a very limited extent:

$$CHPh{<}^{CH_2}_{CH_2} + Br_2 \longrightarrow C_6H_4Br \cdot CH{<}^{CH_2}_{CH_2} +$$

$$HBr \longrightarrow C_6H_4Br \cdot CHEtBr.$$
The last compound readily loses hydrogen bromide, giving the unsaturated bromo-derivative, $C_6H_4Br \cdot CH:CHMe$, which yields *p*-bromobenzoic acid on oxidation.

αγ·Dibromopropylbenzene, $CHPhBr \cdot CH_2 \cdot CH_2Br$ (?), formed in small proportion in the action of bromine on *cyclo*propane in acetic acid solution, crystallises in prisms, m. p. 125°.

4-Bromo-1-allylbenzene, $C_6H_4Br \cdot CH:CHMe$, is a liquid, b. p. 240—241°/764 mm., 124°/20 mm., D_0^{18} 1·3147, n_D 1·5692; owing to the conjugated nature of the double linkings in the ring and the side-chain, it exhibits optical exaltation. On reduction by means of hydriodic acid in a sealed tube, it yields propylbenzene. T. H. P.

Decomposition of Pyrazoline Bases : Synthesis of 1-Methyl-2-*iso*propyl*cyclo*propane. NICOLAI M. KISHNER (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 987—992).—iso*Butylideneacetone* [*β-Methyl-Δγ-hexylene-ε-one*], $CHMe_2 \cdot CH:CH \cdot COMe$, prepared by the condensation of *iso*butyraldehyde and acetone in presence of sodium hydroxide, is a liquid, b. p. 156°/757 mm., D_0^{18} 0·8484, n_D^{18} 1·4394 ; its *semicarbazone*, $C_7H_{13}N \cdot NH \cdot CO \cdot NH_2$, forms hexagonal plates, m. p. 162—163°.

3-*Methyl*-5-*iso*propyl*pyrazoline*, $NH \overset{\displaystyle CHPr^\beta \cdot CH_2}{\underset{\displaystyle N \!=\!=\! CMe}{<}}$, prepared by the action of hydrazine hydrate on *iso*butylideneacetone, is a liquid, b. p. 188·5—189·5°/754 mm., D_0^{17} 0·9081, n_D 1·4640 ; it oxidises readily in the air, its hot vapours igniting. Its *thioureide*, $C_7H_{13}N_2 \cdot CS \cdot NHPh$, crystallises in needles, m. p. 95—100°.

1-*Methyl*-2-*iso*propyl*cyclo*propane, $CH_2 \overset{\displaystyle CHMe}{\underset{\displaystyle CHPr^\beta}{<}}$, prepared by decomposition of the preceding compound in a sealed tube at 230°, is a liquid, b. p. 80—81°/748 mm., D_0^{20} 0·7102, n_D^{20} 1·3927, which is extremely stable towards potassium permanganate, combines slowly with bromine in acetic acid solution, and reacts vigorously with fuming nitric acid with formation of a heavy oil. Reduction of 1-methyl-2-*iso*propyl*cyclo*propane by Sabatier and Senderens' method takes place less readily than that of 1 : 1 : 2-trimethyl*cyclo*propane, but at 170° it seems to yield a mixture of *ββ*-dimethylpentane and *βγ*-dimethylpentane. With fuming hydrobromic acid it yields *γ-bromo-ββ-dimethylpentane*, b. p. 158—161°/763 mm., D_0^{20} 1·1585, n_D 1·4548, which gives *ββ*-dimethylpentane on reduction with hydriodic acid. T. H. P.

Catalytic Reactions at High Temperatures and Pressures. XXXII. VLADIMIR N. IPATIEV (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 994—995. Compare this vol., i, 693, 694).—In presence of nickel oxide, indene unites with hydrogen at 250—260° and 110 atmospheres, yielding *octahydrindene*, $\overset{\displaystyle CH_2 \cdot CH_2 \cdot CH \cdot CH_2}{\underset{\displaystyle CH_2 \cdot CH_2 \cdot CH \cdot CH_2}{}} > CH_2$, which is a liquid, b. p. 165—166°/767 mm., D^{20} 0·8334, n_D^{20} 1·46287 (compare Padoa and Fabris, A., 1908, i, 255). T. H. P.

Metaquinonoids. OTTO STARK, O. GARBEN, and L. KLEBAHN, (*Ber.*, 1913, **46**, 2542—2544. Compare this vol., i, 362, 849).—It is

found that the hydrocarbon, m-*xylylene*, described earlier decomposes at 303—305°, the lower figure given previously being due to insufficient drying.

The substance in the solid state is in a polymerised condition, but the chloroform solutions give ebullioscopic results agreeing with a depolymerised unimolecular product; the solution in chloroform is, however, much more sensitive than that in benzene. The benzene solutions of the substance obtained in the original preparation exhibit a decided fluorescence, and dye paper and linen, whilst the chloroform solutions of the previously separated substance do not possess these characteristics.

A preliminary examination of the absorption spectra of the two solutions indicated complete analogy with the behaviour of Thiele's tetraphenyl-*p*-xylylene; an absorption of blue and violet light which commenced in the green portion of the spectrum was observed both with the chloroform and the original benzene solutions.   D. F. T.

Elimination of Halogen Acids by Phosphoric Oxide. I. HANS LECHER (*Ber.*, 1913, **46**, 2664—2668).—Recent publications by Leuchs and his co-workers (this vol., i, 855, 972), in which mention is made of the catalytic action of compounds of phosphorus on the elimination of hydrogen chloride from certain acid chlorides, have led the author to publish a preliminary account of the use of phosphoric oxide in this direction.

Benzoyl chloride does not react with an excess of naphthalene at 180—200°. If, however, a small quantity of phosphoric oxide is added, a vigorous evolution of hydrogen chloride occurs, at the conclusion of which a mixture of much α- and less phenyl β-naphthyl ketone can be isolated, the total amount being 90% of that theoretically possible. Phosphoric oxide has the advantage over aluminium chloride that only small quantities of it are necessary, larger amounts having an unfavourable influence on the course of the reaction. On the other hand, the requisite temperature is high, and, in those cases in which the b. p. of the mixture lies below this temperature, the operation must be performed in sealed tubes. In these circumstances, the liberated hydrogen chloride can only be removed periodically, and greatly diminishes the velocity of the reaction. Thus, only small yields of benzophenone could be obtained by this method from benzoyl chloride and benzene.

Boiling benzyl chloride rapidly and completely eliminates hydrogen chloride in the presence of phosphoric oxide, forming a mixture of hydrocarbons which has not yet been completely investigated. ω-Chlorotriphenylmethane is similarly decomposed at about 150° into 9-phenylfluorene and much triphenylmethane.

A series of experiments has been performed to determine the exact nature of the catalyst. Bailey and Fowler (T., 1888, **53**, 755) have shown that phosphoric oxide reacts with hydrogen chloride according to the equation: $P_4O_{10} + 3HCl = POCl_3 + 3HPO_3$, but the author finds that no appreciable action occurs within a reasonable time at temperatures up to 260°, and, hence, that phosphoryl chloride cannot

be the actual catalyst. Direct experiment with metaphosphoric acid has shown that this substance is also inactive.

Finally, the active catalyst can easily be recovered by the removal of organic matter by extraction with benzene. In this manner, a mixture of a phosphorus compound (which yields metaphosphoric acid with water) and small quantities of carbon is obtained, which can be employed in the same manner as fresh phosphorus pentoxide.

H. W.

Morphological Studies in the Benzene Series. IV. The Crystalline Form of Sulphonates in Relation to their Molecular Structure. ERNEST H. RODD (*Proc. Roy. Soc.*, 1913, *A*, 89, 292—313. Compare T., 1910, 97, 1578; A., 1912, i, 756).— A number of salts of *p*-dichlorobenzenesulphonic acid have been prepared, and their crystallographic constants have been compared. Lanthanum *p*-dichlorosulphonate, $La(C_6H_3Cl_2SO_3)_3,15H_2O$, is deposited from solution between 10° and 50°; it forms triclinic prisms, which rapidly effloresce [$a:b:c = 1.6193:1:1.6028$; $a = 76°26'$; $\beta = 113°48'$; $\gamma = 68°6'$]. Neodymium *p*-dichlorobenzenesulphonate,
$$Nd(C_6H_3Cl_2SO_3)_3,12H_2O,$$
crystallises in short, thick, rose-coloured, monoclinic prisms between 15° and 50°, closely isomorphous with $Gd(C_6H_3Br_3SO_3)_3,12H_2O$ [$a:b:c = 0.5872:1:0.3810$; $\beta = 76°34'$]. Praseodymium *p*-dichlorobenzenesulphonate, $Pr(C_6H_3Cl_2SO_3)_3,12H_2O$, forms pale green, monoclinic prisms isomorphous with the corresponding neodymium salt [$a:b:c = 0.5887:1:0.3819$; $\beta = 76°26'$]. A salt of the composition $Pr(C_6H_3Cl_2SO_3)_3,15H_2O$, isomorphous with the corresponding lanthanum salt, is formed when a supersaturated solution is allowed to spontaneously crystallise at the ordinary temperature. A number of other sulphonates have also been prepared and measured. Gadolinium *p*-dibromobenzene sulphonate, $Gd(C_6H_3Br_2SO_3)_3,7H_2O$, monoclinic prisms [$a:b:c = 1.2595:1:0.6031$; $\beta = 89°16'$]. Didymium benzenesulphonate, $Di(C_6H_5\cdot SO_3)_3,9H_2O$, crystallises from a mixture of aqueous alcohol and ethyl acetate in thin, hexagonal-shaped plates belonging to the rhombic system [$a:b:c = 2.0795:1:1.9374$]. Potassium *p*-dichlorobenzenesulphonate, $C_6H_3Cl_2SO_3K$, crystallises anhydrous from aqueous solutions between 20° and 37° in thin, monoclinic prisms [$a:b:c = 1.5054:1:0.7636$; $\beta = 83°27'.5'$]. Sodium *p*-dichlorobenzenesulphonate, $C_6H_3Cl_2SO_3Na,H_2O$, crystallises in large, monoclinic tablets at 37° [$a:b:c = 3.0529:1:1.9583$; $\beta = 88°46'$]. Zinc *p*-dichlorobenzenesulphonate, $Zn(C_6H_3Cl_2SO_3)_2,8H_2O$, forms long, monoclinic prisms, which are always distorted [$a:b:c = 2.9985:1:2.4539$; $\beta = 79°20'$]. Magnesium *p*-dichlorobenzenesulphonate,
$$Mg(C_6H_3Cl_2SO_3)_2,8H_2O,$$
crystallises in stout, monoclinic, hemimorphic plates [$a:b:c = 2.9970:1:2.4450$; $\beta = 79°41'.5'$]. Ferric *p*-dibromobenzenesulphonate, $Fe(C_6H_3Br_2SO_3)_3,13H_2O$; basic ferric *p*-dibromobenzenesulphonate, $Fe(OH)(C_6H_3Br_2SO_3)_2,12H_2O$; chromium *p*-dibromobenzenesulphonate, $Cr(C_6H_3Br_2SO_3)_3,14H_2O$; aluminium *p*-dibromobenzenesulphonate,
$$Al(C_6H_3Br_2SO_3)_3,18H_2O;$$
scandium *p*-dibromobenzenesulphonate, $Sc(C_6H_3Br_2SO_3)_3,14H_2O$, and
cobaltous p-dibromobenzenesulphonate, $Co(C_6H_3Br_2SO_3)_2,9H_2O$, have been prepared and described without crystallographic details. It is shown that similar conclusions may be drawn with regard to the structure of p-dichlorosulphonic acid as were drawn in the case of p-dibromosulphonic acid in the previous paper (*loc. cit.*). The structure of the sulphonates of monad and dyad metals is discussed ; it is argued that in the formation of the latter the molecules of benzene in contiguous rows become separated by the intervention of the sulphonic radicles which are united in pairs by the metallic atom. The structure of the salts containing monad metals appears in some cases to be pseudo-trigonal like that of the acid ; in others to resemble that of the dyad metals.   J. F. S.

p- and o-Toluenesulphinic Acids. ALFRED HEIDUSCHKA and HANS LANGKAMMERER (*J. pr. Chem.*, 1913, [ii], **88**, 425—442).—An extension of the work of E. von Meyer and others (A., 1901, i, 264 ; 1903, i, 808) on the formation of aminodiaryl sulphides by the inter· action of aromatic sulphinic acids and amines.

The authors find that the sulphides are obtained in a purer condition and better yield by fusing the sulphinic acids with the hydrochlorides of the amines, instead of with the free bases.

When p-toluenesulphinic acid is fused at 215° with aniline hydrochloride and the product extracted with ether, p-*aminophenyl* p-*tolyl sulphide* p-*toluenesulphonate*, $C_{20}H_{21}O_3NS_2$, is obtained in white needles, m. p. 216° ; extraction of the residue with hydrochloric acid yields the corresponding *hydrochloride*.

p-Aminophenyl p-tolyl sulphide condenses with 4-bromo-2-hydroxybenzaldehyde in boiling alcoholic solution to form p-4-*bromo-2-hydroxybenzylideneaminophenyl* p-*tolyl sulphide*,

$$C_6H_4Me·S·C_6H_4·N:CH·C_6H_3Br·OH,$$
which crystallises in lustrous, brownish-yellow leaflets, m. p. 148° ; the m-*xylylidene* derivative, $C_6H_4(CH:N·C_6H_4·S·C_6H_4Me)_2$, from m-phthalaldehyde, has m. p. 163°.

The *benzylidene* derivative, $C_6H_4Me·S·C_6H_4·N:CHPh$, is obtained in the form of its *hydrochloride* (yellow needles, m. p. 164°, which rapidly acquire a greenish colour) by condensing benzaldehyde with p-aminophenyl p-tolyl sulphide hydrochloride ; the *hydrochlorides* of the *salicylidene* and *vanillylidene* derivatives have m. p. 175° and 195° respectively.

The aqueous extract of the product obtained by fusing o-anisidine hydrochloride with p-toluenesulphinic acid at 225° yields o-*anisidine* p-*toluenesulphonate*, $C_{14}H_{17}O_4NS$, which has m. p. 150°, and has also been prepared directly from its components in alcoholic solution ; extraction of the product with hydrochloric acid yields 4-*amino-3-methoxyphenyl* p-*tolyl sulphide hydrochloride*,.

$$C_6H_4Me·S·C_6H_3(OMe)·NH_2,HCl.$$
This has m. p. 215°, and on treatment with aqueous ammonia yields the free *base*, which, however, could not be obtained in a pure condition. The free base combines with phenylcarbimide in ethereal solution to form the *carbamide*, m. p. 163°,
$$NHPh·CO·NH·C_6H_3(OMe)·S·C_6H_4Me.$$

o-*Anisidine* p-*toluenesulphinate*, prepared from its components in alcoholic solution, has m. p. 112°. o-*Chloroaniline* p-*toluenesulphonate*, m. p. 198°, and o-*chloroaniline* p-*toluenesulphinate*, m. p. 130°, were prepared in a similar manner.

3-*Chloro*-4-*aminophenyl* p-*tolyl sulphide hydrochloride*,

$$C_6H_4Me·S·C_6H_3Cl·NH_2,HCl,$$
obtained by fusing p-toluenesulphinic acid with o-chloroaniline hydrochloride, forms colourless crystals, m. p. 150°, and on treatment with aqueous ammonia yields the free *base*, which combines with phenylcarbimide in ethereal solution to form the *carbamide*,

$$NHPh·CO·NH·C_6H_3Cl·S·C_6H_4Me,$$
crystallising in white needles, m. p. 190°; the corresponding *thiocarbamide* prepared in a similar manner has m. p. 147°.

p-*Aminophenyl* o-*tolyl sulphide*, $NH_2·C_6H_4·S·C_6H_4Me$, obtained in the form of its o-*toluenesulphonate*, $C_{20}H_{21}O_3NS_2$, m. p. 190°, by fusing aniline hydrochloride with o-toluenesulphinic acid and extracting the product with water, separates from ether in flat, hexagonal, brown pyramids, m. p. 50°, forms a *hydrochloride*, crystallising in slender, white needles, m. p. 137°, and condenses with benzaldehyde in alcoholic solution, yielding the *benzylidene* derivative, which was isolated in the form of its *hydrochloride*, $C_6H_4Me·S·C_6H_4·N:CHPh,HCl$, as a yellow powder, m. p. 195°. It combines with phenylcarbimide in ethereal solution yielding the *carbamide*, $NHPh·CO·NH·C_6H_4·S·C_6H_4Me$, crystallising in white needles, m. p. 164°. **F. B.**

Electrochemical Reduction of Organic Halogen Compounds. II. Kurt Brand (*Ber.*, 1913, **46**, 2935—2942).—This and the succeeding paper give the results of attempts to reproduce by electrochemical methods the conversion of diaryltrichloroethanes into stilbene derivatives, first effected by chemical methods by Goldschmidt, and later by Elbs (Abstr., 1893, i, 271). The results show that the products obtained depend in part on the nature of the cathode used. The apparatus used is described. The cathode liquid, which was kept boiling, consisted of the substance under examination in alcohol and hydrochloric acid.

Lead cathode.—ββ β-Trichloro-aa-diphenylethane yielded stilbene (4% of the theoretical) and dichlorodiphenylethane. ββ β-Trichloro-aa-di-p-tolylethane gave 6% of the theoretical yield of p : p′-dimethylstilbene. ββ β-Trichloro-aa-di-p-anisylethane gave about 10% of the calculated yield of p : p′-dimethoxystilbene, and a similar yield of p : p′-diethoxystilbene was obtained from ββ β-trichloro-aa-di-p-phenetylethane. These alkylstilbenes were identified by means of their dibromides.

Copper cathode.—The four diaryltrichloroethanes mentioned in the preceding paragraph were also submitted to electrolytic reduction in presence of a copper cathode, and then yielded the corresponding diaryldichloroethanes, but the first-named product gave only a small yield. The last-named substance also yielded a minute amount of the corresponding diethoxystilbene. The diaryldichloroethanes were identified by conversion into the corresponding ethylenes, which give characteristic colours with sulphuric acid. **T. A. H.**

**Electrochemical Reduction of Organic Halogen Compounds.
III.** KURT BRAND and M. MATSUI (*Ber.*, 1913, **46**, 2942—2951).
—It has been shown previously (Brand, *Zeitsch. Elektrochem.*, 1910,
16, 669) that the principal product of the electrolytic reduction of
hot alcoholic solutions of $\beta\beta\beta$-trichloro-aa-diphenylethane in presence
of a lead cathode is a hydrocarbon, $C_{26}H_{22}$, which may have the con-
stitution $CHPh_2 \cdot C \vdots C \cdot CHPh_2$ or $CPh_2 \vdots C \cdot CH \cdot CHPh_2$ (see also preceding
abstract). It is now shown that the cathodic reduction of $\beta\beta\beta$-tri-
chloro-aa-di-p-tolylethane and of di-$\beta\beta\beta$-trichloro-aa-di-p-anisyl-ethane
under analogous conditions furnishes similar substances, some reactions
of which are described. These reactions do not enable a final
decision as to the constitution to be arrived at, but on the whole they
tend to support formulæ of the kind represented by the second given
above.

$\beta\beta\beta$-Trichloro-aa di-p-tolylethane furnishes the *hydrocarbon*, $C_{32}H_{30}$,
m. p. 123°, which crystallises from boiling alcohol in colourless, small
needles, shows a faint blue fluorescence, and on oxidation in acetone
solution with potassium permanganate yields di-p-tolylacetic acid and
di-p-tolyl ketone; the same products are formed with calcium perman-
ganate in presence of pyridine, and with chromic acid in acetic acid, but
in different amounts. On reduction with excess of sodium in amyl
alcohol, the hydrocarbon yields the corresponding *tetra*-p-*tolylbutane*,
m. p. 126°, crystallising from alcohol in colourless needles showing a
slight blue fluorescence. With insufficient sodium, a *substance*, m. p.
186°, crystallising in glancing leaflets, is formed in small quantity.
With sodium in absolute alcohol, the same reduction takes place. On
treatment with sodium ethoxide in alcohol, the hydrocarbon is con-
verted into $aa\delta\delta$-*tetra*-p-*tolyl*-$\Delta^{a\gamma}$-*butadiene*,

$$C(C_6H_4Me)_2 \vdots CH \cdot CH \vdots C(C_6H_4Me)_2,$$
m. p. 255°, which crystallises from methyl ethyl ketone in heavy,
green, fluorescent needles, is sparingly soluble in boiling alcohol, but
readily so in chloroform or benzene, giving solutions which are green in
colour and show absorption in the extreme violet end of the spectrum.
The hydrocarbon, $C_{32}H_{30}$, reacts with mercuric acetate to form an
orange-yellow *compound* of uncertain composition, which with hydrogen
chloride or with zinc and acetic acid yields the tetratolylbutadiene
described above.

Di-p-anisyltrichloroethane yields in addition to di-p-methoxystilbene
(preceding abstract) the *phenol ether*, $C_{32}H_{30}O_4$, which, as indicated
above, is probably $aa\delta\delta$-tetra-p-anisyl-$\Delta^{a\beta}$-butadiene,

$$(C_6H_4 \cdot OMe)_2 C \vdots C \cdot CH \cdot CH(C_6H_4 \cdot OMe)_2.$$
It melts at 111°, crystallises from boiling alcohol in colourless needles,
and on oxidation with chromic acid gives di-p-anisyl ketone and a
small amount of di-p-anisylacetic acid. On reduction with sodium
in amyl alcohol, $aa\delta\delta$-*tetra*-p-*anisylbutane*, m. p. 116°, crystallising
in colourless needles with a blue fluorescence, is formed, whilst
with sodium ethoxide in alcohol, $aa\delta\delta$-*tetra*-p-*anisyl*-$\Delta^{a\gamma}$-*butadiene*,
m. p. 149°, which crystallises from methyl ethyl ketone in green,
fluorescent needles, is produced. These two substances closely
resemble their analogues described in the preceding paragraph.

                                                    T. A. H.

Dehydrobenzylidenebisfluorene. ROBERT STOLLÉ (*Ber.*, 1913, 46, 2979).—In preparing benzoylfluorene by Werner's method (A., 1906, i, 436), but using potassium ethoxide instead of sodium, the author has obtained a small quantity of *dehydrobenzylidenebisfluorene*, $C_{32}H_{22}$, m. p. 350°, which crystallises from chloroform in small, orange needles, and on heating sublimes to form red crystals. It is hardly soluble in ether or alcohol, and sparingly soluble in hot benzene or acetic acid. The analogous ethylidene compound has been described by Pummerer and Dorfmüller (this vol., i, 963).   T. A. H.

Studies in the Fluorene Series. FRITZ MAYER (*Ber.*, 1913, 46, 2579—2587).—The author has attempted to synthesise fluoranthene by the ring condensation of 9-ethylfluorene, fluorene-9-acetic acid or fluorenepropionic acid, but without success. On heating distilled ethylfluorene with litharge and distilling the product, 9-ethylidene-fluorene, $\begin{matrix} C_6H_4 \\ C_6H_4 \end{matrix}\!>\!C{:}CHMe$ (Ullmann, A., 1906, i, 77), which formed a picrate, m. p. 156°, was obtained. When crude ethylfluorene was employed, however, and the product was not distilled, a 9-fluorene-ethyl alcohol, which also gave a picrate, m. p. 155—156°, was formed. It was not identical with Ullmann's carbinol (*ibid.*) and has therefore the constitution $\begin{matrix} C_6H_4 \\ C_6H_4 \end{matrix}\!>\!CH{\cdot}CH(OH)Me$ or $\begin{matrix} C_6H_4 \\ C_6H_4 \end{matrix}\!>\!CH{\cdot}CH_2{\cdot}CH_2{\cdot}OH$. In each case, very small quantities of high-melting, red hydrocarbons of the formula $C_{15}H_{10}$ were obtained. It was expected that one of them would be identical with the compound,

$$\begin{matrix} C_6H_4 \\ C_6H_4 \end{matrix}\!>\!CH{\cdot}CH{:}C\!<\!\begin{matrix} C_6H_4 \\ C_6H_4 \end{matrix},$$
described by Wislicenus and Densch (A., 1902, i, 291), but the author could not prepare this substance by any means.

Twenty grams of crude 9-ethylfluorene, from the action of ethyl iodide on ethyl fluorene-9-oxalate (*loc. cit.*), were heated for fifteen minutes at 310—360° with 40 grams of litharge, when the product was extracted with boiling chloroform. The solvent deposited a red *hydrocarbon*, $C_{15}H_{10}$ or $C_{27}H_{18}$, m. p. over 360°, on cooling, and the dark brown *picrate* of a fluorene-ethyl alcohol, $C_{21}H_{17}O_8N_3$, m. p. 155—156°, was obtained from the mother liquor. The *picrate* of Ullmann's carbinol has the same m. p., but not so a mixture of the two.

Two parts of distilled 9-ethylfluorene, b. p. 306—310°, were heated with five parts of litharge for one hour, the product was extracted with hot chloroform, which deposited a red *hydrocarbon*, $(C_{15}H_{10})x$, m. p. 300—310°, and the residue, after evaporating the solvent, was distilled. The fraction, b. p. 310—320°, contained ethylidenefluorene and formed a *picrate*, $C_{21}H_{15}O_7N_3$, m. p. 155—156°.

For the preparation of *fluorene-9-acetic acid*, $\begin{matrix} C_6H_4 \\ C_6H_4 \end{matrix}\!>\!CH{\cdot}CH_2{\cdot}CO_2H$, ethyl fluorene-9-oxalate was treated with sodium in alcohol and ethyl bromoacetate, and the product was hydrolysed by 20% aqueous sodium hydroxide. The acid has m. p. 129—130°, forms a *methyl* ester,

$C_{16}H_{14}O_2$, m. p. 60°, an *amide*, $C_{15}H_{13}ON$, slender needles, m. p. 189°, and yields 9-methylfluorene (*ibid.*) on distillation with soda-lime. *Fluorene-9-propionic acid*, $C_{16}H_{14}O_2$, was also prepared, using ethyl β-iodopropionate; it forms white needles, m. p. 144°. Neither the acids themselves nor their chlorides gave definite products on condensation.   J. C. W.

Tri-β-naphthylmethane and Certain of its Derivatives. ALEXEI E. TSCHITSCHIBABIN and S. I. KOBJAGIN (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 766—781 ; *J. pr. Chem.*, 1913, [ii], **88**, 505—578).— Tri-β-naphthylcarbinol (compare Schmidlin and Huber, A., 1910, i, 832) may be readily obtained by the interaction of di-β-naphthyl ketone and magnesium β-naphthyl bromide (see A., 1911, i, 969) in presence of ether.

The authors were unable to prepare 2-bromonaphthalene by Darzens and Berger's method (A., 1909, i, 297), but obtained it readily from β-naphthylamine by passing through the diazo-compound.

Di-β-naphthyl ketone (compare Grucarevic and Merz, A., 1873, 263, 264) was prepared by the dry distillation of calcium β naphthoate, by oxidising di-β-naphthylcarbinol by the action of β-naphthoyl chloride on naphthalene in presence of zinc and by the action of magnesium β-naphthyl bromide on β-naphthoyl chloride. The first method gives poor, and the last good yields.

Tri-β-naphthylcarbinol, $C_{31}H_{22}O$, forms snow-white crystals, m. p. 204°, and dissolves in concentrated sulphuric acid with an intense coloration, which is greenish in thin layers or low concentrations, and violet-red when more concentrated. These solutions show an absorption band gradually weakening from the violet to the blue, with a maximum intensity at about 490 μμ, and also a faint band in the red, beginning at about 755 μμ. Unlike the isomeric tri-α-naphthyl-carbinol (A., 1911, i, 969), it shows no inclination to oxidise in the air. *Tri-β-naphthylchloromethane*, $C_{31}H_{21}Cl$, forms white crystals, m. p. 199—201° (decomp.), the fused mass solidifying later, and then showing m. p. 231—236° ; with sulphuric acid it gives the same coloration as the carbinol.

Tri-β-naphthylmethane, $C_{31}H_{22}$, prepared by reducing the above carbinol or chloride by means of hydriodic and glacial acetic acids (A., 1911, i, 277), forms colourless, prismatic crystals, m. p. 178—179°, and exhibits the normal molecular weight in freezing benzene. When crystallised from benzene, it yields crystals containing varying proportions of benzene, possibly owing to the formation of a solid solution.

β-Naphthyldi-ββ-naphthafluorene, $C_{31}H_{20}$, obtained on reduction of the impure tri-β-naphthylchloromethane or by heating the latter above its melting point in an atmosphere of carbon dioxide, forms white, nodular crystals, which melt at 235—237° in a sealed capillary filled with carbon dioxide. Its solutions exhibit intense blue fluorescence and react with magnesium methyl iodide with evolution of methane.

The action of copper-bronze or of Gomberg and Cone's molecular silver (A., 1906, i, 822) on a solution of tri-β-naphthyl-

chloromethane yields a dark violet-red liquid from which dark violet crystals were separated. These have not been analysed, but from their colour and ready oxidisability in the air, and the molecular weights indicated by cryoscopic measurements in benzene and naphthalene, it seems probable that they consist principally of *tri-β-naphthylmethyl*, $C(C_{10}H_7)_3$, and to a small extent of hexa-β-naphthylethane. T. H. P.

Phenyldichloroamine [Di-ω-chloroaniline]. STEFAN GOLD-SCHMIDT (*Ber.*, 1913, **46**, 2728—2736).—The existence of di-ω-chloroaniline and ω-chloroaniline as intermediate products in the action of hypochlorites on aniline has already been indicated by Raschig (*Zeitsch. angew. Chem.*, 1907, **20**, 2065; compare also Bamberger, A., 1894, i, 238).

The dichloro-compound has now been isolated by the author by the interaction of aniline and hypochlorous acid in ethereal solution at a low temperature. The ethereal solution of hypochlorous acid is obtained by extracting an aqueous solution of the acid, prepared according to Wohl's method (A., 1907, i, 194), with ether, and rapidly cooling to $-15°$. At the ordinary temperature the solution is unstable and rapidly decomposes, yielding acetaldehyde and hydrogen chloride.

When treated with slightly less than the calculated amount of aniline in ethereal solution at $-15°$ to $-20°$, a yellow solution is obtained, which on evaporation at $-40°$ yields *di-ω-chloroaniline*, $NPhCl_2$, as a viscid oil, having a colour similar to that of potassium dichromate. Although in the free condition, the dichloroamine is very unstable and decomposes explosively when removed from the freezing mixture; in ethereal solution it may be kept for several hours without undergoing appreciable change. It liberates iodine from potassium iodide, and on treatment with ethereal hydrogen chloride rapidly decomposes, with the formation of 2:4-dichloroaniline and 2:4:6-trichloroaniline.

When treated with sodium hydroxide, alcoholic ammonia, sodium thiosulphate, aniline or copper powder, it yields *p*-aminodiphenylamine hydrazobenzene and benzoquinonephenyldi-imine; it is probable that the free radicle NPh: is formed as an intermediate product in these decompositions.

Attempts to prepare ω-chloroaniline by the interaction of molecular quantities of aniline and hypochlorous acid in ethereal solution at a low temperature were unsuccessful.

ωω-2:4:6-Pentachloroaniline, prepared from 2:4:6-trichloroaniline and hypochlorous acid in a similar manner to that described above for the preparation of di-ω-chloroaniline, is much more stable than the latter compound, and forms a viscid oil having the colour of diphenylketen. It has a sweet, disagreeable odour resembling that of chlorine, and solidifies at $-80°$ to a glassy mass. When heated, it becomes dark in colour and decomposes explosively with the production of flame. It dissolves in strong sulphuric acid, yielding violet solutions, which become yellow and evolve chlorine, when warmed.

On the addition of potassium iodide in aqueous alcoholic solution to an ethereal solution of the dichloro-compound, iodine (2 atoms) is liberated and $2:4:6:2':4':6'$--hexachloroazobenzene is formed; in the presence of hydrochloric acid, $2:4:6$-trichloroaniline is produced, the amount of iodine liberated in this case being twice that given above.

A sketch of the apparatus employed in the preparation of the dichloroamines is given.   F. B.

A New Group of Metallic Compounds of the Aromatic Thiocarbamide Series. RUDOLF KRULLA (*Ber.*, 1913, **46**, 2669—2672).—Aryl thiocarbamides are readily prepared by the action of aryl amines on carbon disulphide in the presence of a substance which absorbs the liberated hydrogen sulphide. For this purpose, the author recommends nitrobenzene, which reacts in accordance with the equation : $5NH_2Ph + 3CS_2 + Ph \cdot NO_2 = 3(PhNH)_2CS + 2H_2O + 3S$. He has also employed a number of metallic oxides and salts for this purpose, and thus obtained a new series of organometallic derivatives, of which the *tin* compounds have been most completely investigated.

When an alcoholic solution of aniline and carbon disulphide is treated with tin hydroxide, a yellow tin salt, $Sn(S \cdot CS \cdot NHPh)_2$, is immediately precipitated in a practically pure condition. Like the similar salts of other metals, it is almost insoluble in most solvents except acetone and a mixture of acetone and alcohol, and is readily decomposed when warmed, even in solution. Warm acids immediately convert it into diphenylthiocarbamide and the corresponding metallic salt, whilst prolonged contact with aniline causes a similar change. Lead hydroxide similarly yields a *lead* salt, fine needles, when added to a dilute alcoholic solution of aniline and carbon disulphide ; in concentrated solution, however, a dark green coloration is observed, and hydrogen sulphide is evolved with perceptible heat evolution. This appears to be the only case in which hydrogen sulphide is given off.

The *bismuth* salt forms long needles, readily soluble in alcohol.

In the cases of arsenic and antimony, the organometallic derivatives could not be isolated, the thiocarbamide and the metallic sulphide being the products of the action. Copper behaved similarly to the alkali metals, forming xanthates.

Homologues of aniline which do not contain too many acidic groups react analogously. In these cases it often occurs that lead oxide or hydroxide is active when tin is no longer useful. Organometallic derivatives have been obtained from *p*-toluidine, monomethylaniline, *p*-aminophenol, *a*- and *β*-naphthylamine. Diphenylamine did not react.   H. W.

New Methods of Preparing Thiocarbanilides. HARRY S. FRY (*J. Amer. Chem. Soc.*, 1913, **35**, 1539—1546).—The method of preparing thiocarbanilides by the interaction of carbon disulphide and an aromatic amine frequently fails in its desired object, and the cause is attributed to the alcohol and potassium hydroxide which are generally introduced into the reaction mixture. By omitting the

alcohol and replacing the alkali by pyridine, the process is so improved that a better yield of a purer product is just as readily obtained. A specimen of di-o-chlorophenylthiocarbamide prepared in this manner had m. p. 130·5° (compare Grosch, A., 1899, i, 599).

By applying iodine together with pyridine, the former to remove the hydrogen sulphide from the primary reaction and the latter to combine with the hydriodic acid formed in the secondary reaction of the hydrogen sulphide, excellent yields of the various thiocarbanilide compounds can be obtained; the process in this respect is greatly superior to the previous one. The reaction may be summed up by the equation: $2NH_2R + CS_2 + I_2 + 2C_5H_5N = CS(NHR)_2 + 2C_5H_5N,HI + S$. An excess of carbon disulphide is applied (both in this and in the previous method), and during the action which occurs without warming, pyridine hydriodide separates. The reaction product is steam distilled, and the mixture of thiocarbanilide and sulphur obtained by filtration of the aqueous residue is then separated by extraction with alcohol.

In the preparation by the latter process with iodine it is important that only the theoretical proportions of aniline and iodine should be used. With excess of iodine, the reaction proceeds quantitatively to the formation of a thiocarbimide according to the equation: $NH_2R + CS_2 + I_2 + 2C_5H_5N = RNCS + 2C_5H_5N,HI + S$. Indeed, this reaction provides a convenient method for the estimation of aniline (dissolved in a mixture of carbon disulphide and pyridine) by direct titration with a solution of iodine in carbon disulphide. D. F. T.

Transformation of Phenyl Allyl Ethers into the Isomeric Allylphenols. LUDWIG CLAISEN and OTTO EISLEB (*Annalen*, 1913, 401, 21—119).—It has been shown (A., 1912, i, 965) that the allyl ethers of several phenols change almost quantitatively by heating, sometimes even below the b. p., to the isomeric allylphenols. In order to test the generality of the change, a large number of aromatic allyl ethers have been examined; all without exception undergo the change.

The ethers are of the types (i) R⟨◯⟩$O·C_3H_5$, (ii) ⟨◯⟩$O·C_3H_5$ with R, R,

and (iii) ⟨◯⟩$O·C_3H_5$ with R. Those of type (i) change very easily to o-allylphenols, and those of type (ii) readily to p-allylphenols. Ethers of type (iii) yield o-allylphenols, so the allyl group preferentially enters the nucleus in the ortho-position to the hydroxyl group. The b. p.'s /0 mm. of the allylphenols and also the densities are generally higher than the corresponding constants of the isomeric allyl ethers; exceptions, however, are the allyl ethers of phenols containing a negative substituent in the ortho-position to the hydroxyl group, the b. p.'s of these being higher than the b. p.'s of the isomeric allylphenols.

With suitable ethers changes such as:

$(o)OMe·C_6H_4·O·C_3H_5 \longrightarrow OMe·C_6H_3(C_3H_5)·OH \longrightarrow$
$OMe·C_6H_3(C_3H_5)·O·C_3H_5 \longrightarrow OMe·C_6H_2(C_3H_5)_2·OH$
proceed with good yields. Such changes occur particularly easily with allyl ethers of phenolaldehydes and phenolcarboxylic acids and their esters. However, when the aldehyde or carboxyl group occupies a position in the nucleus into which the allyl group desires to enter, it is eliminated as carbon monoxide or carbon dioxide respectively; for example, by alternate heating and allylation, esters of *o*-allyloxybenzoic acid are converted into 2-allyloxy-3 : 5-diallylbenzoates ; the latter then change to 2 : 4 : 6-triallylphenol by hydrolysis and heating.

In addition to the change to *o*-propenylphenols by heating with aqueous potassium hydroxide (*loc. cit.*), *o*-allylphenols are changed in another manner by heating with an acid catalyst, such as pyridine hydrochloride ; this change, whereby dihydrocoumarones are produced,

$$\text{OH·C}_6\text{H}_4\text{·CH}_2\text{·CH:CH}_2 \;\rightarrow\; \text{C}_6\text{H}_4\overset{\text{CH}_2}{\underset{\text{O}}{<}}\text{>CHMe, will be described}$$

in a future communication.

The aromatic allyl ethers described below are prepared generally by boiling the phenol in acetone with allyl bromide and finely powdered potassium carbonate. For the preparation of the allyl bromide, Merling and Jacobi's hydrogen bromide method (A., 1894, i, 162) is recommended, the yield being 85%. An apparatus is figured and described by which 120—150 grams of hydrogen bromide per hour can be obtained quantitatively from its elements.

Although the change frequently occurs at lower temperatures, the optimum temperature, at which the change is complete usually in a few seconds or minutes, for the conversion of the aromatic allyl ether into the allylphenol is 230—250°. Difficultly volatile phenyl allyl ethers cannot have a b. p. under ordinary pressures, because they change to the allylphenol before the b. p. is reached.

p-*Chlorophenyl allyl ether*, $\text{C}_6\text{H}_4\text{Cl·O·C}_3\text{H}_5)$, b. p. 106—107°/12 mm., D^{15} 1·131, a colourless liquid having an odour of aniseed, is converted by boiling for twenty to twenty-five minutes into 4-*chloro-2-allylphenol*, $\text{OH·C}_6\text{H}_3\text{Cl·C}_3\text{H}_5$, m. p. 48°, b. p. 256—260° or 124—125°/12 mm., D^{15} 1·171 (supercooled liquid), which develops an olive-green coloration with alcoholic ferric chloride and forms a p-*nitrobenzoate*, m. p. 82°. p-*Bromophenyl allyl ether*, b. p. 126°/14 mm., yields by boiling for a few minutes 4-*bromo-2-allylphenol*, m. p. 50°, b. p. 274—280° or 142—144°/14 mm. p-*Nitrophenyl allyl ether*, m. p. 18·5°, b. p. 160°/12 mm., faintly yellow prisms, yields about 40% of 4-*nitro-2-allylphenol* at 260°; the latter has m. p. 79°, b. p. 190°/11 mm., and crystallises in colourless leaflets. p-*Benzeneazophenyl allyl ether*,

$$\text{C}_6\text{H}_5\text{·N}_2\text{·C}_6\text{H}_4\text{·O·C}_3\text{H}_5,$$

m. p. 52°, yellowish-red needles and prisms, yields by heating in petroleum at 230° about 70% of o-*allylbenzeneazophenol*, m. p. 97—98°, yellow needles and prisms (*benzoate*, m. p. 92°, brownish-red crystals).

p-*Tolyl allyl ether*, b. p. 211—213° or 91°/12 mm., D^{15} 0·967, yields by boiling for one hour 3-*allyl-p-cresol*, b. p. 236—238° or 112°/12 mm., D^{15} 1·006 (p-*nitrobenzoate*, m. p. 69°). By heating with potassium hydroxide and water at 140—145°, 3-allyl-p-cresol is converted into 3-*propenyl-p-cresol*, b. p. 120—124°/11 mm., the *methyl ether* of which is oxidised to 4-*methoxyisophthalic acid* by potassium permanganate. By allylation, 3-allyl-p-cresol yields 3-*allyl-p-tolyl allyl ether*, b. p.

123—127°/14 mm., from which is obtained by prolonged heating a very small quantity of a *substance*, b. p. 135—145°/14 mm., which is possibly 4-*methyl*-3 : 5-*diallylphenol*.

Eugenyl allyl ether, b. p. 140°/9 mm., D^{15} 1·024, changes very easily at 230° to o-*allyleugenol*, b. p. 285—287° or 149°/10 mm., D^{15} 1·036, which develops a deep blue to deep green coloration with alcoholic ferric chloride and forms a p-*nitrobenzoate*, m. p. 136°.

The eugenol obtained previously (*loc. cit.*) by the transformation of guaiacyl allyl ether is now definitely proved to be o-eugenol (o-allyl-guaiacol), since it yields by treatment with aqueous potassium hydroxide at 170° a propenylguaiacol, m. p. 78°, which is identical with Pauly and Buttlar's o-*isoeugenol*, (A., 1911, i, 785). o-*Eugenyl allyl ether*, b. p. 128°/10 mm., D^{15} 1·016, changes at 200° to o-allyleugenol, identical with the substance obtained by the transformation of eugenyl allyl ether.

o-*Tolyl allyl ether*, b. p. 205—208° or 85°/12 mm., D^{15} 0·969, is changed by boiling to 2-*methyl*-3-*allylphenol*, b. p. 231—233° or 106—107°/12 mm., D^{15} 1·007, which must contain the allyl group in the ortho-position to the hydroxyl group, since it is also obtained by heating 2-allyloxy-m-toluic acid (see below).

m-*Tolyl allyl ether*, b. p. 211—214° or 92—94°/12 mm., D^{15} 0·965, is changed by boiling to 3-*methyl*-2(or 4)-*allylphenol*, b. p. 239—240° or 111—112°/11 mm., D^{15} 1·012; since the liquid has been separated into a liquid and a solid, m. p. 53°, possibly both allyl-m-cresols are present in it. By further allylation it yields *allyl*-m-*tolyl allyl ether*, which changes at 230° to 3-*methyl*-2 : 4-*diallylphenol*, b. p. 272—274° or 140°/15 mm., to the extent of about 30%.

o-*Nitrophenyl allyl ether*, b. p. 155°/12 mm., is changed by heating at 180° for five hours to 6(?)-*allyl-o-nitrophenol*, m. p. 9°, b. p. 130—135°/15 mm. (*barium* salt, golden-red leaflets).

α-*Naphthyl allyl ether* is an oil which cannot be distilled, even under diminished pressure, without partly changing to 2-*allyl-α-naphthol*, b. p. 171°/12 mm. (p-*nitrobenzoate*, m. p. 99°). The allylnaphthol, which is obtained in 50—60% yield at 230°, condenses with benzenediazonium chloride to form 4-*benzeneazo*-2-*allyl-α-naphthol*, m. p. 157—158°, red crystals with green reflex.

The behaviour of ethyl o-allyloxybenzoate has been recorded (*loc. cit.*). The position of the allyl group in the transformed product is proved by elimination of the carbethoxy group, whereby o-allylphenol is obtained. *Methyl o-allyloxybenzoate*, b. p. 143°/12 mm., D^{15} 1·118, changes by heating to *methyl* 3-*allylsalicylate*, b. p. 130°/10 mm., D^{15} 1·120°, with almost explosive violence; the latter gives a bluish-violet coloration with alcoholic ferric chloride, and yields 3-*allylsalicyl-amide*, $C_3H_5 \cdot C_6H_3(OH) \cdot CO \cdot NH_2$, m. p. 99°, colourless plates, by prolonged keeping with concentrated methyl-alcoholic ammonia. By heating 2-allyloxybenzoic acid, the allyl does not displace the carboxyl group as in the cases recorded below, but enters position 3, as is proved by the conversion of the resulting 3-allylsalicylic acid into o-allylphenol at 300°. o-Allylphenol condenses with benzenediazonium chloride to form the benzeneazo-o-allylphenol mentioned above. 2-*Methoxy*-3-*allylbenzoic acid*, m. p. 53°, is obtained by hydrolysing

the methyl ester, and 2-*acetoxy-3-allylbenzoic acid*,

$$C_8H_5 \cdot C_6H_3(OAc) \cdot CO_2H,$$
m. p. 96°, colourless needles, by boiling 3-allylsalicylic acid with acetic anhydride and potassium acetate.

Methyl 2-allyloxy-3-allylbenzoate, b. p. 152—162°/9 mm., obtained by heating methyl 3-allylsalicylate with allyl bromide and methyl alcoholic sodium methoxide, yields 2-*allyloxy-3-allylbenzoic acid*, m. p. 57°, by hydrolysis. By heating at about 250—260°, the acid is converted into 3 : 5-*diallylsalicylic acid*, m. p. 99°, and 2 : 6-*diallylphenol*, b. p. 256—258°, whilst the methyl ester yields *methyl* 3 : 5-*diallylsalicylate*, b. p. 155—165°/9 mm., which develops a dark blue coloration with ferric chloride. 3 : 5-*Diallylsalicylic acid*, m. p. 99°, colourless needles, gives an indigo blue colour with ferric chloride, and forms an *acetyl* derivative, m. p. 94°.

The allylation of methyl 3 : 5-diallylsalicylate yields *methyl* 2-*allyloxy-3 : 5-diallylbenzoate*, b. p. 180—182°/10 mm. This ester decomposes completely by heating under ordinary pressure, but the corresponding *acid*, m. p. 55°, is converted into 2 : 4 : 6-*triallylphenol*, b. p. 293—295° or 152—153°/10 mm., D^{15} 0·978 (*phenylcarbamate*, m. p. 97°).

Methyl 2-allyloxy-3-methylbenzoate, b. p. 130—140°/10 mm., is converted by heating into *methyl* 2-*hydroxy-3-methyl-5-allylbenzoate*, b. p. 275—290°, whilst 2-*allyloxy-3-methylbenzoic acid*, m. p. 59°, yields chiefly 2-*methyl-3-allylphenol*, b. p. 231—233°, 2-*hydroxy-3-methyl-5-allylbenzoic acid*, m. p. 127—129°, being obtained as a by-product.

Ethyl p-*allyloxybenzoate*, b. p. 156°/10 mm., is changed at 220—250° to *ethyl 4-hydroxy-3-allylbenzoate*, m. p. 78°, b. p. 185°/9 mm., the hydrolysis of which yields 4-*hydroxy-3-allylbenzoic acid*, m. p. 128°.

4-*Allyloxybenzoic acid*, m. p. 162°, crystallises in colourless plates and leaflets. By heating with concentrated aqueous potassium hydroxide at 180°, 4-hydroxy-3-allylbenzoic acid is converted into 4-*hydroxy-3-propenylbenzoic acid*, m. p. 169°.

Ethyl 4-allyloxy-3-allylbenzoate, b. p. 176°/9 mm., obtained by the allylation of ethyl 4-hydroxy-3-allylbenzoate (corresponding acid, $C_{13}H_{14}O_3$, m. p. 140°), is easily converted into *ethyl 4-hydroxy-3 : 5-diallylbenzoate*, m. p. 94°, b. p. 184—194°/9 mm., at 220—230°. 4-*Hydroxy-3 : 5-diallylbenzoic acid* has m. p. 108°. By allylation its ester is converted into *ethyl 4-allyloxy-3 : 5-diallylbenzoate*, b. p. 190°/10 mm., which decomposes when heated under ordinary pressure; the *acid*, $C_{16}H_{18}O_3$, m. p. 97°, however, is converted into 2 : 4 : 6-triallylphenol quantitatively at 300°.

2-*Allyloxybenzaldehyde*, b. p. 130°/10 mm., D^{15} 1·094, obtained almost quantitatively by boiling salicylaldehyde with allyl bromide and potassium carbonate in absolute alcohol, changes at 220—230° to 3-*allylsalicylaldehyde*, b. p. 245·5—246° or 111°/11 mm., D^{15} 1·098, which develops a bluish-violet coloration with alcoholic ferric chloride, forms a *copper* salt, $Cu(C_{10}H_9O_2)_2$, m. p. 181°, olive-brown needles, and *ferric* salt, $Fe(C_{10}H_9O_2)_3$, m. p. 110—111°, black crystals, condenses with benzenediazonium chloride in alkaline solution to form *benzeneazo-3-allylsalicylaldehyde*, $C_6H_5N_2 \cdot C_6H_2(OH)(C_3H_5) \cdot CHO$, m. p. 71°, yellow needles or prisms, and forms an *aldoxime*,

$$C_3H_5 \cdot C_6H_3(OH) \cdot CH:NOH,$$
m. p. 79°. The oxime is converted by acetyl chloride into the *acetyl*

derivative, $C_3H_5 \cdot C_6H_3(OH) \cdot CH:NOAc$, m. p. 58° (from which the *nitrile* is obtained by heating), and the *hydrochloride*,

$$C_3H_5 \cdot C_6H_3(OH) \cdot CH:NOH, HCl.$$

By methylation by the potassium carbonate method, 3-allylsalicyl-aldehyde is converted into 2-*methoxy-3-allylbenzaldehyde*, b. p. 128°/9 mm., which is oxidised to 2-methoxy-3-allylbenzoic acid by alkaline hydrogen peroxide. The formation of this acid is the proof that the allyl group is in position 3 in the allylsalicylaldehyde obtained by the transformation of 2-allyloxybenzaldehyde.

2-*Allyloxy-3-allylbenzaldehyde*, b. p. 145—147°/11 mm., obtained by the allylation of 3-allylsalicylaldehyde, is converted at 200° into a 2 : 6-diallylphenol (75%) and 3 : 5-*diallylsalicylaldehyde*, b. p. 138—143°/10 mm. (*semicarbazone*, m. p. 154—156°). 2 : 6-Diallylphenol condenses with benzenediazonium chloride to form 4-*benzeneazo-2 : 6-diallylphenol*, m. p. 37°, reddish-yellow prisms.

2-*Allyloxybenzyl alcohol*, $C_3H_5O \cdot C_6H_4 \cdot CH_2 \cdot OH$, b. p. 133—150°/9 mm., obtained by the allylation of saligenin, yields formaldehyde and resinous products by heating.

4-*Allyloxybenzaldehyde*, b. p. 142°/10 mm., changes violently at 260—270°, and yields about 66% of 4-*hydroxy-3-allylbenzaldehyde*, m. p. 66°, b. p. 179°/9 mm. By allylation, the latter yields 4-*allyloxy-3-allylbenzaldehyde*, b. p. 164°/10 mm., which changes at 250° to 4-*hydroxy-3 : 5-diallylbenzaldehyde*, m. p. 67·5°, b. p. 185—190°/10 mm., to the extent of about 66%. This in its turn, by allylation, yields 4-*allyloxy-3 : 5-diallylbenzaldehyde*, which even by distillation under low pressures loses carbon monoxide and is converted into 2 : 4 : 6-triallylphenol.

The behaviour of 2-*allyloxy-3-methoxybenzaldehyde* (o-*vanillin allyl ether*), b. p. 156—160°/12 mm., obtained by the allylation of o-vanillin, is particularly interesting. By heating at 170—240°, it yields mainly o-eugenol, carbon monoxide being eliminated ; in addition, however, 2-*hydroxy-3-methoxy-5-allylbenzaldehyde* (5-*allyl-o-vanillin*), m. p. 48—49°, pale yellow crystals, and 4-*hydroxy-3-methoxy-5-allyl-benzaldehyde* (5-*allylvanillin*), m. p. 86°, b. p. 173°/9 mm., are formed. 5-Allyl-o-vanillin is almost odourless, develops a dark blue coloration with alcoholic ferric chloride, dissolves in 10% aqueous sodium carbonate, forms a *semicarbazone*, m. p. 195°, and in alcohol reacts with con-centrated aqueous ammonia to form an *imino*-derivative,

$$C_3H_5 \cdot C_6H_2(OMe)(OH) \cdot CH:NH,$$

m. p. 114°, yellow needles. By allylation, it is converted into 3-*methoxy-2-allyloxy-5-allylbenzaldehyde*, which changes at 170—285° into o-allyleugenol.

3-*Methoxy-4-allyloxybenzaldehyde* (p-*vanillin allyl ether*) changes very vigorously at ordinary pressure, and appreciably even at low pressures, to 5-allylvanillin ; at 210—220°, the yield is 80%. 3-*Methoxy-4-allyloxy-5-allylbenzaldehyde*, obtained by its further allylation, changes to o-allyleugenol by distillation, the amount of carbon monoxide evolved corresponding with an 82% yield. O. S.

Preparation of the Thymyl Ester of *iso*Valeryloxyacetic Acid. J. D. RIEDEL (D.R.-P. 260471. Compare this vol., i, 63).— *Thymyl chloroacetate*, a yellow oil, b. p. 262°, with a faint odour of thymol, is prepared by the condensation of thymol and chloroacetyl

chloride ; when treated with sodium *iso*valerate it furnishes *thymyl* iso-*valeryloxyacetate*, $C_6H_3MePr^\beta\cdot O\cdot CO\cdot CH_2\cdot O\cdot CO\cdot CH_2\cdot CHMe_2$, a yellow liquid, b. p. 207—209°/19 m.m., D 1·037, and of therapeutic value.

<div align="right">F. M. G. M.</div>

Action of Bromine and of Chlorine on Phenols. Substitution Products, ψ-Bromides, and ψ-Chlorides. XXVI. Action of Bromine on Di-*o*-cresoldimethylmethane [6 : 6'-Dihydroxy-ββ-di-*m*-tolylpropane]. THEODOR ZINCKE, J. KEMPF, and W. UNVERZAGT (*Annalen*, 1913, **400**, 27—47).—*m*- and *p*-Cresols condense with acetone in the presence of hydrogen chloride to form indifferent substances, $C_{20}H_{24}O_2$, which are probably ethers (Zincke and Gaebel, A., 1912, i, 442). *o*-Cresol (7 parts), acetone (1 part), and 0·7 part of hydrochloric acid, D 1·19, react at the ordinary temperature to form 6 : 6'-dihydroxy-ββ-di-*m*-tolylpropane,

$$CMe_2(C_6H_3Me\cdot OH)_2,$$

m. p. 136°, colourless needles, which is quite analogous to *pp*-dihydroxy-ββ-diphenylpropane (Zincke and Grüters, A., 1906, i, 172 ; Zincke, *ibid.*, i, 737) in its behaviour. It forms a *diacetyl* derivative, $C_{21}H_{24}O_4$, m. p. 88—89°, and reacts with bromine in cold glacial acetic acid to form 5 : 5'-*dibromo*-6 : 6'-*dihydroxy-ββ-di-*m*-tolylpropane*,

$$CMe_2(C_6H_2MeBr\cdot OH)_2,$$
m. p 119—120°, colourless plates or double pyramids (*diacetyl* derivative, m. p. 145°). When treated in the cold with an excess of bromine without a solvent, dihydroxy-ββ-di-*m*-tolylpropane or the preceding dibromo-derivative yields 3 : 4 : 5-tribromo-*o*-cresol, tetrabromo-*o*-cresol (in one experiment a *substance*, $C_{10}H_6Br_5$, m. p. 250—251°), and ψ-3-*bromo-5-pentabromo*iso*propyl-o-cresol* (ψ-*hexabromo*-5-iso*propyl-o-cresol*), $OH\cdot C{<}^{CBr-CH}_{CMe\cdot CH}{>}C\cdot CBr(CHBr_2)_2$, m. p. 169—170° (decomp.), colourless, monoclinic prisms, which is insoluble in aqueous sodium hydroxide. The hexabromo-ψ-bromide resembles ψ-heptabromo-*p*-iso-propylphenol (Zincke and Grüters, *loc. cit.*) in its behaviour, and since the latter has the constitution $OH\cdot C_6H_2Br_2\cdot CBr(CHBr_2)_2$ (Zincke, A., 1912, i, 443), ψ-hexabromo-5-*iso*propyl-*o*-cresol probably has the constitution recorded above ; it certainly contains only one bromine atom in the benzene nucleus. It readily yields an *acetyl* derivative, $C_{12}H_{10}O_2Br_6$, m. p. 135—136°, stout plates, by treatment with acetic anhydride and concentrated sulphuric acid. By the action of alcohol and 2 *N*-sodium hydroxide at the ordinary temperature, the acetyl derivative is converted into 3-*bromo-5-tetrabromo*isopropenyl-o-cresol*, $OH\cdot C{<}^{CBr-CH}_{CMe\cdot CH}{>}C\cdot C(CHBr_2):CBr_2$, m. p. 94—95°, which forms an *acetyl* derivative, $C_{12}H_9O_2Br_5$, m. p. 114—115°, and *methyl ether*, $C_{11}H_9OBr_5$, m. p. 110—111°. By oxidation with boiling dilute nitric acid and silver nitrate, the methyl ether is converted into 3-*bromo*-2-*methoxy*-m-*toluic acid*, $C_9H_9O_3Br$, m. p. 206—207°, the formation of which proves the presence of only one bromine atom in the benzene nucleus of the methyl ether and, therefore, also in that of the hexabromo-ψ-bromide.

ψ-3-Bromo-5-pentabromo*iso*propyl-*o*-cresol, dissolved in acetone, is

converted by careful treatment with water at the ordinary temperature into 3-*bromo*-5-*tetrabromo*isopropylidenetoluquinone,

$$CO\overset{CBr=CH}{\underset{CMe:CH}{<}}>C:C(CHBr_2)_2,$$
m. p. 180—181°, golden-yellow prisms, which is quite stable. It is reconverted into the hexabromo-ψ-bromide by hydrogen bromide in glacial acetic acid, yields a *diacetate*,

$$OAc\cdot C\overset{CBr-CH}{\underset{CMe:CH}{<}}>C\cdot C(CHBr_2)_2\cdot OAc,$$
m. p. 160—161°, colourless needles, by treatment with acetic anhydride and concentrated sulphuric acid, and is converted into 3-*bromo*-5-*tetrabromomethoxy*isopropyl-o-*cresol*,

$$OH\cdot C\overset{CBr-CH}{\underset{CMe:CH}{<}}>C\cdot C(CHBr_2)_2\cdot OMe,$$
m. p. 100—101°, colourless prisms (*acetyl* derivative, $C_{18}H_{18}O_3Br_5$, m. p. 163°), by boiling methyl alcohol and a few drops of concentrated sulphuric acid.

The *phenol-alcohol*, $OH\cdot C\overset{CBr-CH}{\underset{CMe:CH}{<}}>C\cdot C(CHBr_2)_2\cdot OH$, m. p. 126°, colourless needles or prisms, corresponding with the preceding diacetate, cannot be prepared from the hexabromo-ψ-bromide or from the toluquinone by the addition of water, but is obtained from the latter in a curious manner by the action of glacial acetic acid and fuming sulphuric acid (20% SO_3) on the water-bath, water being subsequently added to the solution.

3-Bromo-5-tribromoisopropenyl-ᴏ-cresol is produced by the reduction of 3-bromo-5-tetrabromoisopropylidenetoluquinone by stannous chloride solution and hot glacial acetic acid, but has only been identified in the form of its *acetate*,

$$OAc\cdot C\overset{CBr-CH}{\underset{CMe:CH}{<}}>C\cdot C(CHBr_2):CHBr,$$
m. p. 90—91°, rhombic prisms or plates.

By shaking with aniline and glacial acetic acid, the hexabromo-ψ-bromide or the toluquinone is converted into *pentabromo*isopropyl-o-*cresol*-ψ-*anilide*, $C_{16}H_{14}ONBr_5$, m. p. 128—129°, which is given the quinonoid constitution, $CO\overset{CBr=CH}{\underset{CMe:CH}{<}}>CH\cdot C(CHBr_2)_2\cdot NHPh$, on account of its insolubility in alkalis. It forms colourless crystals which easily become yellow, and dissolves in boiling methyl or ethyl alcohol or glacial acetic acid; the yellow solutions deposit a *substance*, m. p. 223—224° (decomp.), intensely yellow prisms, which forms an orange-yellow *sodium* salt. The nature of the yellow substance has not yet been ascertained.　　　　　　　　　　　　　　　　　　　C. S.

[Preparation of Compounds containing Selenium.] August von Wassermann and Ernst Wassermann (D.R.-P. 261793).—When a solution of *p*-nitrosodimethylaniline in concentrated hydrochloric acid solution is treated with hydrogen selenide a bluish-red scum is formed; when this *leuco*-derivative (which was not isolated) is oxidised and subsequently treated with an aqueous solution of zinc chloride, a double

compound with zinc chloride is precipitated; this "selenoazine blue" is an analogue of methylene-blue, and can be employed as a dye and for the introduction of selenium into animal tissues; it forms a glistening, dark green bronze powder, readily soluble in water, sparingly so in alcohol.   F. M. G. M.

Action of Methyl Iodide on Aromatic Tellurides. KARL LEDERER (*Annalen*, 1913, **399**, 260—271).—Aromatic tellurides, unlike aromatic sulphides and selenides, readily react additively with methyl iodide, forming diarylmethyltelluronium iodides. From these, other salts can be prepared, specially characteristic being the sparingly soluble picrates, chromates, dichromates, and platinichlorides; the chlorides form double salts with the chlorides of mercury, gold, zinc, and copper.

The diarylmethyltelluronium hydroxides, prepared from the iodides by means of moist silver oxide, are extremely hygroscopic, oily liquids which have a strong alkaline reaction, liberate ammonia from its salts, precipitate the heavy metals in the form of their hydroxides, but do not combine with carbon dioxide. Aryl tellurides react with ethyl iodide only to a very small extent.

Phenyl telluride and methyl iodide, after being kept for two days, yield a crystalline *compound*, $TePh_2MeI,MeI$, which is converted by ether into *diphenylmethyltelluronium iodide*, $TePh_2MeI$, m. p. or decomp. 123—124° (bath at 110°), colourless needles (from hot water), which is decomposed by alcohol, as also are the *bromide*, m. p. 137—138°, small prisms, and *chloride*, m. p. 129—130° (decomp.). The *nitrate*, m. p. 168—169°, rhombic plates; *platinichloride*, m. p. 157—158°, microscopic, yellow plates; *chromate*, m. p. 151°, orange-red needles; *dichromate*, decomp. 153°, orange-red, quadratic leaflets; *picrate*, $C_{19}H_{15}O_7N_3Te,H_2O$, m. p. 93—94°, long, yellow needles; *mercurichloride*, $C_{13}H_{13}TeCl,HgCl_2$, m. p. 135—136°, colourless needles, and *zincichloride*, m. p. 149—150°, are described. *Diphenylmethyltelluronium hydroxide* has an odour of piperidine or pyrrolidine, and is decomposed by warm water.

p-Tolyl telluride and methyl iodide, after being kept for five days, yield, after treating the product with ether, *di-p-tolylmethyltelluronium iodide*, m. p. 85—86° (decomp.); the *picrate*, m. p. 157—158°, yellow needles; *mercurichloride*, m. p. 149—150° (decomp.); *chloride*, *bromide*, m. p. 73—74°; *dichromate*, m. p. 54—55°; *chromate*, m. p. 51—52°; *platinichloride*, m. p. 104—105°, and *aurichloride*, m. p. 35—36°, have been prepared, but the salts and also the *hydroxide* are not particularly stable, several of the preceding salts certainly being impure.

Di-o-tolylmethyltelluronium iodide, m. p. 125—126°, small crystals, is obtained directly from its components after keeping for fourteen days. The *bromide*, m. p. 134—135° (bath at 120°), small prisms; *nitrate*, m. p. 155—157°, hexagonal plates; *picrate*, m. p. 143—144°; *platinichloride*, m. p. 186°, microscopic, yellow prisms; *dichromate*, m. p. 171—172° (decomp.), orange-red needles; *chromate*, m. p. 161—162°, small, yellow prisms; *mercurichloride*, m. p. 134—135° (decomp.), felted needles, and basic *zincichloride*, $TeMe(C_7H_7)_2Cl,ZnCl\cdot OH$, micro-

scopic prisms, have been prepared; the *hydroxide* is not hygroscopic, and is comparatively stable, not being decomposed by boiling water.

<div align="right">C. S.</div>

Oxonium Compounds. GEORGE L. STADNIKOFF (*Ber.*, 1913, **46**, 2496—2503. Compare A., 1912, i, 109, 971).—In connexion with the conclusion drawn by the author from the occurrence of tetraphenylethane and αα-diphenylbutane after the action of water on the reaction product of diphenylmethyl butyl ether and magnesium propyl iodide, that the additive compound of the latter two substances is of the structure $\mathrm{CHPh_2}^{\mathrm{C_4H_9}}{>}\mathrm{O}{<}^{\mathrm{Pr}}_{\mathrm{MgI}}$, it may be objected that the formation of the tetraphenylethane and αα-diphenylbutane possibly preceded the addition of water.

To meet this objection, diphenylmethyl butyl ether has been allowed to react with various magnesium alkyl haloids in solution in ether (which does not prevent the formation of such additive compounds) for considerable periods. The procedure was to add the diphenylmethyl butyl ether to the cooled ethereal solution of the magnesium alkyl haloid and to find the quantities of any gaseous products evolved on boiling, and of the total organic products obtained on subsequently treating the cooled reaction product with water.

There are three main directions of decomposition of the ether additive compound which is believed to be the primary product on the addition of water : (1) the regeneration of diphenylmethyl butyl ether ; (2) the formation of tetraphenylethane, and (3) the production of a αα-diphenyl-substituted paraffin hydrocarbon.

With diphenylmethyl butyl ether and magnesium propyl iodide all the above reactions occur, although the relative amounts of the different products vary from those obtained earlier (A., 1912, i, 971) with the same Grignard reagent in the absence of ethyl ether. The results, however, confirm the author's views.

Diphenylmethyl butyl ether was allowed to form additive compounds also with magnesium ethyl iodide and magnesium methyl iodide ; the former gave similar results to the propyl compound ; the latter gave as hydrocarbon products only methane and tetraphenylethane.

Magnesium propyl iodide either in benzene or in ethereal solution when treated with diphenylmethyl *iso*amyl ether, and subsequently with water, gave propane and unaltered diphenylmethyl *iso*amyl ether.

In each case, except with the methyl Grignard reagent, a quantity of the corresponding ethylenic hydrocarbon was evolved during the heating after the addition of the "mixed" ether.

<div align="right">D. F. T.</div>

The Isomerism of Tri-α-naphthylcarbinol. ALEXEI E. TSCHITSCHIBABIN (*Ber.*, 1913, **46**, 2554—2556).—The author is of opinion that of the so-called isomeric forms of tri-α-naphthylcarbinol described by Schmidlin and Bergmann (this vol., i, 46), the more stable is in reality merely the ether-free carbinol described earlier by himself (A., 1911, i, 969), and is not identical with the stable "isomeride" obtained by Schmidlin and Massini (A., 1909, i, 563), which he has

shown to be an oxidation product, namely, α-naphthyldi-αα-naphtha-fluoryl alcohol.   This view receives further confirmation from the fact that the free tri-α-naphthylcarbinol when dissolved in amyl acetate and treated with much ether is slowly deposited in needles or prisms of the easily oxidisable substance containing ether of crystallisation. The ether-free carbinol has a higher m. p., namely, 160—180° (decomp.), than that recorded hitherto.

There is consequently here no case of isomerism unless the compound containing ether of crystallisation is regarded as a distinct isomeride of the ether-free substance.   D. F. T.

Aromatic Selenium Compounds.   II.   RUDOLF LESSER and R. WEISS (*Ber.*, 1913, **46**, 2640—2658.   Compare A., 1912, i, 642). —An extended account of the results of attempts to prepare compounds containing a selenium atom in place of a sulphur atom, a preliminary note of which has previously appeared (*loc. cit.*).

Diphenyldiselinide-di-*o*-carboxylic acid, $Se_2(C_6H_4·CO_2H)_2$, is more conveniently prepared by the addition of a diazotised solution of anthranilic acid to a solution of potassium or sodium diselinide in an atmosphere of carbon dioxide.   After decomposition of the diazo-compound by heat, the acids are liberated by addition of mineral acid to the hot solution.   The crude diphenyldiselinide-di-*o*-carboxylic acid is freed from diphenylselinide-di-*o*-carboxylic acid by digestion with glacial acetic acid, which leaves the former undissolved.

o-*Methylselenolbenzoic acid*, $SeMe·C_6H_4·CO_2H$, long needles, m. p. 180—181°, is obtained in practically quantitative yield when an alkaline solution of sodium *o*-selenolbenzoate is shaken with methyl sulphate.   The corresponding *methyl* ester, m. p. 64—66°, is best obtained by the action of methyl iodide on the *silver* salt, and, in contrast with methyl *o*-methylthiolbenzoate, is odourless.   *o*-*Benzoyl-selenolbenzoic acid*, $SeBz·C_6H_4·CO_2H$, has m. p. 163—164°.

o-Selenonbenzoic acid, $SeO_3H·C_6H_4·CO_2H$, is a very strong acid, the salts of which are not decomposed by dilute nitric acid.   It has not been obtained in the crystalline state, but yields a *barium* salt, $C_7H_4O_5SeBa$, which separates from water in colourless, anhydrous needles.   An aqueous solution of the acid is transformed by hydro-chloric acid into *o*-seleninbenzoic acid, m. p. 228—229° (decomp.), which is also obtained by the oxidation of diphenyldiselenide-di-*o*-carboxylic acid by nitric acid, or a mixture of nitric and sulphuric acids.   When heated at 130—140° until constant in weight, it is transformed into the *anhydride*, $O(SeO·C_6H_4·CO_2H)_2$, without change in m. p.

When diphenyldiselenide-di-*o*-carboxylic acid is warmed with thionyl chloride and excess of the latter removed, a crystalline residue is obtained which can be separated by means of light petroleum into two portions.   The smaller of these, m. p. 173—174°, is the normal chloride, $C_{14}H_8O_2Cl_2Se_2$, whilst the larger, m. p. 65—66°, consists of a *compound* of this substance and hydrogen chloride, and has the composition $C_{14}H_{10}O_2Cl_4Se_2$.   When the latter is boiled with methyl alcohol, the *hydrochloride* of *methyldiphenyl-diselenide-di-o-dicarboxylate*, $C_{16}H_{16}O_4Cl_2Se_2$, yellow needles, m. p. 74—75°, is obtained, which, when treated with warm sodium hydroxide, is converted into the corresponding *ester*, m. p. 143—144°.   The *hydrochloride* of the *ethyl*

ester, m. p. 91—92°, is similarly formed and converted in the same manner into the *ethyl* ester, m. p. 129—130°. The normal esters can also be prepared by the action of the requisite alcohol on the normal chloride or on the free acid in the presence of hydrogen chloride.

Phosphorus pentachloride resembles thionyl chloride in its action on the free acid, yielding, however, a less pure product which contains a rather greater proportion of the normal chloride.

Pure diphenylselenide-di-*o*-carboxylic acid has m. p. 234—235° (instead of 228—229° as previously given). Thionyl chloride converts it into the corresponding normal *chloride*, lemon-yellow crystals, m. p. 107—108°, which gradually decomposes when preserved without, however, yielding a uniform product. Boiling methyl and ethyl alcohols transform the chloride into the *methyl* ester, m. p. 70—71°, and the *ethyl* ester, m. p. 64—65°, respectively. The *amide* forms colourless plates, m. p. 212—213°.

When warmed with concentrated sulphuric acid on the water-bath, diphenylselenide-di-*o*-carboxylic acid yields two products which can be separated by means of sodium hydroxide. The soluble portion consists of *selenoxanthone-o-carboxylic acid*, $C_6H_4\!<\!^{CO}_{Se}\!>\!C_6H_3\cdot CO_2H$, which sublimes from 250° in yellow needles and decomposes at 290—300°. In the dry state it is stable, but, when dissolved, readily eliminates carbon dioxide, for example, when a hot solution of its alkali salt is acidified. Attempts to transform it into the corresponding selenoxanthone by loss of carbon dioxide were, however, unsuccessful, benzophenone-selenone, $C_6H_4\!<\!^{CO}_{SeO_2}\!>\!C_6H_4$, being invariably produced. This substance also constitutes the portion obtained in the above action which is insoluble in alkali and is obtained as by-product of the action of thionyl chloride on diphenylselenide-di-*o*-carboxylic acid. It forms large, glassy prisms, m. p. 317—318° (decomp.), and sublimes partly undecomposed from about 260°. It thus differs remarkably from the benzophenoneselenone described by Doughty and Elder (this vol., i, 962) for which the m. p. 183° is given.

Acetic anhydride is without action on diphenylselenide-di-*o*-carboxylic acid, whilst potassium permanganate, in neutral or alkaline solution, converts it into the selenone.

o-Carboxyphenylselenolacetic acid is readily converted into its *methyl* ester, leaflets, m. p. 62—63°, by means of methyl alcohol and hydrogen chloride. The ethyl ester is oily.

When a diazotised solution of *m*-aminobenzoic acid is added to a solution of potassium hydrogen selenide or of potassium diselenide under the conditions described for anthranilic acid, *diphenylselenide-di-m-carboxylic acid* is produced, the diselenide acid being apparently not formed. It has m. p. 296—297°, and sublimes from about 260°. Concentrated sulphuric acid dissolves it with a yellow colour; fuming sulphuric acid with an intense bluish-green colour. Potassium permanganate oxidises it in the form of its salts to *diphenylselenon-di-m-carboxylic acid*, colourless prisms, which becomes yellow at about 255°, and has m. p. 262—263° (decomp.).

p-Aminobenzoic acid, when similarly treated, yields a difficultly separable mixture of the *p*-diselenide and selenide acids. *Diphenyl-*

*diselenide-di-*p-*carboxylic acid* is a pale yellow, crystalline powder, m. p. 314—315°. *Diphenylselenide-di-*p-*carboxylic acid*, two preparations of which had m. p. 312—313° and 315—316°, resembles the above acid so closely that it can only be distinguished from it by ultimate analysis.

Hydroxyselenonaphthen reacts with 5-bromoisatin in alcoholic solution in the presence of piperidine to form "2-*selenonaphthen*-[5-*bromo*-3-*indole*]-*indigo*" (3'-*bromoindoxyl*-2-*selenonaphthen*-3-*one*),

$$C_6H_4{<}^{CO}_{Se}{>}C{:}C{<}^{CO---}_{C_6H_3Br}{>}NH,$$
red, silky needles, which sublime at about 260°, have m. p. about 355°, and are soluble in fuming sulphuric acid, yielding a sulphonic acid which is soluble in water. Similarly, 3'-*methylindoxyl*-2-*seleno-naphthen*-3-*one* (red needles which sublime at about 250°, and have m. p. approximately 325—330°) is obtained from methylisatin, whilst by heating molecular quantities of isatin chloride and hydroxyseleno-naphthen in benzene solution, "2-*selenonaphthen*-2-*indole-indigo*" [2'-*indoxyl*-2-*selenonaphthen*-3-*one*], $C_6H_4{<}^{CO}_{NH}{>}C{:}C{<}^{CO}_{Se}{>}C_6H_4$, is formed. It consists of blackish-violet needles, which sublime undecomposed at approximately 250°, and have m. p. about 335°.

A series of condensation products of hydroxyselenonaphthen with aldehydes and fluorenone has been prepared by boiling molecular quantities of their components in methyl- or ethyl-alcoholic or glacial acetic acid solution in the presence of a few drops of concentrated hydrochloric acid. In general, the compounds are rapidly precipitated in good yield. They dissolve unchanged in concentrated sulphuric acid, but are converted by the fuming acid into sulphonic acids which dissolve in water. The following compounds have been prepared: Glyoxal yields the *substance*,

$$C_6H_4{<}^{CO}_{Se}{>}C{:}CH{\cdot}CH{:}C{<}^{CO}_{Se}{>}C_6H_4,$$
violet needles, m. p. 299—300°. Heptaldehyde and citral give oily products. *Furylidene*-2-*selenonaphthen*-3-*one*,

$$C_6H_4{<}^{CO}_{Se}{>}C{:}CH{\cdot}C_4H_3O,$$
orange needles, m. p. 145—147°, p-*nitrobenzylidene*-2-*selenonaphthen*-3-*one*, reddish-golden needles or rods, m. p. 243—244°; 2:4-*dinitrobenzyli-dene*-2-*selenonaphthen*-3-*one*, which exists in two modifications, red or orange needles, both having m. p. 226—227° (decomp.); o-*hydroxy-benzylidene* - 2 - *selenonaphthen*-3-*one*, brownish-yellow rods, m. p. 206—207° (decomp.); o-*carboxybenzylidene* - 2 - *selenonaphthen*-3-*one*,

$$C_6H_4{<}^{CO}_{Se}{>}C{:}CH{\cdot}C_6H_4{\cdot}CO_2H,$$ yellow plates, m. p. 226—227°;

4-*hydroxynaphthylidene*-2-*selenonaphthen*-3 - *one*, red needles, m. p. 244—248°; 2-*methoxynaphthylidene* - 2 - *selenonaphthen*-3-*one*, yellow crystals, m. p. 127—128°; 2-hydroxynaphthaldehyde yields a *compound*, $C_{27}H_{16}O_2Se_2$, pale red crystals, m. p. 210—211° after previous darkening, which does not dissolve in sodium hydroxide, and appears to be derived from two molecules of hydroxyselenonaphthen and one of the aldehyde. Terephthalaldehyde yields the *substance*,

$$C_6H_4{<}^{CO}_{Se}{>}C{:}CH{\cdot}C_6H_4{\cdot}CH{:}C{<}^{CO}_{Se}{>}C_6H_4,$$ orange needles, which sub-

lime at about 296°, and have m. p. approximately 330°, whilst β-anthra-
quinonealdehyde gives the *compound*, $C_6H_4\underset{Se}{\overset{CO}{<}}\hspace{-2pt}>C{:}CH{\cdot}C_{14}H_7O_2$,
orange-red needles, subliming at about 270°, and having m. p.
348—349°. Prolonged warming with fluorenone in alcohlic solution
yields the *substance*, $C_6H_4\underset{Se}{\overset{CO}{<}}\hspace{-2pt}>C{:}C\underset{C_6H_4}{\overset{C_6H_4}{<}}$, deep red crystals, m. p.
169—171°.

p-Nitrobenzeneazo-3-hydroxyselenonaphthen,

$$C_6H_4\underset{Se}{\overset{C(OH)}{<}}\hspace{-2pt}>C{\cdot}N{:}N{\cdot}C_6H_4{\cdot}NO_2,$$
reddish-brown crystals, m. p. 239—241° (decomp.), is obtained by the
addition of p-nitrobenzene diazonium chloride to a solution of the
sodium salt of hydroxyselenonaphthen in the presence of sodium
acetate. H. W.

Diphenyleneacetic Acid [Fluorene - 9 - carboxylic Acid].
WILHELM WISLICENUS and ALEXANDER RUTHING (*Ber.*, 1913, **46**,
2770—2771).—An aqueous solution of fluorene-9-carboxylic acid and
sodium hydroxide (1 mol.) remains clear when kept in an atmosphere
of hydrogen. In the presence of oxygen, it rapidly becomes turbid
and deposits fluorenone; the yield of the latter is about 20% of the
theoretical, and is increased to about 50% when another mol. of sodium
hydroxide is present. At higher temperatures the decomposition
proceeds differently, an aqueous solution of sodium fluorene-9-
carboxylate at the b. p. yielding fluorene and sodium carbonate, most
readily when sodium hydroxide has been added. C. S.

Syntheses by means of Ethyl Diphenyleneacetate [Fluorene
9-carboxylate]. WILHELM WISLICENUS and WILLY MOCKER (*Ber.*,
1913, **46**, 2772—2793).—The *potassium* derivative of ethyl fluorene-
9-carboxylate is best obtained by adding rather more than the
theoretical quantity of alcohol to ethyl fluorene-9-carboxylate and
potassium (1 atom) in dry ether, a current of hydrogen being passed
through the apparatus. It is thus obtained as a yellow, microcrystal-
line powder containing EtOH, which decomposes rapidly in moist air,
and is converted in dry air into the additive *compound*,

$$\underset{C_6H_4}{\overset{C_6H_4}{<}}\hspace{-2pt}>C(OK){\cdot}CO_2Et,EtOH,$$
from which ethyl 9-hydroxyfluorene-9-carboxylate, m. p. 93°, is obtained
by the action of sulphuric acid. The *sodium* derivative,

$$C_{16}H_{13}O_3Na,EtOH,$$
of ethyl fluorene-9-carboxylate is prepared in a similar manner and
reacts in the same manner with atmospheric oxygen. In consequence
of the easy oxidisability of the alkali derivatives of ethyl fluorene-
9-carboxylate, syntheses with these reagents must be effected in an
atmosphere of hydrogen, otherwise 9-hydroxyfluorene-9-carboxylic acid
is the final product.

The following syntheses have been performed. By treatment
with the calculated amount of iodine, a solution of the alkali
derivative, prepared as above, readily yields ethyl bisdiphenylene-
succinate [9 : 9'-difluorene-9 : 9'-dicarboxylate] (Staudinger, A.,

1906, i, 824), which cannot be hydrolysed to the corresponding acid. The solution of the potassium derivative and methyl iodide gives a nearly quantitative yield of *ethyl α-diphenylene-propionate* [9-*methylfluorene*-9-*carboxylate*], $\begin{smallmatrix} C_6H_4 \\ C_6H_4 \end{smallmatrix}$>CMe·CO$_2$Et, b. p. 188—190°/14 mm., m. p. 33°, which, however, is not obtained quite pure by this method. 9-*Methylfluorene*-9-*carboxylic acid* yields 9-methyl-fluorene at 250°; the latter has b. p. 154—156°/15 mm. and m. p. 45°. *α-Diphenylenebutyric* [9-*ethylfluorene*-9-*carboxylic*] *acid*,

$$\begin{smallmatrix} C_6H_4 \\ C_6H_4 \end{smallmatrix}>CEt·CO_2H,$$
obtained in a similar manner by means of ethyl iodide, forms an *ethyl* ester, b. p. 200—205°/14—15 mm., and decomposes at 230—240° into carbon dioxide and 9-ethylfluorene. The latter is a liquid, b. p. 169—171°/14 mm., not a solid as stated by Wislicenus and Densch, and does not react with potassium even at 250°. 9-*Allylfluorene*-9-*carboxylic acid*, $\begin{smallmatrix} C_6H_4 \\ C_6H_4 \end{smallmatrix}$>C(CO$_2$H)·CH$_2$·CH:CH, colourless prisms containing $\frac{1}{2}$C$_6$H$_6$ (*ethyl* ester, b. p. 200—203°/14 mm.), yields 9-*allyl-fluorene*, b. p. 174—176°/15 mm., at 240—250°. 9-*Benzylfluorene*-9-*carboxylic acid*, $\begin{smallmatrix} C_6H_4 \\ C_6H_4 \end{smallmatrix}$>C(CO$_2$H)·CH$_2$Ph, m. p. 201—202°, colourless leaflets (*ethyl* ester, m. p. 90—91°), yields 9-benzylfluorene at 240—250°; the latter is also produced by boiling the ester with alcoholic potassium hydroxide.

Ethyl αα-bisdiphenyleneadipate [9 : 9'-*ethylenedifluorene*-9 : 9'-*dicarboxy-late*], $\begin{smallmatrix} C_6H_4 \\ C_6H_4 \end{smallmatrix}$>C$<$$\begin{smallmatrix} CH_2 \\ CO_2Et \end{smallmatrix}$——$\begin{smallmatrix} CH_2 \\ CO_2Et \end{smallmatrix}$>C$<$$\begin{smallmatrix} C_6H_4 \\ C_6H_4 \end{smallmatrix}$, m. p. 179—180°, colourless needles, prepared by the aid of ethylene dibromide, yields, by hydrolysis with alcoholic sodium hydroxide at the ordinary temperature and subsequent acidification, 9 : 9'-*ethylenedifluorene*-9 : 9'-*dicarboxylic acid*, m. p. about 260° (decomp.), *αδ-bisdiphenylenebutane* [9 : 9'-*ethylenedifluorene*], C$_2$H$_4$(C$_{13}$H$_9$)$_2$, colourless needles, being produced when the hydrolysis is effected on the water-bath.

Iodobenzene does not react with the solution of the potassium derivative of ethyl fluorene-9-carboxylate even at 150—180°. 1-Bromo-2 : 4-dinitrobenzene, however, yields ethyl 9-*op-dinitrophenylfluorene-carboxylate*, C$_{13}$H$_9$(CO$_2$Et)·C$_6$H$_3$(NO$_2$)$_2$, m. p. 130—131°, faintly yellow crystals, which cannot be hydrolysed to the corresponding acid. In a similar manner, ethyl chloroacetate yields *ethyl diphenylene-succinate* [9-*carboxyfluorene*-9-*acetate*],
$$CO_2Et·C_{13}H_8·CH_2·CO_2Et,$$
m. p. 73—75°, colourless crystals; by hydrolysis at the ordinary temperature, the ester yields the corresponding *acid*, C$_{16}$H$_{12}$O$_4$, m. p. 195—196° (decomp.), which is converted at its m. p. into its *anhydride*,

$$\begin{smallmatrix} C_6H_4 \\ C_6H_4 \end{smallmatrix}>C<\begin{smallmatrix} CO——O \\ CH_2·CO \end{smallmatrix}, \text{ m. p. 158—159°, b. p. about 255°/16 mm.}$$
Ethyl β-iodopropionate reacts with the solution of the sodium or potassium derivative of ethyl fluorene-9-carboxylate to form, after hydrolysis of the impure ester, *α-diphenyleneglutaric* [9-*carboxyfluorene-*

9-*propionic*] *acid*, $CO_2H \cdot C_{13}H_8 \cdot CH_2 \cdot CH_2 \cdot CO_2H$, m. p. 195—196°, colourless prisms or needles. The acid forms an *ethyl* ester, $C_{21}H_{22}O_4$, b. p. 235—240°/14 mm., yields the *anhydride*,
$$\begin{array}{c} C_6H_4 \\ C_6H_4 \end{array} > C < \begin{array}{c} CH_2 \cdot CH_2 \\ CO \quad\quad O \end{array} > CO,$$

m. p. 175—176°, colourless prisms, by boiling with acetyl chloride, and is converted into γ-*diphenylenebutyric* [*fluorene-9-propionic*] *acid*, $C_{16}H_{14}O_2$, m p. 148—149° (*ethyl* ester, b. p. 224—226°/17 mm.), by heating at about 260°.

Ethyl β-*benzoyl-α-diphenylenepropionate* [9-*phenacylfluorene-9-carboxylate*], $CO_2Et \cdot C_{13}H_9 \cdot CH_2 \cdot COPh$, m. p. 123—124°, obtained by means of ω-bromoacetophenone at about 80°, is converted by the action of aqueous alcoholic sodium hydroxide into *phenyl* β-*diphenylene-ethyl ketone* [9-*phenacylfluorene*], $C_{12}H_8 \cdot CH \cdot CH_2 \cdot COPh$, m. p. 96—97°, colourless needles. C. S.

Solubility of Salicylic Acid and of Some Other Substances. EGLIE SAVARRO (*Atti R. Accad. Sci. Torino*, 1913, **48**, 948—959).— Tables are given showing the solubility of salicylic acid at various temperatures, the figures obtained by previous observers being discordant. Some experiments have also been made on isomeric substances (compare Carnelley and Thompson, T., 1888, **53**, 782). The solubilities of the three hydroxybenzoic acids in water at 15° and at 50° increase in the order: ortho, para, meta, whilst those in methyl alcohol follow the order of the melting points: ortho, meta, para. According to the law of Carnelley and Thompson the order of solubilities should be para, meta, ortho. The solubilities in methyl alcohol of four pairs of isomeric pyridine derivatives prepared by Guareschi (*Atti R. Accad. Sci. Torino*, 1900–01, **50**) have also been determined; here the law already mentioned is followed with some exceptions. R. V. S.

Iron Compounds of Phenols. V. Iron Compounds of Salicylic Acid. RUDOLF F. WEINLAND and ALFRED HERZ (*Annalen*, 1913, **400**, 219—268. Compare this vol., i, 458).—The reaction between alkali salicylates and ferric salts in aqueous or alcoholic solution gives rise to very complex iron derivatives of salicylic acid. Their formation is due to the fact that salicylic acid forms, by virtue of its phenolic hydroxyl group, di- and tri-salicylatoferric acids analogous to the catecholferric acids (A., 1912, i, 445), and, by virtue of its carboxyl group, a hexasalicylatotriferric hydroxide analogous to hexabenzoatotriferric hydroxide (A., 1912, i, 854); this complex base can then react with the complex acids to form still more complex salts. In the preparation of the following substances, the concentrations of the reacting solutions and the order of their addition are matters of great importance. All quantities mentioned below are in atomic or molecular proportions.

(I.) $\left[Fe \left< \begin{array}{c} O \quad\quad\quad \\ O \cdot C_6H_4 \cdot CO \\ O \cdot C_6H_4 \cdot CO_2 \cdot \end{array} \right] H \right.$

(II.) $\left[Fe \left< \begin{array}{c} O \quad\quad\quad \\ O \cdot C_6H_4 \cdot CO \\ O \cdot C_6H_4 \cdot CO_2 \cdot \end{array} \right] K,4H_2O \right.$

Salts of Disalicylatoferric Acid (I). —*Potassium disalicylatoferrate* (II), dark copper-red powder, is obtained by adding aqueous ferric chloride to aqueous salicylic acid and potassium hydroxide ($Fe : C_7H_6O_3 : KOH = 1 : 4 : 7$).

Rubidium disalicylatoferrate, dark copper-red powder, is obtained in a similar manner ($Fe : C_7H_6O_3 : RbOH = 1 : 3 : 6$). These two salts form blood-red aqueous solutions, which change to violet by the addition of hydrochloric acid or of ferric chloride, and yield hexasalicylatotriferric monosalicylate (see below) by treatment with dilute acetic acid.
Salts of Trisalicylatoferric Acid, $\left[Fe_{(C_6H_4\cdot CO_2)_3}^{\quad O}\right]H_3$.—The gradual addition of very dilute aqueous ferric chloride to concentrated aqueous sodium salicylate produces successively a reddish-yellow, blood-red, and finally violet solution. The blood-red solution contains sodium disalicylatoferrate, and the violet solution a ferric salt of this acid (see below). The reddish-yellow solution contains *sodium trisalicylatoferrate*, which, however, cannot be isolated from aqueous solution. *Potassium trisalicylatoferrate*, $[Fe(C_7H_4O_3)_3]K_3,1\frac{1}{2}H_2O$, brick-red, crystalline powder, is obtained from ferric acetate [of the composition $Fe_6(OAc)_{15}(OH)_3,3H_2O$], potassium salicylate, and potassium hydroxide in 96% alcohol ($Fe : C_7H_6O_3 : KOH = 1 : 4 : 7$). The *rubidium* salt, orange-red, crystalline powder containing $2H_2O$, is obtained in a similar manner. These salts are easily soluble in water, but the solutions rapidly decompose; however, if the alkali salicylate is also present, the solutions can be boiled without decomposition.

The free di- and tri-salicylatoferric acids have not been isolated. The union of the iron with the phenolic oxygen of the acid complex is proved by the fact that ferric acetate, methyl salicylate, and potassium hydroxide ($Fe : C_8H_8O_3 : KOH = 1 : 15 : 3$) in alcoholic solution yield *potassium tetramethylsalicylatoferrate*, $[Fe(C_7H_4O_3Me)_4]K$, reddish-brown, crystalline powder.
Salts of Hexasalicylatotriferric Hydroxide,
$$[Fe_3(O\cdot CO\cdot C_6H_4\cdot OH)_6](OH)_3.$$
—The reddish-yellow, blood-red, and violet solutions obtained, according to the quantities of the reagents used, by the addition of aqueous ferric chloride (at least 1 mol.) to a not too dilute aqueous solution of sodium salicylate (4 mols.) soon yield reddish-brown precipitates. By keeping in the mother liquor, these precipitates soon change to a black, crystalline substance (compare Hopfgartner, A., 1908, i, 891). The reddish-brown substance can be isolated unchanged if ether is added to either solution before the solutions of ferric chloride and sodium salicylate ($Fe : Na = 1 : 3$) are mixed; by shaking, the salicylic acid liberated in the reaction is removed from the aqueous phase, and the precipitate then remains unchanged. The same substance is also obtained unchanged when hot solutions of ferric chloride and sodium salicylate are mixed. It has been isolated as a brown powder containing $3H_2O$, and also as a reddish-brown, crystalline powder containing $2EtOH,2H_2O$. Since the ratio of iron to salicylic acid is 3 : 7 and the substance behaves like hexabenzoatotriferric monobenzoate A., 1912, i, 854), it is regarded as *hexasalicylatotriferric monosalicylate,*
$$Fe_3^{(O\cdot CO\cdot C_6H_4\cdot OH)_6}_{(OH)_2}\Big]\cdot O\cdot CO\cdot C_6H_4\cdot OH. \quad \text{A } sesquisalicylate,$$
$$\left[Fe_3^{(O\cdot CO\cdot C_6H_4\cdot OH)_6}_{(OH)_2}\right]C_7H_5O_3,\left[Fe_3^{(C_7H_5O_3)_6}_{(OH)}\right](C_7H_5O_3)_2,7H_2O,$$
of the base is obtained as a red, crystalline powder (which rapidly becomes almost black) by treating the preceding substance with a

warm saturated solution of salicylic acid in acetone; chloroform or ethyl alcohol may also be used as the solvent, in the latter case the sesquisalicylate being obtained as a reddish-brown, crystalline powder containing $3EtOH$ and $9H_2O$.

The ferrisalicylic acid described by Hantzsch and Desch (A., 1902, i, 708) contains acetic acid and is in reality *hexasalicylatotriferric diacetate*, $\left[Fe_3{(O \cdot CO \cdot C_6H_4 \cdot OH)_6 \atop (OH)}\right](OAc)_2, 3Et_2O$, garnet-red prisms (from ether); by heating at $100°$, it changes to the *monoacetate*, $\left[Fe_3{(O \cdot CO \cdot C_6H_4 \cdot OH)_6 \atop (OH)_2}\right] \cdot OAc$. Other salts of hexasalicylatotriferric hydroxide have been obtained by the reaction between lithium salicylate and ferric chloride, bromide, or nitrate in alcoholic solution; in some of these reactions a little water must be added. None of these salts contains iron and salicylic acid in a ratio less than $3:6$; therefore, they are regarded as complex derivatives of the hexasalicylatotriferric base. Thus lithium salicylate and ferric chloride yield, according to the proportions of the reagents, a *chloride salicylate*, $\left[Fe_3{(O \cdot CO \cdot C_6H_4 \cdot OH)_6 \atop (OH)}\right]{O \cdot CO \cdot C_6H_4 \cdot OH \atop Cl}, 4\frac{1}{2}H_2O$, red, crystalline powder, or a double *salt* of the chloride and the chloride salicylate,

$$\left[Fe_3{(C_7H_5O_3)_6 \atop (OH)_2}\right]Cl, \left[Fe_3{(C_7H_5O_3)_6 \atop (OH)}\right]{C_7H_5O_3 \atop Cl}, H_2O,$$

red, amorphous powder (which becomes crystalline after two days), or a double *salt* of the salicylate and the chloride salicylate,

$$\left[Fe_3{(C_7H_5O_3)_6 \atop (OH)_2}\right]C_7H_5O_3, 2\left[Fe_3{(C_7H_5O_3)_6 \atop (OH)}\right]{C_7H_5O_3 \atop Cl}, 11H_2O,$$

brownish-red, crystalline powder. Ferric bromide ($Fe_2Br_6, 6H_2O$, see below) forms a double *salt*,

$$\left[Fe_3{(C_7H_5O_3)_6 \atop (OH)_2}\right]C_7H_5O_3, 2\left[Fe_3{(C_7H_5O_3)_6 \atop (OH)}\right]{C_7H_5O_3 \atop Br}, 11H_2O,$$

carmine, crystalline powder, and ferric nitrate yields a double *salt*,

$$\left[Fe_3{(C_7H_5O_3)_6 \atop (OH)_2}\right]C_7H_5O_3, \left[Fe_3{(C_7H_5O_3)_6 \atop (OH)}\right]{C_7H_5O_3 \atop NO_3}, 2H_2O,$$

reddish-yellow, crystalline powder.

The great similarity between the salts of hexabenzoatotriferric hydroxide and hexasalicylatotriferric hydroxide indicates that in the latter the iron is attached to the carboxyl group of the salicylic acid, as represented in the preceding formulæ. This is also proved by the fact that salts of a similar base, *hexa-o-methoxybenzoatotriferric hydroxide*, can be obtained from o-methoxybenzoic acid. Thus by treating aqueous ferric chloride with aqueous sodium o-methoxybenzoate ($Fe:Na = 1:3$) or with warm aqueous o-methoxybenzoic acid ($Fe:acid = 1:3$), *hexa-o-methoxybenzoatotriferric mono-o-methoxybenzoate*,

$$\left[Fe_3{(O \cdot CO \cdot C_6H_4 \cdot OMe)_6 \atop (OH)_2}\right] \cdot O \cdot CO \cdot C_6H_4 \cdot OMe, 7\frac{1}{2}H_2O,$$

is obtained as a yellow, crystalline substance; its alcoholic solution reacts with 20% perchloric acid to form the *perchlorate*,

$$\left[Fe_3{(O \cdot CO \cdot C_6H_4 \cdot OMe)_6 \atop (OH)_2}\right]ClO_4, H_2O,$$

orange-yellow leaflets.

In a similar manner, by treating aqueous ferric chloride with sodium *m*- or *p*-hydroxybenzoate (Fe : Na = 1 : 3), *hexa*-m-*hydroxy-benzoatotriferric mono*-m-*hydroxybenzoate*

$$\left[Fe_3 \frac{(O \cdot CO \cdot C_6H_4 \cdot OH)_6}{(OH)_2} \right] \cdot O \cdot CO \cdot C_6H_4 \cdot OH, 5H_2O,$$
dark brown powder, and the corresponding para-*isomeride*, brown, prismatic crystals, are obtained. The latter reacts with 5% aqueous ferric chloride in excess to form *p*-hydroxybenzoic acid and a very soluble *substance*, garnet-red prisms, which contains Fe : Cl : $C_7H_5O_3$ = 1 : 1 : 1, and is regarded as having the constitution

$$\left[Fe_3(O \cdot CO \cdot C_6H_4 \cdot OH)_6 \right]\left[Fe \frac{Cl_2}{(OH)_2} \right]_3, 10H_2O.$$
Hexa-p-*hydroxybenzoatotriferric chloride* p-*hydroxybenzoate*,

$$\left[Fe_3 \frac{(O \cdot CO \cdot C_6H_4 \cdot OH)_6}{(OH)} \right] \frac{Cl}{O \cdot CO \cdot C_6H_4 \cdot OH}, 1\tfrac{1}{2}H_2O,$$
brown, crystalline powder, is obtained by the reaction of ferric chloride and lithium *p*-hydroxybenzoate (Fe : Li = 1 : 1·5) in alcohol containing a little water.
Compounds of Hexasalicylatotriferric Hydroxide and the Salicylato-ferric Acids or a Salicylatoferrous Acid.—The reddish-brown precipitate obtained from aqueous ferric chloride and sodium salicylate (Fe : Na = 1 : 3) changes by keeping in the mother liquor for about a day to a black, crystalline *substance* (the streak is violet), which contains Fe : $C_7H_5O_3$ = 4 : 9, not 1 : 2 (compare Hopfgartner, *loc. cit.*), and is regarded as *hexasalicyl-atotriferric sali-cylate disali-cylatoferrate* (annexed formula).

$$\left[Fe_3 \frac{(O \cdot CO \cdot C_6H_4 \cdot OH)_6}{(OH)} \right]\left[Fe \begin{matrix} O \cdot CO \cdot C_6H_4 \cdot OH \\ O \\ O \cdot C_6H_4 \cdot CO \\ O \cdot C_6H_4 \cdot CO_2 \end{matrix} \right], 8\tfrac{1}{2}H_2O.$$
In a similar manner, by keeping the initial reddish-brown precipitates in the mother liquors, ferric nitrate and sodium salicylate (Fe : Na = 1 : 3) yield a double *compound* of the preceding salt and hexasalicylato-triferric monosalicylate,

$$\left[Fe_3 \frac{(C_7H_5O_3)_6}{(OH)} \right]\left[Fe \begin{matrix} C_7H_5O_3 \\ O \\ O \cdot C_6H_4 \cdot CO \\ O \cdot C_6H_4 \cdot CO_2 \end{matrix} \right], \left[Fe_3 \frac{(C_7H_5O_3)_6}{(OH)_2} \right] C_7H_5O_3, 15H_2O,$$

black, crystalline powder, ferric sulphate and sodium salicylate (Fe : Na = 1 : 1·5) yield a double *salt* of the bisdisalicylatoferrate and the salicylatedisalicylatoferrate of the hexa-base,

$$\left[Fe_3 \frac{(C_7H_5O_3)_6}{(OH)} \right][Fe(C_7H_4O_3)_2]_2, \left[Fe_3 \frac{(C_7H_5O_3)_6}{(OH)} \right]\frac{O \cdot CO \cdot C_6H_4 \cdot OH}{[Fe(C_7H_4O_3)_2]}, 23H_2O,$$

violet-black, crystalline powder, and ferric acetate and sodium salicylate (Fe : Na = 1 : 3 and 1 : 4 respectively) yield *substances*,

$$\left[Fe_3 \frac{(C_7H_5O_3)_6}{(OH)_2} \right][Fe(C_7H_4O_3)_2], 8\tfrac{1}{2}H_2O$$

and

$$\left[Fe_3 \frac{(C_7H_5O_3)_6}{(OH)_2} \right][Fe(C_7H_4O_3)_2], \left[Fe_3 \frac{(C_7H_5O_3)_6}{(OH)_2} \right] \cdot O \cdot CO \cdot C_6H_4 \cdot OH, 14H_2O,$$

violet, crystalline powders ; the former of the last two substances is

also obtained from the reddish-brown precipitate resulting from the addition of dilute acetic acid to cold saturated aqueous potassium disalicylatoferrate (see above).
The compositions of the preceding complex salts are deduced from the ratio of the iron to the salicylic acid in them, and are most simply explained by assuming that the violet and black substances are salts of hexasalicylatotriferric hydroxide and salicylic or di- or tri-salicylato-ferric acid. Thus the violet substance, two methods of preparing which are mentioned above, contains iron and salicylic acid in the ratio $4:8$ $(1:2)$, and is therefore hexasalicylatotriferric disalicylato-ferrate. Again, the reddish-yellow, aqueous solution obtained from ferric chloride, salicylic acid, and potassium hydroxide

$$(Fe:C_7H_6O_3:KOH=1:3:5)$$
deposits a reddish-brown precipitate which changes to a *substance*, black, crystalline powder (violet streak), which contains

$$Fe:C_7H_6O_3:K=12:27:2\ ;$$
since reddish-yellow solutions are indicative of the alkali salt of trisalicylatoferric acid, the black substance is regarded as

$$2\left[Fe_3{(C_7H_5O_3)_6 \atop (OH)}\right]K[Fe(C_7H_4O_3)_3],[Fe_3(C_7H_5O_3)_6][Fe(C_7H_4O_3)_3],25H_2O.$$

The preceding complex salts of the hexa-base differ from the simpler salts of the base mentioned under the third section in their black or violet colour, and in their insolubility in alcohol, acetone, and ether. Hexasalicylatotriferric monosalicylate changes to the violet and black salts of the hexa-base in the presence of water, and, conversely, the violet and black salts are converted into hexasalicylatotriferric mono-salicylate by alcoholic salicylic acid; hence the changes hexa-base $\underset{\substack{\text{alcohol}\\ \text{and } C_7H_6O_3}}{\overset{H_2O}{\rightleftarrows}}$ disalicylatoferric acid are partly the cause of the large number of the iron compounds of salicylic acid.

The violet and black salts are very sparingly soluble in water, forming faintly violet solutions. Possibly the intensely violet colora-tion developed in the usual ferric chloride test for salicylic acid is due to the formation of a salt of disalicylatoferric acid containing a complex iron cation such as $[Fe(H_2O)_6]$ (salts of disalicylatoferric acid con-taining a simple cation such as potassium or sodium are red); such a salt would be more soluble than the violet or black salts described above, and would, therefore, produce a more intensely violet colora-tion. The authors have been unable to isolate such a salt; they have prepared, however, a *salt* of the hexasalicylatotriferric and hexa-acetotriferric hydroxides with disalicylatoferric acid, $\left[Fe_3{(C_7H_5O_3)_6 \atop (OH)_2}\right][Fe(C_7H_4O_3)_2],[Fe_3(OAc)_6](OH)_3,4H_2O$, which is much more soluble in water than the violet and black salts, forming a reddish-violet solution changing to violet by the addition of hydrochloric acid, owing to the decomposition of the hexa-aceto-base.

Intensely violet solutions are obtained from aqueous sodium salicylate and an excess of ferric chloride, from aqueous salicylic acid and ferric chloride, and from all the salts of hexasalicylatotriferric hydroxide by warming them with very dilute hydrochloric acid; in all

these cases, disalicylatoferric acid and (complex) iron cations, that is, the two components necessary for the production of the intensely violet ferric disalicylatoferrate, are formed. Conversely, the addition of soium sal icylate or of sodium carbonate to solutions of salts of hexasalicylatotriferric hydroxide produces, according to the relative quantities of the reagents, red solutions of sodium disalicylatoferrate or reddish-yellow solutions of sodium trisalicylatoferrate. Similarly, the addition of aqueous calcium hydrogen carbonate to the violet solution produces a red solution of calcium disalicylatoferrate.

The residue obtained by the evaporation of aqueous ferric bromide has the composition $Fe_2Br_8,6H_2O$, and contains ferrous iron. In alcoholic solution it reacts with lithium salicylate ($Fe:Li = 1:3$) to form a *substance*, olive-brown crystals, which contains

$$Fe^{III}:Fe^{II}:C_7H_6O_3 = 3:1:9,$$

and is therefore regarded as *hexasalicylatotriferric salicylate disalicylatoferrite*, $\left[Fe_3{}^{III}(C_7H_5O_3)_6 \right]\begin{matrix} O\cdot CO\cdot C_6H_4\cdot OH \\ [Fe^{II}(C_7H_4O_3)_2] \end{matrix},6H_2O$. The same substance is obtained from lithium salicylate and alcoholic ferric chloride which has been partly reduced by the addition of iron. An alcoholic solution of $Fe_2Br_8,6H_2O$, which has been still further reduced by iron, reacts with lithium salicylate ($Fe:Li = 1:3$) to form *hexasalicylatotriferric hydrogen trisdisalicylatoferrite*,

$$[Fe_3{}^{III}(C_7H_5O_3)_6]H_3[Fe^{II}(C_7H_4O_3)_2]_3,5\tfrac{1}{2}H_2O,$$
blackish-brown, crystalline powder.   C. S.

Methylcarbonato-derivatives of Hydroxy-acids. EMIL FISCHER and HERMANN O. L. FISCHER (*Ber.*, 1913, 46, 2659—2664).—Hydroxy-acids either do not react with methyl chloroformate in aqueous alkaline solution or give very poor yields of methylcarbonato-derivatives. The latter, however, are readily obtained by the combined action of methyl chloroformate and tertiary bases on hydroxy-acids dissolved in anhydrous solvents (compare Fischer, A., 1909, i, 161).

r-*Methylcarbonatomandelic acid*, $CO_2Me\cdot O\cdot CHPh\cdot CO_2H$, is obtained by the addition of methyl chloroformate to a well cooled solution of had r-mandelic acid in a mixture of chloroform and dimethylaniline. It m. p. 118—119° (corr.), after slight softening, and begins to decompose at about 140°. Alkalis readily transform it into r-mandelic acid, for which the authors give m. p. 120·5° (corr.) after previous softening, instead of 118° as recorded in the text books. r-*Methylcarbonatomandelyl chloride*, colourless prisms, m. p. 39—40°, is obtained by the action of phosphorus pentachloride at the ordinary temperature on a solution of the acid in chloroform, and is converted by cold methyl alcohol into *methyl r-methylcarbonatomandelate*, $CO_2Me\cdot O\cdot CHPh\cdot CO_2Me$, prisms, m. p. 51—52°. This ester is rapidly saponified by sodium hydroxide when dissolved in aqueous acetone; when two and a-half molecules of alkali are used, mandelic acid is formed, but when only one molecule is employed, methylcarbonatomandelic acid is the main product.

When mixed with an excess of aniline in ethereal solution, methyl-carbonatomandelyl chloride yields a *compound*, $C_{16}H_{15}O_4N$, needles,

m. p. about 142° (corr. decomp.), which is converted by prolonged contact with 2N-sodium hydroxide (2 mols.) into an acid which melts with decomposition, and has not been completely investigated. In any case, normal formation of the anilide of mandelic acid does not occur, and the authors therefore do not assign a definite structure to the aniline compound.

Glycollic acid reacts with methyl chlorocarbonate in a manner similar to mandelic acid, but yielding a product which is difficult to purify.

The authors have also prepared a compound from r-mandelic acid and acetylcarbimide in the expectation that the latter group would be readily eliminated, and that the product could thus be used in place of the methylcarbonato-derivatives. This is, however, not the case, since the re-conversion into mandelic acid does not occur with sufficient ease.

r-*Acetylaminocarboylmandelic acid*, $NHAc\cdot CO\cdot O\cdot CHPh\cdot CO_2H$, colourless needles, m. p. about 168—169° (decomp.), is obtained by the gradual addition of acetylcarbimide to a solution of well dried r-mandelic acid in anhydrous ether. It is converted by 2N-sodium hydroxide at the ordinary temperature into the *urethane* of *mandelic acid*, $NH_2\cdot CO\cdot O\cdot CHPh\cdot CO_2H$, m. p. 172—173° (corr. decomp.), when quickly heated.   H. W.

Hydrogenation of Santonin. HEINRICH WIENHAUS (*Ber.*, 1913, **46**, 2836—2839).—Polemical. The author assumes the presence of two conjugated double bonds in santonin based on the fact that at the ordinary temperature and without increased pressure in neutral solution it takes up four atoms of hydrogen (compare Weinhaus and Oettingen, this vol., i, 474; Wedekind and Beniers, this vol., i, 476; Angeli, this vol., i, 864).

Chromosantonin gives the same products on hydrogenation in presence of colloidal palladium chloride as santonin.   E. F. A.

Hydrogenation of Santonic Acid. Dihydrosantonin. GUIDO CUSMANO (*Annalen*, 1913, **400**, 332—337).—Results already recorded (this vol., i, 864).   C. S.

Action of Sodium Hypochlorite on Amides of Unsaturated Acids. RUDOLF A. WEERMAN (*Annalen*, 1913, **401**, 1—20. Compare A., 1906, i, 665; 1907, i, 132; 1908, i, 22; 1909, i, 589).—Freundler, van Linge, Jeffreys, and Baucke have attempted unsuccessfully to apply Hofmann's reaction to the production of amines from unsaturated acid amides.

Finely-powdered cinnamamide, by shaking with amyl alcohol and aqueous sodium hypochlorite, is converted into the *chloroamide*, $CHPh{:}CH\cdot CO\cdot NHCl$, m. p. 125° (decomp.), white plates, which yields *barium styrylcarbamate*, $Ba(C_9H_8O_2N)_2$, by treatment with aqueous barium hydroxide. The salt yields only a trace of phenylacetaldehyde by treatment with even the weakest acids; however, by decomposition with sodium hydrogen sulphite or hydroxylamine hydrochloride, the aldehyde is obtained in the form of its sodium hydrogen sulphite compound or oxime respectively.

The following substances are obtained by reactions similar to the preceding.

o-*Nitrocinnamchloroamide*, m. p. 142° (decomp.), colourless needles, is converted into *barium o-nitrostyrylcarbamate* by 0·3*N*-barium hydroxide on the water-bath; the latter yields o-*nitrophenylacetaldoxime*, m. p. 110°, colourless needles, with aqueous hydroxylamine hydrochloride.

m-*Nitrocinnamide*, m. p. 195—196°, prepared from the acid chloride and gaseous ammonia in benzene, is converted into *methyl* m-*nitrostyrylcarbamate*, m. p. 140°, yellow needles, from which m-*nitrophenylacetaldehyde*, $C_8H_7O_3N,H_2O$, m. p. 78—79°, can be prepared. m-*Nitrocinnamchloroamide*, m. p. 178° (decomp.), is converted as above into *barium* m-*nitrostyrylcarbamate*, yellow leaflets, from which m-*nitrophenylacetaldoxime*, m. p. 105—106°, colourless leaflets, can be obtained.

p-Nitrocinnamamide, m. p. 217° (not 155—160°, as stated by Chiozza in 1853), is converted by methyl alcohol and aqueous sodium hypochlorite into *methyl* p-*nitrostyrylcarbamate*, m. p. 188°, yellow needles, from which *p*-nitrophenylacetaldehyde, m. p. 85°, can be prepared. p-*Nitrocinnamchloroamide*, m. p. 169° (decomp.), colourless needles, is converted into *barium* p-*nitrostyrylcarbamate*, yellow needles, from which p-*nitrophenylacetaldoxime*, m. p. 155°, can be prepared.   C. S.

Camphenecarboxylamide and Hydrocamphenecarboxyl-amide. JOSEF HOUBEN and ERNST WILLFROTH (*Ber.*, 1913, **46**, 2530—2537).—The authors have recently shown (this vol., i, 970) that the action of methyl-alcoholic potash on methyl chloro*allo*camphanecarboxylate yields two isomeric unsaturated acids, the occurrence of which may be attributed to the unsymmetrical nature of chloro*allo*camphanecarboxylic acid or to the disturbing effect of the alkali on the single course of the reaction. The latter view receives support from the fact that chloro*allo*camphanecarboxylamide passes into a crystalline unsaturated amide, m. p. 210°, when merely boiled with water (*loc. cit.*), and the product appears to be free from any isomeride. Reduction of the unsaturated amide in acetic acid by platinum black and hydrogen causes a quantitative conversion into a saturated amide, *hydrocamphenecarboxylamide*, leaflets, m. p. 189°, which is quite distinct from *allo*camphanecarboxylamide. If the difference is not due to stereoisomerism, the above elimination of hydrogen chloride must therefore be accompanied by a change from the bornylene to the camphene group.

The mixture of unsaturated esters from methyl chloro*allo*camphanecarboxylate was then converted into the corresponding mixture of acids and treated with thionyl chloride; the resulting acid chlorides, when submitted together in ethereal solution to the action of ammonia, yielded two isomeric unsaturated amides, m. p. 209° and 98° respectively. The former, which preponderated, was identical with the amide (above) obtained by the action of water on the chlorine-substituted amide, and must be related to the camphenecarboxylic acid of m. p. 105°, whilst the latter amide, m. p. 98°, must be related to the second camphenecarboxylic acid.

The action of sodium nitrite and hydrochloric acid on the saturated amide, m. p. 189° (see above), gave a saturated acid, *hydrocamphene-carboxylic acid*, hexagonal leaflets, m. p. 126°, which is also obtainable by hydrolysis with hot concentrated hydrochloric acid.   D. F. T.

Preparation of Purpurin-3-carboxylic Acid. FARBENFABRIKEN VORM. FRIEDR. BAYER & Co. (D.R.-P. 260765.   Compare Perkin and Cope, T., 1894, **65**, 848).—Purpurin-3-carboxylic acid, a red powder, m. p. 222—224° (with loss of carbon dioxide), is obtained when 1 : 2-dihydroxyanthraquinone-3-carboxylic acid dissolved in 20 parts of concentrated sulphuric acid is slowly treated at 15—20° with manganese dioxide (0·3—0·4 part); it is identical with the "ψ-purpurin" (purpurincarboxylic acid) present in madder.   F. M. G. M.

Preparation of 1:4-Diaminoanthraquinone-2-carboxylic Acid and of 1 : 4-Diaminosulphoanthraquinone-2-carboxylic Acid. AKTIEN-GESELLSCHAFT FÜR ANILIN-FABRIKATION (D.R.-P. 261885. Compare this vol., i, 1206).—1 : 4-*Diaminoanthraquinone-2-carboxylic acid*, dark blue, glistening, bronze needles, m. p. 350° (about), is obtained from 2-amino-5-acetylamino-4-carboxybenzoyl-*o*-benzoic acid (this vol., i, 621) ; the *sulphate* forms brownish-red needles ; when heated with anhydrous boric acid (1 part) and 6 parts of fuming sulphuric acid (5% SO_3) at 190° and subsequently at 130—140° with the addition of 1 part of sulphuric acid (50% SO_3), it gives rise to 1 : 4-*diaminosulphoanthraquinone-2-carboxylic acid sulphate* as a brownish-red, crystalline precipitate.   F. M. G . M

Oxonium and Alkali Salts of Fluorones. HANS VON LIEBIG (*Ber.*, 1913, **46**, 2736—2745).—The composition of the chloride of fluorescein trimethyl ether-ester [Kehrmann and Scheunert's (A., 1910, i, 407) methyl 3 : 6-dimethoxy-9-phenylxanthonium-2'-carboxylate] varies according to the treatment to which it is subjected.   When prepared by the author's method (this vol., i, 865) and kept for five days at the ordinary temperature, a methyl-alcoholic solution of the chloride deposits fluorescein dimethyl ether of m. p. 198°; after removal of the latter compound, the addition of ether precipitates a *chloride*, $2C_{23}H_{20}O_6,3HCl,MeOH,2H_2O$, which has m. p. 110—125° (decomp.), and on crystallisation from water has the composition $C_{23}H_{20}O_6,HCl,MeOH,2H_2O$.   The above chlorides resemble those previously described in yielding with 33% aqueous potassium hydroxide a blue *o*-quinonoid potassium salt. The hydrate, $C_{23}H_{20}O_6,H_2O$, obtained by acidifying an aqueous solution of the potassium salt with acetic acid, probably has the constitution represented in formula II. (*loc. cit.*, 867).   On treatment with water the potassium salt yields a substance, $C_{23}H_{20}O_6$, which was previously considered to be a trimethyl ether-ester of fluorescein. The same substance is obtained by treating the potassium salt with methyl alcohol. It crystallises from cold methyl alcohol in slender, white needles, which sinter at 105—110° and gives off vapour at 126°, and again at a temperature a little above

180°; by warm methyl alcohol it is transformed into fluorescein dimethyl ether. It does not yield blue salts with alkalis, and therefore must contain the pyrone ring. It probably has the annexed constitution (I, where X = OMe).
Solutions of the preceding methoxy-compound and the hydrate mentioned above, in 10—15% hydrochloric acid, deposit a *chloride*, which melts with evolution of gas at 150°, then solidifies, and has m. p. 205°. This chloride differs from the chlorides of fluorescein trimethyl ether-ester already described in being practically insoluble in water. It yields blue salts with alkalis and probably has the formula I (X = Cl).

By heating the disodium salt of fluorescein with methyl sulphate and shaking the product with ether and ammonia, the author has obtained a substance, m. p. 255°, which he considered to be a dimethyl ether of fluorescein (A., 1912, i, 381). The same substance is formed by treating the chloride of fluorescein trimethyl ether ester with strong aqueous ammonia. When pure it has m. p. 256—257°, and is stable towards boiling alcoholic hydrogen chloride and potassium hydroxide. Its constitution is now represented by formula II.
By the action of ammonia on a methyl-alcoholic solution of the chloride of fluorescein trimethyl ether-ester, Loth (*Diss.*, Lausanne, 1913) has obtained a substance, m. p. 257°, which he considers to be identical with the compound just mentioned, and to have the following structure:

$$NH\left[CO\cdot C_6H_4\cdot C(OMe)\!\!<\!\!{}^{C_6H_3(OMe)}_{C_6H_3(OMe)}\!\!>\!\!O\right]_2.$$
The stability of the author's compound towards alcoholic hydrogen chloride and potassium hydroxide is, however, not in agreement with this formula. It is possible that both substances are formed in the action of ammonia on the chloride; but that the particular compound isolated depends on the conditions under which the reaction is carried out and the method of working up the product.

In agreement with this view, the author finds that the action of ammonia on the product formed from ethyl sulphate and the disodium salt of fluorescein gives rise to two substances of m. p. 234° and 221°.

The former compound has been described previously (this vol., i, 80) as a diethyl ether of fluorescein, but is now considered to have a similar structure to that of the methyl compound represented in II, whilst the second *compound*, m. p. 221°, is presumably the ethyl analogue of Loth's compound.

When heated with acetic anhydride and sodium acetate, and the product treated with water, the chloride of fluorescein trimethyl ether-ester is partly converted into fluorescein dimethyl ether, of m. p. 198°. The dichloride of resorcinolbenzein dimethyl ether, when subjected to

same treatment, yields an *acetyl* derivative, $OAc \cdot CPh \begin{smallmatrix} C_6H_3(OMe) \\ C_6H_3(OMe) \end{smallmatrix} > O$, crystallising with benzene (1 mol.) in slender, colourless leaflets, which melt and lose their benzene at 110°, then solidify, and have m. p. 178°. This is converted by prolonged boiling with ethyl alcohol into the ethyl ether of m. p. 158°, the acetyl group being replaced by ethyl.

When shaken with ether and ammonia, the dichloride of resorcinol-benzein dimethyl ether yields a *substance*, which forms pale yellow crystals, m. p. 112—113°, and has the following structure:

$$OH \cdot CPh \begin{smallmatrix} C_6H_3(OMe) \\ C_6H_3(OMe) \end{smallmatrix} > NH.$$
Evidence of the existence of eosin in various forms, corresponding with those of fluorescein (A., 1912, i, 379), has been obtained as follows : The chloride, formed by treating fluorescein with a hot mixture of alcohol and hydrochloric acid, is brominated in alcoholic solution and the resulting eosin fractionally extracted with methyl alcohol. The first extractions deposit a dark red eosin, the later fractions a reddish-white or flesh-coloured modification, whilst the residue is either reddish-white or orange. When heated, the eosin from the later fractions acquires a red colour at 200°, then becomes almost white at a temperature below 300°, and finally turns red again and melt at 304—305°. On crystallisation from benzene, the light-coloured eosin separates as a mixture of colourless, yellow and red prisms. The red variety probably corresponds with the red multi-molecular modification of fluorescein, the light-coloured form to the yellow unimolecular fluorescein, and the colourless variety to the lactone-form.

When boiled with aqueous alcoholic potassium hydroxide, the light-coloured eosin yields intensely violet or blue solutions. The addition of sulphuric acid to these solutions precipitates a brown substance, which on extraction with boiling chloroform leaves an eosin of the composition $2C_{20}H_8O_5Br_4,CHCl_3$ as a reddish or bluish-white, crystalline residue. The latter compound differs from ordinary eosin in giving a deep violet coloration with strong sulphuric acid, and in yielding with aqueous alkalis deep blue solutions having a green fluorescence ; when kept, the blue solutions slowly become violet and finally red. It loses its chloroform at 185—186°, and then dissolves in alkalis with a red colour. Attempts to isolate the blue salt formed by warming the compound with 33% aqueous potassium hydroxide were unsuccessful ; instead of the blue salt a brownish-red *tripotassium* salt, $C_{20}H_5O_5Br_4K_3$, was obtained.

Hydroxyquinolbenzein, to which Kehrmann has assigned formula III, yields with aqueous alcoholic potassium hydroxide a *tripotassium* salt IV, which separates in brownish-red crystals of the composition $C_{19}H_{19}O_5K_3,EtOH,H_2O$.

(III.)   (IV.)
The author considers that the constitution of hydroxyquinolbenzein is best represented by a quinonoid structure, similar to that given above for the potassium salt, and thus avoids the assumption that the betaine-linking is stable towards alkalis, or that transformation into the quinonoid form occurs.   F. B.

Oxidation with Oxygen in Presence of Metallic Osmium. I. RICHARD WILLSTÄTTER and EUGEN SONNENFELD (*Ber.*, 1913, **46**, 2952—2958).—Unsaturated substances alone or diluted with acetone are agitated in special flasks with a small quantity of metallic osmium, prepared by igniting osmium ammonium chloride in a current of hydrogen, in an atmosphere of oxygen. The other metals of the platinum group do not act as oxygen-carriers under these conditions, but tellurium is active, although less so than osmium. A detailed account of the oxidation of *cyclo*hexene by this method is given ; the products are Δ²-*cyclo*hexenol, Δ¹-*cyclo*pentenealdehyde, much adipic acid, and a little adipoin (*cyclo*hexan-2-ol-1-one).

The first two were separated by converting the *cyclo*hexenol into the *naphthylurethane*, m. p. 156°, which crystallises in needles from alcohol or ethyl acetate on cooling its solution in either. Adipoin gives a p-*nitrophenylhydrazone*, m. p. 146° (decomp.), which crystallises from boiling alcohol in orange-red, hexagonal leaflets.   T. A. H.

Action of Light on the Colour Changes of Aldehyde Phenylhydrazone Solutions. HANS STOBBE and ROBERT NOWÁK (*Ber.*, 1913, **46**, 2887—2902).—The change of colour of solutions of the phenylhydrazones of benzaldehyde, cuminaldehyde, anisaldehyde, piperonaldehyde, and acetaldehyde on exposure to light has been investigated. In all cases the change is extremely sensitive to the action of light. Acid solutions are much more quickly affected than neutral solutions. The change is not due, as supposed by Baly and Tuck (T., 1907, **91**, 1572), to photo-isomerisation of the hydrazones to azo-compounds, but it is an oxidation process which takes place slowly in the dark and is greatly accelerated by light. The colour changes of other hydrazones and of osazones is likewise attributed to oxidation.

Benzaldehydephenylhydrazone is oxidised to dibenzylidenediphenyl-hydrotetrazone, whilst in no case were azo-compounds formed.
                                                                E. F. A.

Halogenated Alicyclic Ketones. II. Monohalogenides of Penta-, Hexa-, and Hepta-cyclic Ketones. ARTHUR KÖTZ, K. BLENDERMANN, E. KÁRPÁTI, and RICHARD ROSENBUSCH (*Annalen*, 1913, **400**, 47—54. Compare Kötz and Steinhorst, A., 1911, i, 210).—When *cyclo*pentanone, 1 : 4-dimethyl*cyclo*hexan-3-one, and *cyclo*hepta-none are halogenated by Kötz and Götz's method (A., 1908, i, 173), chlorine or bromine is substituted most easily in dimethyl*cyclo*hexanone and least readily in *cyclo*pentanone. The chloro-ketones are stable in the absence of light, but the bromo-ketones decompose very easily. 2-*Chloro*cyclopentanone, b. p. 76—77°, 2-*bromo*cyclopentanone, b. p. 79—82°/15 mm., 2-*chloro*cyclo*heptanone, b. p. 95°/13 mm., 2-*bromo*-cyclo*heptanone, b. p. 103°/13 mm., and 2-*chloro*-1 : 4-dimethyl*cyclo*hexan-3-one, b. p. 108—109°/15 mm., are described.   C. S.

α-**Hydroxy-ketones of the** *cyclo***Hexanone and** *cyclo***Heptanone Series.** ARTHUR KÖTZ, K. BLENDERMANN, RICHARD ROSENBUSCH, and E. SIRRINGHAUS (*Annalen*, 1913, **400**, 55—72).—Comparative experiments on the hydrolysis of 2-chloro*cyclo*pentanone, 2-chloro*cyclo*-hexanone, and 2-chloro*cyclo*heptanone by aqueous alkali carbonates or hydrogen carbonates show that *cyclo*pentan-2-olone cannot be thus obtained, that 2-chloro*cyclo*hexanone is readily hydrolysed by aqueous potassium carbonate in the cold, and that the formation of *cyclo*heptan-2-olone in satisfactory yield requires the action of boiling concentrated potassium carbonate for six hours. *cyclo*Hexan-2-ol-1-one, m. p. 98°, forms a *benzoyl* derivative, m. p. 122—123°, *semicarbazone*, m. p. 238°, *oxime*, m. p. 102—103°, *methyl ether*, m. p. 162°, and *ethyl ether*, m. p. 137° (which is converted into the methyl ether by warm methyl alcohol). *cyclo*Heptan-2-ol-1-one, m. p. 28°, unlike *cyclo*hexan-2-ol-1-one, possesses acidic properties and forms a *potassium* derivative. It forms a *methyl ether*, b. p. 65—66°/12 mm., but not a semicarbazone or oxime. The ethers of *cyclo*hexan-2-olone also do not form oximes or semicarbazones, and 2-hydroxy*cyclo*-hexanoneoxime cannot be etherified; the group

$$OR\cdot CH\cdot C\vdots NOH,$$
therefore, apparently cannot be formed.

2-Methoxy*cyclo*hexanone does not react with magnesium methyl iodide. *cyclo*Hexan-2-olone reacts only with difficulty, and yields ultimately *cyclo*hexanone (compare Sabatier and Mailhe, A., 1905, i, 706), whilst 1-methyl*cyclo*hexan-3-ol-2-one is similarly converted into 1 : 2-*dimethyl*cyclohexan-3-one, b. p. 178—179°.

*cyclo*Hexan-2-olone and its methyl and ethyl ethers react with phenylhydrazine in glacial acetic acid to form the same *osazone*, $C_{18}H_{20}N_4$, m. p. 150—151°, red crystals. *cyclo*Hexan-2-olone and its methyl ether are oxidised to adipic acid by alkaline potassium permanganate, and to glutaric acid by boiling nitric acid, D 1·22 ; the oxidation of the methyl ether is effected much less readily in both cases.

It is well known that hydroaromatic cyclic ketones condense with aldehydes except when a methyl group is present in the ortho-position to the carbonyl group. Hydroxyl and methoxy-groups apparently exert a similar inhibiting influence, because *cyclo*hexanolone or its methyl ether does not condense with benzaldehyde or cinnamaldehyde in the presence of alcoholic sodium hydroxide. 2-Methoxy-*cyclo*hexanone, however, reacts with sodium and amyl formate in ether to form, after acidification of the product, 2-*methoxy*-6-*hydroxymethyl-enecyclohexanone*, $C_8H_{12}O_3$, b. p. 98—100°/11 mm. (*semicarbazone*, m. p. 212—215°).

1 : 4-*Dimethyl*cyclohexan-2-ol-3-one, $C_8H_{14}O_2$, b. p. 91°/13 mm. (*benzoyl* derivative, m. p. 162°), is obtained by boiling 2-chloro-1 : 4-dimethyl*cyclo*hexan-3-one with saturated aqueous potassium carbonate, or, in a similar manner, from ethyl 2-chloro-1 : 4-dimethyl*cyclo*-hexan-3-one-4-carboxylate. Since the last compound, being produced by the chlorination of ethyl 1:4-dimethyl*cyclo*hexan-3-one-4-carboxylate by Kötz and Götz's method, must contain the chlorine atom in position 2 (compare Kötz and Steinhorst, A., 1911, i, 210), it follows, from the

production of 1 : 4-dimethyl*cyclo*hexan-2-ol-3-one by the hydrolysis of both chlorinated substances, that 2-chloro-1 : 4-dimethyl*cyclo*hexan-3-one (preceding abstract) must have this constitution, not that of the 4-chloro-isomeride. The chlorination of ethyl 1-methyl-4-*iso*propyl*cyclo*-hexan-3-one-4-carboxylate yields *ethyl 2-chloro-1-methyl-4-isopropyl-cyclohexan-3-one-4-carboxylate*, by the hydrolysis of which 2-*hydroxy*-1-*methyl*-4-*isopropyl*cyclo*hexan-3-one*, b. p. 139°/17 mm., is obtained.

<div align="right">C. S.</div>

Unsaturated Cyclic Ketones. Δ^2-*cyclo*Hexenone and Δ^2-*cyclo*-Heptenone (Tropilene). ARTHUR KÖTZ, K. BLENDERMANN, F. MÄHNERT, and RICHARD ROSENBUSCH (*Annalen*, 1913, **400**, 72—86).— Comparative experiments on the production of unsaturated cyclic ketones from the α-halogenated saturated ketones prove that hydrogen iodide is most readily, and hydrogen chloride is least readily, eliminated, and that the difficulty of eliminating hydrogen haloid increases from halogen-*cyclo*pentanones to halogen-*cyclo*heptanones. Aniline or trimethylamine is the most suitable eliminating reagent; to avoid the formation of hydroxy-ketones, water must not be present.

Willstätter's tropilene is identical with Δ^2-*cyclo*heptenone, obtained by the action of aniline on 2-bromo*cyclo*heptanone; it forms an *oxime*, m. p. 80—88°, and yields *cyclo*heptanone by reduction by Paal's method.

1 : 4-*Dimethyl*-Δ^1-cyclohexen-3-one, $C_8H_{12}O$, b. p. 75°/19 mm., is obtained by heating 2-hydroxy-1 : 4-dimethyl*cyclo*hexan-3-one with anhydrous oxalic acid at 110°. *Ethyl* 1 : 2-*dimethyl*-Δ^1-cyclohexen-3-one-6-carboxylate, $C_{11}H_{16}O_3$, b. p. 144—146°/13 mm. (*semicarbazone*, m. p. 202°; *oxime*, m. p. 109—110°), obtained by the action of methyl iodide and sodium ethoxide on ethyl 1-methyl-Δ^1-*cyclo*hexen-3-one-6-carboxylate, yields *ethyl* 1 : 2-*dimethyl*cyclohexan-3-one-6-carboxylate, b. p. 256—258° (*semicarbazone*, m. p. 210—211° [decomp.]), by reduction by Paal's method, and is converted into 1 : 2-*dimethyl*-Δ^1-cyclo-*hexen-3-one*, b. p. 118—119°/12 mm. (*semicarbazone*, m. p. 225° [decomp.]), by hydrolysis by alcoholic potassium hydroxide and distillation in a vacuum of the resulting acid. 1 : 2-Dimethyl-Δ^1-*cyclo*hexen-3-one is reduced to the corresponding saturated *ketone*, b. p. 84°/11 mm. (*semicarbazone*, m. p. 203—204°), by Paal's method, and yields γ-acetyl-butyric acid by oxidation by aqueous potassium permanganate at 0—6°.

<div align="right">C. S.</div>

Zinc Chloride as a Condensing Agent. III. Auto-condensation of Anils. G. REDDELIEN (*Ber.*, 1913, **46**, 2712—2717).—The author has shown previously (A., 1910, i, 118, 746) that acetophenone condenses with aniline in the presence of aniline zincichloride as a catalyst, yielding acetophenoneanil, together with a small quantity of a yellow substance, m. p. 98—99°. The by-product is now found to be dypnoneanil, and is formed by the auto-condensation of acetophenone anil. If the condensation is carried out at 180—190° a better yield of the substance is obtained. It was observed that in all cases in which dypnoneanil was formed as a by-product, the aniline zincichloride used as a catalyst underwent slight decomposition into zinc hydroxide, and

this suggested the possibility that the aniline hydrochloride, simultaneously produced by this decomposition, was the prime factor in the further condensation of acetophenoneanil to dypnoneanil. This view has been confirmed by heating acetophenoneanil for a few minutes with aniline hydrochloride, when a 60% yield of dypnoneanil was obtained ; under the same conditions, using aniline zincichloride, the acetophenoneanil remains unchanged.

If the heating is more prolonged and the temperature higher, 1 : 3 : 5-triphenylbenzene is formed. Exposure to air at the ordinary temperature also causes the transformation of acetophenoneanil into dypnoneanil, the condensation in this case being probably due to traces of hydrochloric acid in the air, for in closed vessels the acetophenoneanil may be kept for a long time without undergoing change.

Miller and Plöchl (A., 1896, i, 609) have already pointed out that there exists a very close resemblance in the reactions of aldehydes and ketones on the one hand, and of their anils on the other. In emphasising this analogy, the author refers to the similarity in the autocondensation products of acetophenone and its anil, and to the similar behaviour of aldehydes and their anils towards organo-magnesium compounds (Busch, A., 1904, i, 663; 1905, i, 519).

Further, anils closely resemble ketones and aldehydes in their behaviour toward phenylhydrazine and semicarbazide : thus, benzophenoneanil and acetophenoneanil readily react with these compounds in alcoholic solution to form the semicarbazones and phenylhydrazones of the corresponding aldehydes.

Finally, the ability of unsaturated and aromatic aldehydes to form coloured additive compounds with strong acids is shared by anils; fluoroneanil and dypnoneanil yield additive compounds with hydrogen chloride which are coloured respectively red and reddish-yellow, and are rapidly resolved by water into their components.

Dypnoneanil, $CMePh:CH\cdot CPh:NPh$, forms lustrous, light yellow, glassy prisms, m. p. 98—99°, and gives an intensely yellow coloration with sulphuric acid. It has also been obtained, together with acetophenoneanil, by heating dypnone and aniline in the presence of aniline zincichloride; if aniline hydrochloride is used as a condensing agent, triphenylbenzene is produced.

Dypnone-p-tolil, prepared from dypnone and aniline, using p-toluidine zincichloride as a catalyst, has m. p. 110°. It is accompanied by acetophenone-p-tolil, which crystallises from alcohol in yellowish-white needles, m. p. 31°. F. B.

Catalytic Action of Hydrogen Haloids in Condensations. I. Preparation of Ketoneanils. G. REDDELIEN (*Ber.*, 1913, **46**, 2718—2723. Compare preceding abstract).—In the preparation of ketoneanils by the condensation of aromatic ketones with amines, hydrogen haloids or their salts with aromatic amines may often be employed as catalysts in place of zinc chloride or amine zincichlorides previously used. Thus, benzophenoneanil is readily obtained by heating benzophenone and aniline at 170° in the presence of one drop of hydrochloric acid.

The reaction proceeds more rapidly than when the zinc salts are

employed, but is not so general in its application. Methyl ketones, such as acetophenone and $\alpha\beta$-unsaturated ketones, do not yield anils by this method, although the latter are readily obtained when aniline zincichloride is employed.

With respect to the mechanism of the reaction the author considers that the ketones first combine with the amines in the presence of hydrochloric acid to form compounds of the type OH·CRR·NHR,HCl, which lose water when heated, yielding hydrochlorides of the anils, CRR:NR,HCl; the anils, however, are very feeble bases in comparison with the amines, and, therefore, are liberated from their hydrochlorides by the action of the unchanged amines, the hydrochlorides of the latter compounds thus being regenerated.

It is pointed out that the hydrogen haloids may act as catalysts in opposite directions accordingly as they ionised or not. Whilst unionised hydrogen haloids act as catalysts in the condensation of ketones with amines, in the ionised state they accelerate the decomposition of the anils into their components and thus exert a catalytic action in the opposite direction.

In addition to benzophenoneanil, the following anils were obtained by heating the necessary ketones and amines in the presence of a little hydrochloric acid : phenyl α-naphthyl-ketoneanil, m. p. 93—94° (compare Busch and Falco, A., 1910, i, 747); benzildianil, m. p. 142°; benzophenone-p-tolil, crystallising from alcohol in long, stout, lustrous prisms, m p. 48° (compare Reddelien, A., 1910, i, 118); benzophenone-α-naphthil (Pauly, this Journ., 1877, ii, 614), which has m. p. 137·5°, and gives a blood-red coloration with strong sulphuric acid; fluorenoneanil (A., 1910, i, 746), the *hydrochloride* of which is precipitated in blood-red needles by passing hydrogen chloride into a benzene solution of the anil.   F. B.

Certain Substituted Benzalacetophenones [Phenyl Styryl Ketones]. FRANZ KUNCKELL and MARTIN HAMMERSCHMIDT (*Ber.*, 1913, **46**, 2676—2680. Compare Kunckell and Fürstenberg, A., 1912, i, 118).—*2-Hydroxy-5-acetylaminophenyl 2-nitrostyryl ketone*, golden-brown needles, m. p. 205° (decomp.), is obtained when aqueous sodium hydroxide is gradually added to an alcoholic solution of 2-hydroxy-5-acetylaminoacetophenone and o-nitrobenzaldehyde and the mixture neutralised after some time with dilute sulphuric acid, the temperature being maintained at about 20° during the whole operation. It is somewhat unstable, and decomposes when preserved for a short time. The preparation of the corresponding dibromide and flavone could not be effected.

2-Hydroxy-5-acetylaminophenyl 4-nitrostyryl ketone,

$$\text{OH·C}_6\text{H}_3(\text{NHAc})\text{·CO·CH:CH·C}_6\text{H}_4\text{·NO}_2,$$
red, microcrystalline powder, m. p. 204°, is prepared in a similar manner from 2-hydroxy-5-acetylaminoacetophenone and p-nitrobenzaldehyde. It absorbs bromine in chloroform solution, yielding the corresponding *dibromide*, yellow needles, m. p. 125°, after previous softening, from which the flavone could not be obtained by the action of alcoholic potassium hydroxide.

2-Hydroxy-5-acetylaminophenyl 4-chlorostyryl ketone, golden needles,

m. p. 174°, and *2-hydroxy-5-acetylaminophenyl 2-hydroxystyryl ketone*, yellow crystals, m. p. 134°, are similarly formed from their components. In these cases, complete condensation can only be effected by heating the mixture on the water-bath. In neither case could the corresponding dibromide be obtained.

2-Hydroxy-5-acetylaminophenyl 4-methylstyryl ketone forms yellowish-white needles, m. p. 185°. It combines with bromine in chloroform solution to yield *2-hydroxy-5 acetylaminophenyl αβ-dibromo-β-p-tolyl-ethyl ketone*, m. p. 162°.

Terephthalaldehyde condenses with *2-hydroxy-5-acetylaminoaceto-phenone*, yielding a yellow *substance*, m. p. 217°, the constitution of which has not been definitely determined.   H. W.

Metal Ketyls, a Large Class of Substances with Tervalent Carbon. WILHELM SCHLENK and ALEXANDER THAL (*Ber.*, 1913, **46**, 2840—2854. Compare A., 1911, i, 545).—Phenyl diphenylyl ketone was dissolved in dry ether in an atmosphere of nitrogen, and the boiling point of the solution determined. This remained unchanged on the addition of a piece of bright potassium, indicating that potassium phenyl diphenylyl ketone has the formula

$$Ph \cdot C_6H_4 \cdot CPh(OK) -.$$
When a suspension of benzpinacone in benzene is mixed with a concentrated, alcoholic sodium ethoxide solution, sodiobenzophenone is formed, as indicated by the unstable, dark blue coloration. The sodium salt of the benzpinacone at first formed is dissociated immediately into the free radicles with a tervalent carbon atom, $CPh_2(ONa)-$. The name metal ketylen is proposed for such compounds containing tervalent carbon.

Special apparatus is described for their filtration, isolation, and for drying them in a current of nitrogen.

The sparingly soluble ketyls cannot be prepared in the manner described, since the surface of the metal becomes coated with a film of insoluble ketyl which prevents further action.

In such cases the ketone (dimethylpyrone) is mixed with the very soluble potassium phenyl diphenylyl ketone, when the insoluble ketyl (red potassiodimethylpyrone) separates out. Ether, benzene or pyridine may be used as solvents, but the two latter are more difficult to remove from the ketyl. Potassium, sodium, and lithium react equally well; magnesium in the form of amalgam also reacts with diaryl ketones.

Potassiodimethylpyrone forms a bright red powder, which oxidises so readily that it glows on exposure to the air.

Potassiochromone yields a deep orange-red product, and contains a further molecule of chromone. It chars on exposure.

Potassioxanthone separates together with a molecule of xanthone as deep blue needles.

*Potassio β-benzpinacolin*, $CPh_2:CPh \cdot OK-$, forms dark cubic crystals with a brown surface reflex.

Potassiophthalophenone is dark red.

Potassio-N-methylisatin separates in deep blue flakes.

Potassio-O-methylisatin forms a deep violet precipitate.

Potassio-m-*dibenzoylbenzene*, $COPh \cdot C_6H_4 \cdot CPh \cdot OK-$, forms a dark red powder.

Potassio-p-*dibenzoylbenzene* forms a additive compound with two molecules of potassium per molecule ; a deep red precipitate is formed, and the solution becomes deep red. The alternative ketyl (I) and quinonoid (II) formulæ are considered, but the latter is rejected,

$$-CPh(OK) \cdot C_6H_4 \cdot CPh(OK)- \qquad CPh(OK) \vdots C_6H_4 \vdots CPh(OK)$$
$$\text{(I.)} \qquad\qquad\qquad \text{(II.)}$$
since the compound behaves like the other ketyls and glows on exposure to the air.

Potassiobenzil, $-CPh(OK) \cdot CPh \vdots O$, is obtained as a violet-coloured precipitate.

Potassiofuril is a black or bluish-black substance.

Potassiophenanthraquinone, $C_6H_4 {<}{\overset{CO-}{\underset{C_6H_4}{}}}{>}C(OK)-$, is dark brown.

Potassio-p-*benzoquinone* possesses a quinhydrone structure combining with a molecule of quinone ; it forms a deep bluish-green compound.

When o-benzoquinone is mixed with potassium phenyl diphenylyl ketyl, a dark green precipitate is formed, which soon becomes colourless, and is then potassiocatechol. When the ketyl solution is added slowly to the quinone, a precipitate is formed, and the solution becomes an intense reddish-violet ; this is attributed to the formation of the metal ketyl.

On adding diphenyl ketone to the potassium phenyl diphenylyl ketyl an intense violet-red coloration is produced. Excess of the ketyl causes a separation of a compound containing 1 atom of potassium to 2 molecules of diphenyl ketone. The red compound could not be isolated ; it possibly has the composition $CPh_2 \vdots C(OK)-$.

The atomic groups OK, ONa are considered to exhaust practically the entire valency force of the atoms to which they are attached.

E. F. A.

Preparation of Arylidoquinones. FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R.-P. 262180).—*Di*-p-*chloroanilinobenzoquinone*, a yellowish-brown powder, m. p. over 300°, is obtained by heating together quinol and *p*-chloroaniline in the presence of ammoniacal copper oxide.

Bromoanilinonaphthaquinone is prepared in a similar manner from *p*-bromoaniline and α-naphthaquinone.   F. M. G. M.

Preparation of 1 : 4-Diaminoanthraquinone and its Derivatives, or of Sulphonic Acids of these Compounds. AKTIEN-GESELLSCHAFT FÜR ANILIN-FABRIKATION (D.R.-P. 260899. Compare A., 1904, i, 512; 1905, i, 447; 1909, i, 243).—The preparation of aminoanthraquinones from aminobenzoyl-*o*-benzoic acids has previously been recorded, and that of 1 : 4-diaminoanthraquinones from 2-amino-5-acetylaminobenzoyl-*o*-benzoic acid, or its lactam (this vol., i, 621), is now described ; the operation is carried out at 190—200° with either 95% or fuming sulphuric acid ; under the latter conditions, especially in the presence of boric acid, sulphonated products are also formed. 2 : 5-*Diaminobenzoyl*-o-*benzoic acid*, yellow

crusts, which melt at 185° with conversion into the *lactam*, can also be employed in this reaction.

1 : 4-*Diamino-2-methylanthraquinone*, dark violet, glistening, bronze needles, m. p. 252°, is obtained from 2 : 5-diamino-*p*-toluoyl-*o*-benzoic acid, whilst 4-chloro-2-amino-5-acetylaminobenzoylbenzoic acid gives rise to 2-*chloro*-1 : 4-*diaminoanthraquinone*, dark violet needles, m. p. 234°. F. M. G. M.

Replacement of the Sulphonic Acid Group by Halogens in Hydroxyanthraquinonesulphonic Acids. GUSTAV HELLER [with SIEGFRIED SKRAUP (*Ber.*, 1913, **46**, 2703—2711).—Kelbe's method (A., 1883, 806 ; compare also Ullmann and Ochsner, A., 1911, i, 489, and Schilling, this vol., i, 493) of replacing the sulphonic acid group by chlorine or bromine, by the action of these elements on sulphonic acids in aqueous solution, has been applied by the author to the preparation of halogen derivatives of alizarin and anthrachrysone from the corresponding sulphonic acids.

3-Bromo-1 : 2-dihydroxyanthraquinone (D.R.-P. 77179 and 78643) is obtained in a pure condition by the addition of an aqueous solution of potassium bromide and bromate to sodium alizarin-3-sulphonate, acidified with sulphuric acid, and maintained at 95°. It crystallises in rosettes of brownish-red needles, m. p. 260—261°, yields a pale yellow *diacetyl* derivative, m. p. 204—205°, and dissolves in dilute aqueous alkali hydroxides, yielding bluish-violet solutions ; concentrated solutions of the hydroxides precipitate the corresponding alkali salts.

3-Chloro-1 : 2-dihydroxyanthraquinone, prepared by passing chlorine into a hot aqueous solution of alizarin-3-sulphonic acid, has m. p. 270—271°, and on benzoylation in pyridine solution yields a *dibenzoyl* derivative, m. p. 184°, together with a red *substance*, m. p. above 300°.

When dissolved in an ice-cold mixture of sulphuric and nitric acids, it is oxidised to 3-*chloro*-1 : 2 : 4-*trihydroxyanthraquinone*, m. p. 242—244°.

Nitration in glacial acetic acid solution yields 3-*chloro-4-nitro*-1 : 2-*dihydroxyanthraquinone*. This crystallises in orange-yellow needles, which become dark red and decompose slightly at 220°, then acquire a lighter colour, and finally melt at 285°.
3-*Chloro-4-anilino*-1 : 2-*dihydroxyanthraquinone*, prepared by heating the preceding nitro-compound in aqueous sodium carbonate solution with aniline, crystallises in black needles or plates, m. p. 223—224°.

A solution of anthrachrysone in 33% aqueous sodium hydroxide deposits a lustrous, vivid red *sodium* salt, which is converted by ammonium chloride into the *ammonium* salt.

1 : 3 : 5 : 7-Tetrahydroxyanthraquinone-2 : 6-disulphonic acid, prepared by heating anthrachrysone with an excess of fuming sulphuric acid, forms a *sodium* salt, $C_{14}H_6O_6(SO_3Na)_2$, crystallising in glistening, coppery platelets (compare D.R.-P. 70803). On treatment with bromine in dilute acetic acid solution, the sodium salt is converted into 2 : 4 : 6 : 8-tetrabromo-1 : 3 : 5 : 7-tetrahydroxyanthraquinone, which forms lustrous, dark red needles, m. p. above 300°, and yields a sparingly soluble *ammonium* salt.

2 : 6-*Dibromo*-1 : 3 : 5 : 7-*tetrahydroxyanthraquinone*, prepared by brominating anthrachrysone in glacial acetic acid solution, crystallises in orange-red needles, m. p. above 290°, and also forms a sparingly soluble *ammonium* salt.

2 : 6-*Dichloro*-1 : 3 : 5 : 7-*tetrahydroxyanthraquinone* is obtained in lustrous, orange, silky needles by the addition of sodium hypochlorite to an aqueous solution of the sodium salt of anthrachrysone. The action of chlorine on 1 : 3 : 5 : 7-tetrahydroxyanthraquinone-2 : 6-disulphonic acid yields 4 : 8-*dichloro*-1 : 3 : 5 : 7-*tetrahydroxyanthraquinone*-2 : 6-*disulphonic acid.*

8-*Nitro* - 4 - *anilino* - 1 : 3 : 5 : 7 - *tetra-hydroxyanthraquinone* - 2 : 6 - *disulphonic acid* (annexed formula) is obtained in the form of its *trisodium* salt (dark blüish-violet crystals of a coppery lustre) by heating a solution of 4 : 8-di-nitro - 1 : 3 : 5 : 7 - tetrahydroxyanthra - quinone in aqueous sodium carbonate with aniline.

A similar replacement of the nitro-group by the aniline residue occurs when 4 : 8-dinitro-1 : 3 : 5 : 7 - tetrahydroxyanthraquinone (D.R.-P. 71964) is heated with aqueous sodium carbonate and aniline. The 8-*nitro*-4-*anilino*-1 : 3 : 5 : 7-*tetrahydroxyanthraquinone* thus formed crystallises in blackish-blue needles of a coppery lustre.

An account of the tinctorial properties of the above dyes is given.

F. B.

Preparation of a Menthol Ester. ROBERT MEYER (D.R.-P. 261228).—*Menthylglycine hydrochloride*, slender needles, is obtained when a fused suspension of glycine (20 parts) in menthol (70 parts) is treated with continual agitation at about 100° with dry hydrogen chloride and the product purified by crystallisation from water ; the free *base*, an oil, is decomposed by warm alkaline hydroxides, and with mercuric chloride furnishes a sparingly soluble *mercury* derivative.

F. M. G. M.

Scission of Racemic Amino-acids by means of Active Acids. I. AMEDEO COLOMBANO and GIUSEPPE SANNA (*Atti R. Accad. Lincei,* 1913, [v], **22,** ii, 234—237).—A solution containing equimolecular quantities of *d*-camphorsulphonic acid and glycine deposits a salt, $C_{12}H_{21}O_6NS$, which forms long, hygroscopic prisms, m. p. 165—173°, $[\alpha]_D + 14.69°$ (in 10·664% aqueous solution). Alanine similarly yields a camphorsulphonate, m. p. 105—110°, $[\alpha]_D^{18} + 14.33°$ (in 12·153% aqueous solution). These salts, however, yield racemic products when they are decomposed. Similar results were obtained under many different conditions, and no better success was obtained by substituting *d*-bromocamphorsulphonic acid.

Racemic salts were also produced from leucine and tyrosine in the same way.

R. V. S.

dl-α-Pinene and Ethyl Diazoacetate. EDUARD BUCHNER and KURT REHORST (*Ber.,* 1913, **46,** 2680, 2687. Compare Buchner and Weigand, this vol., i, 376—887).—The application of ethyl diazo-

acetate to the study of the constitution of *dl*-pinene leads the authors to the conclusion that the latter contains an endocyclic double bond and a methyl group directly attached to a carbon atom having a double bond. This is in conformity with Wagner's formula for pinene.

Pure *dl*-pinene was prepared from American turpentine by subjecting the latter to the action of nitrosyl chloride, the product formed being subsequently decomposed by boiling aniline.

A solution of ethyl diazoacetate in a little *dl*-pinene is slowly added to a mixture of the latter substance and copper powder at 160—165°; nitrogen is violently evolved, and, on distillation, *ethyl* 1:6:6-*trimethyl*-[0,1,4$^{5·7}$,1]-*tricyclo*-*octane-2-carboxylate* (annexed formula), b. p. 135°/12·5 mm., is obtained. Since, however, when suspended in alkali it immediately decolorises permanganate, it is probably contaminated with ethyl fumarate. When saponified with methyl-alcoholic potassium hydroxide, it yields 1 : 6 : 6-*trimethyl*-[0,1,4,$^{5·7}$,1]-tricyclo*octane*-2-*carboxylic acid*, crystalline powder, m. p. 165°, which is stable towards permanganate. The *silver* and *barium* salts were prepared, the latter being readily soluble in water. The *amide*, colourless leaflets, has m. p. 181°. Oxidation by potassium permanganate in hot acid solution converts the acid into a mixture of products from which terebic acid, m. p. 175°, separates after some time. Two other acids can be separated from the residue by converting them into their methyl esters. One of these crystallises in large prisms, whereas the other remains liquid. The latter, when saponified, yields an *acid*, m. p. 211—212°, which could not be further identified on account of its small amount. The former gives methyl*cyclo*propane-1 : 2 : 3-tricarboxylic acid, which has m. p. 192°, and does not evolve carbon dioxide at 220°. The identity of this substance is further established by comparison of its methyl ester, m. p. 76·5°, with a synthetically prepared specimen of the same substance (Buchner and Dessauer, A., 1894, i, 347).

The action of ethyl diazoacetate on pinene in the presence of copper powder has been previously investigated by Loose (A., 1909, i, 463), who obtained an oily product which, on saponification, yielded a non-crystallisable substance. This result is attributed to lack of uniformity in the pinene.

The authors have also studied the action of ethyl diazoacetate on *d*-pinene ($a_D + 39·8°$ in 1-dcm. tube) and have obtained a product which, when saponified, yields an acid, colourless needles, m. p. 123°, together with very small quantities of an isomeric acid, m. p. about 165°. With *l*-pinene ($a_D - 31·1°$ in 1-dcm. tube), on the other hand, the main product is the acid, m. p. about 165°, whilst only small amounts of the substance, m. p. about 123°, are obtained. The complete separation of the two acids is difficult, and it is suggested that the acid, $C_{13}H_{18}O_2$, m. p. 123°, is derived from nopinene present in crude optically-active oil of turpentine. H. W.

Bornylene Ozonide. CARL HARRIES and REINHOLD HAARMANN (*Ber.*, 1913, **46**, 2595—2596).—By the action of washed, 8% ozone on

bornylene in hexane solution, the *ozonide*, $C_{10}H_{16}O_3$, was obtained as a white precipitate, which gradually decomposed after some time, but was fairly stable towards boiling water. In order to hydrolyse the product, bornylene was saturated with ozone in glacial acetic acid and the solution heated for thirty minutes. The solvent was then evaporated under reduced pressure and the residue distilled, when a pale yellow oil, containing a dialdehyde, b. p. 90—110°/16 mm., and a solid, b. p. 125—150°/18 mm., containing in all probability an aldehydic acid, were obtained.   ·   J. C. W.

Research on the Eucalypts of Tasmania and their Essential Oils. RICHARD T. BAKER and HENRY G. SMITH (*Reprint* from the *Proc. Roy. Soc. Tasmania*).—Oils distilled from leaves of the various species of eucalyptus occurring in Tasmania have been examined with a view to ascertain their composition and economic value, and of using some of the data thus obtained as a guide in deciding certain outstanding taxonomic problems in connexion with the genus. The results show that the twenty-one species found in Tasmania may be divided into groups as follows:

   I. Eight species yielding oils containing over 50% cineole, much pinene, but no phellandrene or piperitone. The characters of the oils from these species are as follows: *Eucalyptus cordata*, D_{15}^{15} 0·9138, a_D +9·3°, n_D^{18} 1·4965, saponification number 14·8, soluble in 1·25 vols. of 70% alcohol; contains cineole 62%, *d*-pinene, and esters. *E. Muelleri*, D_{15}^{15} 0·9096, a_D +10·4°, n_D^{24} 1·4629, saponification number 15·3, soluble in 4 vols. of 70% alcohol; contains cineole 60%, *d*-pinene, and esters. *E. Perriniana*, D_{15}^{15} 0·9119, a_D +8·9°, n_D^{15} 1·4651, saponification number 10·3, soluble in 2 vols. of 70% alcohol; contains cineole 68%, *d*-pinene, esters, and sesquiterpene. *E. Rodwayi*, D_{15}^{15} 0·9075, a_D +10·6°, n_D^{24} 1·4653, saponification number 3·9, soluble in 6 vols. of 70% alcohol; contains cineole 64%, *d*-pinene, and sesquiterpene. *E. unialata*, D_{15}^{15} 0·9179, a_D +3·1°, n_D^{15} 1·4690, saponification number 11·1, soluble in 1·75 vols. of 70% alcohol; contains cineole 62%, *d*-pinene, esters, and sesquiterpene. *E. urnigera*, D_{15}^{15} 0·9088, a_D +11·8°, n_D^{22} 1·4638, soluble in 5 vols. of 70% alcohol; contains cineole 63%, *d*-pinene, and esters. *E. vernicosa*, D_{15}^{15} 0·9038, a_D +11·3°, n_D^{18} 1·4651, saponification number 5·9, soluble in 1 vol. of 80% alcohol; contains cineole 59%, and *d*-pinene. *E. globulus*, as already frequently recorded.

   II. Two species yielding oils containing cineole from 25—50%, as well as pinene and phellandrene. *E. Gunnii*, D_{15}^{15} 0·9014, a_D +1·5°, n_D^{18} 1·4752, saponification number 6·7, soluble in 4 vols. of 80% alcohol; contains cineole 41%, *d*-pinene, phellandrene, esters, and sesquiterpene. *E. viminalis*, D_{15}^{15} 0·9154, a_D +4·2°, n_D^{19} 1·4711, saponification number 9·5, soluble in 1 vol. of 80% alcohol; contains 50% cineole, *d*-pinene, phellandrene, esters, and sesquiterpene.

   III. Two species yielding oils with over 50% cineole, phellandrene largely replacing pinene, and piperitone being present. *E. linearis*, D_{15}^{15} 0·9096, a_D −10·2°, n_D^{24} 1·4659, saponification number 5·8, soluble in 6 vols. of 70% alcohol; contains cineole 52%, with phellandrene, piperitone, and sesquiterpene. *E. Risdoni*, D_{15}^{15} 0·9045—0·9145, a_D −0·3° to 14·6°, n_D 1·4660 (at 19°) to 1·4733 (at 16°), saponification

number 21·3—27, soluble in 1·25—5 vols. of 70% alcohol; contains cineole 56—58%, phellandrene, piperitone, and esters.

IV. Seven species yielding oils containing much phellandrene, less than 25% of cineole, and having piperitone present. *E. amygdalina*, D_{15}^{15} 0·8668—0·8848, a_D − 59·1° to − 75·1°, n_D^{18} 1·4761—1·4790, saponification number 2·9—3·2, soluble in 7 vols. of 70% alcohol; contains cineole 12—24%, phellandrene, piperitone and sesquiterpene. *E. coccifera*, D_{15}^{15} 0·8810, a_D − 35·8°, n_D^{24} 1·4831, saponification number 4·9, insoluble in 10 vols. of 80% alcohol; contains cineole less than 5%, phellandrene, piperitone and eudesmol. *E. Delegatensis*, D_{15}^{15} 0·8664, a_D − 48·4°, n_D^{24} 1·4828, saponification number 3·1, insoluble in 10 vols. of 80% alcohol; contains traces of cineole, and is chiefly composed of phellandrene with some piperitone and sesquiterpene. *E. regnans*, D_{15}^{15} 0·8802—0·8879, a_D − 28·4° to 31·1°, n_D^{20} 1·4882—1·4901, saponification number 13·2—15·4, soluble in 5 vols. of 80% alcohol; contains phellandrene, eudesmol, piperitone, esters, sesquiterpene and traces of cineole. *E. taeniola*, D_{15}^{15} 0·8864, a_D − 27·6°, n_D^{17} 1·4872, saponification number 3·2, soluble in 5 vols. of 80% alcohol; contains cineole 7%, phellandrene, piperitone, eudesmol and sesquiterpene. *E. virgata*, D_{15}^{15} 0·8883, a_D − 20·9°, n_D^{18} 1·4819, saponification number 3·3, soluble in 3 vols. of 80% alcohol; contains cineole 21%, phellandrene, piperitone, eudesmol and sesquiterpene. *E. obliqua*, D_{15}^{15} 0·8836—0·8845, a_D − 24·2° to 28·8°, n_D 1·4839 (at 19°) to 1·4852 (at 24°), saponification number 7·2—8·1, soluble in 3—4 vols. of 70% alcohol; contains phellandrene, aromadendral, less than 5% of cineole and no piperitone.

The two remaining species do not fall readily into any of the above groups. *E. acervula*, D_{15}^{15} 0·8956, a_D − 1·1°, n_D^{18} 1·4756, saponification number 32·8, soluble in 1 vol. of 80% alcohol; contains cineole 21%, *d*-pinene, phellandrene, geraniol, geranyl acetate, liquid and solid paraffins, sesquiterpene. *E. phlebophylla*, D_{15}^{15} 0·8925, a_D − 22·4°, n_D^{18} 1·4761, saponification number 3·2, insoluble in 10 vols. of 80% alcohol; contains cineole 9%, *l*-pinene, phellandrene and eudesmol.

The cineole was determined by the resorcinol method.   T. A. H.

The Presence of the 8-Carbon Ring in Normal Caoutchoucs. CARL HARRIES (*Ber.*, 1913, 46, 2590—2595. Compare this vol., i, 286).—The author has succeeded in degrading Para caoutchouc to *cyclo*octane-1 : 5-dione. The caoutchouc regenerated by heating the dihydrochloride with pyridine (this vol., i, 380) was converted into the diozonide in ethyl acetate solution, and the residue, after removing the solvent under reduced pressure, was heated for an hour with water at 125°. The filtrate was then neutralised with calcium carbonate, filtered, evaporated in a vacuum, and extracted twenty times with ether. The extract was distilled, and the fraction b. p. 60—90°/14 mm. contained chiefly lævulinaldehyde, the fraction b. p. 100—125°/14 mm. partly solidified and contained *cyclo*octane-1 : 5-dione, and the fraction b. p. 180—200°/14 mm. deposited non-aldehydic crystals, m. p. 88°. The syrup of calcium salts was acidified and extracted with ether, and the extract distilled. The products included much formic and lævulic acids and an oily ketonic acid, b. p. 160—180°/14 mm.

The fraction containing *cyclo*octane-1 : 5-dione was redistilled, and the pale yellowish-green distillate, b. p. 107—110°/14 mm., was found to solidify in ice to large, colourless leaflets. It was difficult to remove the last traces of lævulinaldehyde, so the *disemicarbazone*, $C_{10}H_{18}O_2N_6$, was prepared. It forms a white, crystalline mass, m. p. 186·5°.

The variety of products shows that the regenerated caoutchouc consists of a mixture of at least three forms, due to the displacement of the double linkings in the 8-ring, but the formation of so much lævulinaldehyde and acid indicates that a large part of the caoutchouc is regenerated in its natural form. The degradation into *cyclo*butane-1 : 5-dione is represented by the scheme :

Estimation of Free Sulphur in Vulcanised Caoutchouc. PAUL BARY (*Rev. gen. Chim. pure appl.*, 1913, **16**, 142—145).—Polemical against Alexander (this vol., i, 67), and in agreement with Hinrichsen and Kindischer (A., 1912, i, 706).   F. M. G. M.

New Glucosamine Compound and the Constitution of Chitin. YASHIRO KOTAKE and YOSHITA SERA (*Zeitsch. physiol. Chem.*, 1913, **88**, 56—72).—α- and β-Modifications of *lycoperdin*,

$$C_{18}H_{24}O_9N_2,$$

are obtained from the fungus *Lycoperdon gemmatum*. Both show the biuret and iodine reactions and reduce Fehling's solution : they occupy a mean position between the polypeptides and polysaccharides.

α-Lycoperdin is insoluble in water and crystallises in characteristic, granular crystals, $[a]_D$ − 6·7°, changing to − 5·28°. It becomes black at 240°. β-Lycoperdin forms a soluble sulphate crystallising in needles.

On hydrolysis, 90% of glucosamine and 14% of formic acid are obtained, equivalent to the formation of two molecules of glucosamine and one molecule of formic acid. Constitutional formulæ are assigned to lycoperdin and to chitin, which is assumed to contain four glucosamine molecules, in all of which the NH_2 group is acetylated. The carbon to which the amino-group is attached is supposed to be directly joined to the potentially aldehydic carbon in the next molecule.

E. F. A.

Application of the Bio-chemical Method to Gentiana acaulis, L. Isolation of a New Glucoside; Gentiacaulin. MARC BRIDEL (*J. Pharm. Chim.*, 1913, [vii], **8**, 241—250).—Investigation of a purified alcoholic extract of *Gentiana acaulis* showed that it contained products hydrolysable by both invertase and emulsin, and in addition a new glucoside, which is not attacked by emulsin, which was isolated and characterised. No gentiopicrin was present.

The new glucoside, *gentiacaulin*, $C_{47}H_{60}O_{29}$, crystallises from hot alcoholic extracts of the plant in transparent, golden-yellow needles, has no definite melting point, but decomposes from 145° to 160°, and is lævorotatory, $[a]_D - 63.84°$ in water. It is precipitated by lead subacetate solution, gives an unstable green coloration with ferric chloride, and reduces Fehling's solution on boiling. It is hydrolysed by boiling dilute sulphuric acid, yielding xylose and *gentiacaulein*, m. p. 177°, crystallising in bright yellow needles, soluble in alcohol or ether, and dissolving in alkalis to give solutions which rapidly become dark brown on exposure to air. T. A. H.

Gitonin, a New Digitalis Glucoside. ADOLF WINDAUS and A. SCHNECKENBURGER (*Ber.*, 1913, **46**, 2628—2633).—Merck's "digitonin" (compare Kiliani, A., 1911, i, 139) is not an individual substance, but contains another glucoside to which the name gitonin is applied. The solubilities of the two substances in alcohol vary considerably with the strength of the solvent. *Gitonin*, $C_{49}H_{80}O_{23}$, is less soluble in 95% alcohol, but more soluble in 85% alcohol, than digitonin, and was obtained in white, amorphous granules when a solution of 100 grams of crude material in 3 litres of 95% alcohol was left for some weeks. It decomposes at 272°, has $[a]_D^{20} - 50.69°$, and gives a rose-red to wine-red coloration on boiling with concentrated hydrochloric acid. It forms an *additive* compound, $C_{76}H_{126}O_{24}$, with cholesterol, in sparingly soluble, small, slender needles, and a similar *compound*, $C_{79}H_{130}O_{24}$, with stigmasterol (compare digitonin compounds, A., 1909, i, 172).

After hydrolysis with alcoholic hydrochloric acid, water caused the crystallisation of *gitogenin*, $C_{26}H_{42}O_4$, which was obtained pure after many recrystallisations, in the form of white, narrow leaflets, m. p. 271—272°. It is indifferent towards hydroxylamine, but forms a *diacetyl* derivative, long needles, m. p. 243—244°, a *dipropionyl* derivative, long, narrow leaflets, 195—196°, and yields on oxidation with chromic acid, a dibasic *acid*, $C_{26}H_{40}O_6$, m. p. 242—243°, the *methyl* ester of which crystallises in leaflets, m. p. 145—146°. The sugar syrup did not readily crystallise, although it contained much galactose. The presence, in addition, of 21% of pentoses agrees with the equation : $C_{49}H_{80}O_{23} + 4H_2O = C_{26}H_{42}O_4 + 3C_6H_{12}O_6 + C_5H_{10}O_5$.
J. C. W.

Mustard Oil Glucosides. II. **Glucocheirolin.** WILHELM SCHNEIDER and LUDWIG A. SCHÜTZ (*Ber.*, 1913, **46**, 2634—2640. Compare A., 1912, i, 1007).—The isolation of the glucoside, glucocheirolin, from wallflower seeds is described. The crude substance was obtained from the dry, fat-free seeds by extraction with several large portions of alcohol which had been dried over sodium. The different fractions contained products in which the proportion, K : S : N, varied, but approached more and more to the expected value 1 : 3 : 1. The very hygroscopic glucoside was then dissolved in water, clarified by shaking with litharge, then quickly treated with lead acetate, and filtered. After precipitating the dissolved lead and exactly neutralising, the solution was concentrated in a vacuum and stirred into absolute alcohol. The precipitate

was then recrystallised a few times from much 90% alcohol, and finally obtained in small, colourless needles, m. p. 158—160°.

Glucocheirolin, $C_{11}H_{20}O_{11}NS_2K,H_2O$, only parts with water after some days in a hot exhausted desiccator over phosphoric oxide. It is tasteless, has $[a]_D^{27}$ — 21·56° to — 21·09°, and gives up one molecule of sulphuric acid on boiling with acidified barium chloride. When silver nitrate is added to the dilute solution, the cheirolin silver sulphate separates after a time as a jelly, in which crystal-centres slowly appear, and finally small, feathery needles, $C_5H_9O_2NS_2,Ag_2SO_4,H_2O$, decomp. 154°, are deposited. The behaviour of glucocheirolin is similar to that of sinigrin and accords with the constitution :

$$SO_2Me \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot N(O \cdot SO_3K) \cdot S \cdot C_6H_{11}O_5.$$
<div align="right">J. C. W.</div>

Derivatives of a- and β-Bromopicrotoxinins. PAUL HORRMANN (*Ber.*, 1913, **46**, 2793—2801).—The author now finds that picrotoxinin really has the old formula, $C_{15}H_{16}O_6$, not $C_{14}H_{16}O_6$ (A., 1912, i, 709).

By treatment with boiling aqueous potassium hydroxide and subsequent acidification, a-bromopicrotoxinin yields an *acid*,

$$C_{15}H_{17}O_7Br,$$
m. p. 248° (decomp.), needles containing H_2O or prisms, $[a]_D^{17\cdot5}$ — 28°51' in alcohol (*c* = 2·889) (*methyl* ester, m. p. 218°, $[a]_D^{17\cdot5}$ — 29°21'; *ethyl* ester, crystals, $[a]_D^{17\cdot5}$ — 31°59'), a boiling alcoholic solution of which is reduced by zinc dust and aqueous ammonium chloride to *a-picrotoxininic acid*, $C_{15}H_{18}O_7$, m. p. 209° (decomp.), $[a]_D^{17\cdot5}$ — 4°53' in alcohol (*c* = 5·981). a-Picrotoxininic acid reacts additively with bromine, reduces alkaline potassium permanganate in the cold and Fehling's solution and ammoniacal silver oxide solution by heating, and neutralises 1 mol. of sodium hydroxide at the ordinary temperature and 2 mols. on the water-bath. It forms a *methyl* ester, m. p. 182°, $[a]_D^{17\cdot5}$ — 9°44' in alcohol (*c* = 1·970), and *ethyl* ester, m. p. 159°, $[a]_D^{17\cdot5}$ — 8°4' (*c* = 4·238) ; its potassium salt reacts with aqueous bromine to form an *acid*, $C_{15}H_{17}O_7Br,H_2O$, m. p. 236° (decomp.), $[a]_D^{17\cdot5}$ — 58°2' in alcohol (*c* = 3·532). By reduction with palladous chloride and hydrogen at 2 atmospheres, a-picrotoxininic acid yields *a-dihydropicrotoxininic acid*, $C_{15}H_{20}O_7$, m. p. 232° (decomp.), $[a]_D^{17\cdot5}$ — 4°10' in alcohol (*c* = 2·006), which is also a lactonic acid, since it neutralises one mol. of alkali in the cold and 2 mol. on the water-bath. By boiling with 2N-sulphuric acid, a-picrotoxininic acid is converted into an isomeride, *β-picrotoxininic acid*, $C_{15}H_{18}O_7$, m. p. 235° (decomp.), $[a]_D^{17\cdot5}$ — 48° in alcohol (*c* = 9·254) (*methyl* ester, m. p. 204°, $[a]_D^{17\cdot5}$ — 50°3' in alcohol [*c* = 1·049]; *ethyl* ester, m. p. 198°, $[a]_D^{17\cdot5}$ — 49°57' in alcohol [*c* = 2·436]), which is stable to aqueous bromine, does not reduce Fehling's solution or ammoniacal silver oxide solution, and neutralises only 1 mol. of alkali on the water-bath.
<div align="right">C. S.</div>

Chlorophyll. XXII. Degradation of the two Components of Chlorophyll by Alkalis. RICHARD WILLSTÄTTER, MAX FISCHER, and LENNART FORSÉN (*Annalen*, 1913, **400**, 147—181. Compare A., 1908, i, 198 ; 1910, i, 126 ; 1911, i, 392).—The monocarboxylic acids,

phyllophyllin and pyrrophyllin, obtained as the final products of the action of alcoholic potassium hydroxide on chlorophyll, are produced, not one from each component of the chlorophyll as might be expected, but both from each component. An explanation of this is to be found in Willstätter and Utzinger's lactam theory of the brown phase (A., 1911, i, 392). The first action of the alkali on, for example, chlorophyll-*a*, indicated in the colour phase, is rupture of the lactam group and its closure in another direction, yielding chlorophyllin-*a* (lactam group, ·CO·NH·, closed and the *a*- and β-carboxyl groups free) and *iso*chlorophyllin $\overset{\gamma}{a}$ (lactam group, ·CO·NH·, closed and β- and γ-carboxyl groups free); in the subsequent changes caused by the alkali, the lactam groups disappear and the β-carboxyl group is destroyed, so that the difference between phyllophyllin and pyrrophyllin is due probably to the different positions of the carboxyl groups *a* and γ.

Rapid hydrolysis of chlorophyll by hot alkalis yields mainly *iso*chlorophyllins *a* and *b* (from which phytochlorin-*e* and phytorhodin-*g* respectively are obtained by eliminating the magnesium by acids) ; in the cold, the chief products are chlorophyllin-*a* and -*b*, from which phytochlorin-*g* and the feebly basic phytorhodins-*k* and -*i* are respectively obtained by the action of acids. In the *a* series, every change shown in the diagram has been accomplished.

Chlorophyll-*a*

—Phytochlorin-*g* ← Chlorophyllin-*a*	*iso*Chlorophyllin-*a* → Phytochlorin-*e* —
Glaucoporphyrin ← Glaucophyllin	Cyanophyllin → Cyanoporphyrin
Rhodoporphyrin ← Rhodophyllin	Erythrophyllin → Erythroporphyrin
→ Pyrroporphyrin ← Pyrrophyllin	Phyllophyllin → Phylloporphyrin ←

The degradation of chlorophyll-*b* is more difficult, because the second oxygen atom must be reduced without any elimination of carbon dioxide occurring; this has been effected by means of concentrated methyl-alcoholic potassium hydroxide in the presence of pyridine, whereby even the very unstable phytorhodin-*g* has been degraded to phylloporphyrin.

Chlorophyll-*b*

Phytorhodin-*k* and -*i* ← Chlorophyllin-*b*	*iso*Chlorophyllin-*b* → Phytorhodin-*g*—
	Rubiphyllin → Rubiporphyrin
Pyrroporphyrin ← Pyrrophyllin	Phyllophyllin → Phylloporphyrin ←

The differentiation and identification of the preceding porphyrins have been effected by the partition method (between hydrochloric acid and ether).

Potassium iso*chlorophyllin*-a, $C_{34}H_{31}O_6N_4MgK_3$, a dark blue powder with a pale green streak, is obtained by boiling gently methylchlorophyllide-*a* with concentrated methyl-alcoholic potassium hydroxide for five minutes and, after further suitable treatment of the solution and dilution with water, adding potassium chloride. Its solutions, in contrast to those of chlorophyllin-*a*, are intensely fluorescent. By heating with pyridine (3 parts) and methyl-alcoholic potassium hydroxide (10 parts) at 150—155° in a silver autoclave for four or five hours, it yields the easily soluble *potassium* salt of the very unstable *cyanophyllin*, $C_{33}H_{34}O_4N_4Mg$. Cyanophyllin is a weaker acid than the isomeric glaucophyllin and is not extracted from ether by 0·003% aqueous ammonia. Its solutions are splendidly blue and intensely fluorescent. By treatment with strong hydrochloric acid it is converted into *cyanoporphyrin*, $C_{33}H_{36}O_4N_4$, reddish-brown needles.

Erythrophyllin, $C_{33}H_{34}O_4N_4Mg$, is prepared from chlorophyll-*a* by boiling with pyridine and methyl alcoholic potassium hydroxide and, after the hydrolysis, heating the alkaline mass in an autoclave at exactly 175—180°; the *potassium* salt, obtained by diluting with water, is then decomposed by sodium dihydrogen phosphate. Erythrophyllin crystallises in pointed rhombic plates, forms a *dimethyl* ester, $C_{35}H_{38}O_4N_4Mg$, long, red prisms, and has weaker acidic properties than rhodophyllin. It is converted into phyllophyllin by methyl-alcoholic potassium hydroxide at 200—210°. Mixtures of cyanophyllin, erythrophyllin, and phyllophyllin can be separated by treating the ethereal solution with 0·2% disodium hydrogen phosphate which extracts the strongest acid, cyanophyllin; somewhat concentrated disodium hydrogen phosphate or not too dilute aqueous ammonia then removes erythrophyllin, the phyllophyllin remaining in the ethereal solution.

Erythroporphyrin, $C_{33}H_{36}O_4N_4$, red, silky prisms, obtained by treating erythrophyllin with concentrated hydrochloric acid and a little ether, forms a *hydrochloride*, pale red needles (insoluble in dilute hydrochloric acid), and a *dimethyl* ester, $C_{35}H_{40}O_4N_4$, brown or reddish-brown prisms, the *hydrochloride* of which is easily soluble in hydrochloric acid.

Di- and mono-basic phyllins derived from the *b* component of chlorophyll are most readily obtained from methylchlorophyllide-*b*. This substance, dissolved in pyridine, is completely hydrolysed by gentle boiling for five minutes with methyl-alcoholic potassium hydroxide, and the blood-red, fluorescent, alkaline solution is heated at 150—155° (whereby an unstable *phyllin* is obtained, the solution of which in ether is green and in alcoholic alkali blue and fluorescent), and finally at 165—170° after dilution with more alcoholic potassium hydroxide. The product is now the *potassium* salt, bluish-violet crystals, of rubiphyllin, from which *rubiphyllin*, $C_{33}H_{34}O_4N_4Mg$, is obtained by treatment with sodium dihydrogen phosphate. Rubiphyllin, which is more easily obtained by hydrolysing methylphæophorbide-*b* or phytorhodin-*g* with methyl-alcoholic potassium hydroxide and heating the resulting solution with magnesium oxide at 170°, crystallises usually in triangular leaflets; its crystalline powder is bluish-black. Rubiphyllin, unlike erythrophyllin and rhodophyllin, is not extracted

from its ethereal solution by 0·5% disodium hydrogen phosphate, but is at once removed by a 1% solution; the *dipotassium* salt,

$$C_{33}H_{32}O_4N_4MgK_2,$$

is a violet powder, which reacts with methyl sulphate to form *rubiphyllin dimethyl* ester, $C_{35}H_{38}O_4N_4Mg$, olive-brown prisms. *Rubiporphyrin*, $C_{33}H_{36}O_4N_4$, obtained by dissolving the preceding potassium salt in 20% hydrochloric acid, crystallises in rhombic leaflets which are olive-brown, in transmitted light, and forms a *hydrochloride*, olive-brown prisms, and *dimethyl* ester, $C_{35}H_{40}O_4N_4$, violet prisms.

By heating with methyl-alcoholic potassium hydroxide above 170°, rubiphyllin is converted into phyllophyllin, which is identified as the characteristic calcium salt.

By hydrolysing a pyridine solution of methylchlorophyllide-*b* with methyl-alcoholic potassium hydroxide in the cold, chlorophyllin-*b* is obtained, but always accompanied with *iso*chlorophyllin-*b*; consequently, the degradation products of the former are always contaminated with the phyllins of the *iso*-series, the final products at 205—210° being pyrrophyllin and phyllophyllin. Pure pyrrophyllin can be obtained by hydrolysing methylphæophorbide-*b* by methyl-alcoholic potassium hydroxide in the cold, and heating the resulting alkaline solution with magnesium oxide in a silver autoclave; up to 200°, several still unknown phyllins are formed, but after heating for five hours at 220°, the product is pyrrophyllin, which is identified by conversion into pyrroporphyrin. The latter is obtained directly when phytorhodins-*i* and -*k* are heated at 205—210° with methyl-alcoholic potassium hydroxide alone.

Phytorhodins-i and -k, the latter usually predominating, are obtained together by several methods; the hydrochloric acid number of *k* is 14—14·5, of *i* 15—16, so that their separation requires very careful fractionation with 14% hydrochloric acid. The best method of preparing them is as follows. Chlorophyll (from stinging-nettle leaves) is kept in petroleum for a few weeks until allomerisation is complete. The solution is shaken with concentrated methyl-alcoholic potassium hydroxide until the hydrolysis of the chlorophyll is complete, and then with hydrochloric acid to remove the magnesium. The products are dissolved in ether, the more basic constituents are removed by repeated extraction with 13% hydrochloric acid, and finally the brown ethereal solution is treated with 14—14·5% hydrochloric acid to remove phytorhodin-*k*, and with 17% hydrochloric acid to separate phytorhodin-*i*; the substances require still further purification.

Phytorhodin-k, $C_{34}H_{84}O_6N_4$, black, metallic leaflets, and *phytorhodin*-i, $C_{34}H_{84}O_6N_4$, black, metallic leaflets, resemble one another in their solubilities, but give different colour reactions with potassium hydroxide, cæsium hydroxide, formic acid, and concentrated nitric acid.

By the term "hydrochloric acid" number of a chlorophyll derivative, the author denotes the percentage strength of the hydrochloric acid which is required to extract about 2/3 of the solute from the solution of the derivative in a volume of ether equal to that of the hydrochloric acid. A more rigidly defined number, however, is required for the differentiation of substances which have very nearly equal basicities. This is found in the "partition" number, which

represents the percentage amount of a substance extracted under definite conditions from ethereal solution by hydrochloric acid of a definite strength; the conditions are, 3 milligrams of substance, 1 litre of ether, and 100 c.c. of hydrochloric acid, the extraction lasting one minute. The concentration of the acid is either that denoted by the hydrochloric acid number, or, in the comparison of substances of different basicity, any other concentration suitable for the extraction.

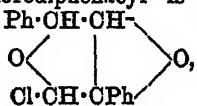
The value of the partition number is illustrated by the comparison of phylloporphyrin and pyrroporphyrin; both have hydrochloric acid number 0·5, but the partition number of the former is about 35 and of the latter about 4.   C. S.

Chlorophyll. XXIII. Parent Substances of the Phyllins and Porphyrins. RICHARD WILLSTÄTTER and MAX FISCHER (*Annalen*, 1913, 400, 182—194).—Since the degradation of hæmin and of chlorophyll yields similar, but not identical, porphyrins, which, however, give identical products by oxidation (A., 1910, i, 499) and by reduction (A., 1912, i, 41), and since the dissimilarity of the porphyrins is possibly conditioned by differences in the position of the carboxyl groups, the elimination of the latter becomes a matter of prime importance. This has been accomplished with the phyllins and porphyrins derived from chlorophyll. The decarboxylation of chlorophyll derivatives by heating with methyl-alcoholic potassium hydroxide in a sealed tube proceeds only as far as the monocarboxylic acid, decomposition then beginning at 250° with the formation of hæmopyrrole and amorphous, brown products. Complete removal of carbon dioxide from the carboxyl groups, however, is effected by heating rapidly and carefully with soda-lime; the yields are small because the product decomposes at temperatures below the temperature of formation. Potassium rhodophyllin is mixed with soda-lime (free from iron), and is heated in small quantities rapidly and carefully by a naked flame until the colour changes suddenly from pale grey to brown. The mass is rapidly cooled, moistened with water, and extracted with warm ether. The ethereal solution is well washed with potassium hydroxide and with 5% hydrochloric acid. After washing finally with dilute ammonia and concentrating the ethereal solution, a *substance*, $C_{31}H_{34}N_4Mg$, m. p. about 205°, bluish-violet crystals, is obtained, which is called *aetiophyllin*, and is the parent of the phyllins. Aetiophyllin forms violet-red, intensely fluorescent solutions, and in ether is remarkably stable to 4—7% hydrochloric acid ; in petroleum, however, even 0·05% hydrochloric acid changes the colour of the solution to that of aetioporphyrin.

Porphyrins lose carbon dioxide much less readily than phyllins, so that the best method of preparing aetioporphyrin, the parent of the porphyrins, is by treating an ethereal solution of aetiophyllin with 20% hydrochloric acid, whereby the magnesium is at once replaced by hydrogen. *Aetioporphyrin*, $C_{31}H_{36}N_4$, m. p. about 280°, hydrochloric acid number 3, partition number for 3% hydrochloric acid 40 (compare preceding abstract), is obtained in violet, crystalline crusts, and forms a *styphnate*, $C_{31}H_{36}N_4,C_6H_3O_8N_3$. m. p. 170°, red prisms, by which it is best purified. It also forms a *hydrochloride*, olive-brown needles,

picrate, red prisms, *aurichloride* and *platinichloride*, and yields characteristic complex compounds with salts of the heavy metals.

Phylloporphyrin, pyrroporphyrin, and rhodoporphyrin when heated with soda-lime each yields aetioporphyrin, thus confirming Willstätter's theory that the two former are different because of the difference in the position of the carboxyl group.

Aetiophyllin can be obtained from aetioporphyrin by treating a concentrated ethereal solution of the latter with magnesium methyl iodide (Willstätter and Forsén, this vol., i, 499), and subsequently with sodium dihydrogen phosphate.


The absorption spectrum of aetiophyllin is very similar to that of pyrrophyllin, and that of aetioporphyrin to that of pyrroporphyrin, but contains much stronger bands.　　　　　　　　　　　　　C. S.

The Quantitative Dyeing of Silk with Basic Dyes. H. SALVATERRA (*J. pr. Chem.*, 1913, [ii], **88**, 502—504. Compare this vol., ii, 258).—Quantitative experiments on the dyeing of silk with a number of magenta-dyes show that the amount of these dyes taken up by the silk is proportional to their molecular weights, and thus supports the view that the dyeing of silk is a chemical process analogous to salt-formation.　　　　　　　　　　　　　　　　　F. B.

Constitution of the So-called α- and β-Halogendiphenacyls. OSKAR WIDMAN [with G. KARL ALMSTRÖM] (*Annalen*, 1913, **400**, 86—130).—The constitutions previously ascribed to the α- and β-halogendiphenacyls (A., 1909, i, 822) are withdrawn and are to be replaced by the following: α-chlorodiphenacyl is cis-2-*chloro*-3 : 4-

$$\begin{array}{c} \text{Ph·CH·CH–} \\ oxido\text{-}3:5\text{-}diphenyltetrahydrofuran, \quad \text{O} \diagdown \quad | \quad \diagup \text{O, and } \beta\text{-chloro-} \\ \text{Cl·CH·CPh} \end{array}$$

diphenylacyl is the corresponding trans-*isomeride*,

$$\begin{array}{c} \text{Ph·CH–CH–} \\ \text{O} \diagdown \quad | \quad \diagup \text{O} \\ \text{H·CCl·C·Ph} \end{array}$$
The evidence on which these constitutions are based is given below the most important proofs being furnished by the reactions of the α- and β-halogendiphenacyls with aniline and with hydrazine hydrate.

Paal and Demeler's statements, that only α-bromodiphenacyl results from the interaction of alcoholic sodium ethoxide and ω-bromoacetophenone and that the α-compound is changed to the β-isomeride by boiling alcohol, are incorrect. The authors show that α-chloro(or bromo-)-diphenacyl is unchanged by boiling alcohol, but that in the presence of sodium chloride and a little sodium hydroxide, it is converted almost quantitatively into the β-isomeride in twenty-four to forty-eight hours at the ordinary temperature. In the preparation of the halogendiphenacyls, therefore, both isomerides are formed, the amount of the β-compound being greater the longer the substances are kept in contact with the alcoholic, alkaline mother liquor. Since β-halogendiphenacyl can be converted indirectly into the α-compound (*loc. cit.*), the two compounds are most probably stereoisomeric.

β-Chlorodiphenacyl (*trans*-2-chloro-3 : 4-oxido 3 : 5-diphenyltetrahydrofuran) has m. p. 147—148°, not 154—155°, as stated in the literature.

The course of the reaction whereby ω-halogenacetophenones and alcoholic sodium ethoxide yield oxido-tetrahydrofurans is, in its first stage, probably analogous to those described by Darzens (A., 1905, i, 116) and by Claisen (A., 1905, i, 286), in which ketones or aldehydes condense with esters of halogenated fatty acids in the presence of sodium ethoxide or of sodamide to form esters of substituted glycidic acids : $2CH_2Cl \cdot COPh + NaOH = O{<}^{CH \cdot COPh}_{CPh \cdot CH_2Cl} + NaCl + H_2O$. The intermediate product then does not yield a four-membered ring by loss of hydrogen chloride, but is converted into a furan derivative, $O{<}^{CH-CHPh}_{CPh \cdot CHCl}{>}O$. The two suppositions in this explanation are supported by experimental evidence. With regard to the formation of the oxido-group, the authors find that ω-chloro- or bromo-acetophenone and benzaldehyde in the presence of alcoholic sodium ethoxide, in accordance with Darzen's statement that esters of halogenated fatty acids condense preferentially with aldehydes rather than with ketones, yield not a trace of a furan derivative, but a *substance*, m. p. 89—90°, which proves to be *α-benzoyl-β-phenylethylene oxide*, $O{<}^{CHPh}_{CH \cdot COPh}$.

The second supposition, that a ketone containing a halogen atom in the γ-position to the carbonyl group is capable of yielding a furan derivative, is supported by the behaviour of a substance described by Perkin (T., 1885, 47, 842) as phenyl ω-bromopropyl ketone; this substance, however, does not exhibit the properties of a ketone, and is most probably 2-bromo-5-phenyltetrahydrofuran.

By heating with a large excess of 99% hydrazine hydrate, α-chlorodiphenacyl (*cis*-2-chloro-3 : 4-oxido-3 : 5-diphenyltetrahydrofuran) is converted into a *substance*, $C_{16}H_{12}N_2$, m. p. 139—140°, faintly yellow, rhombic plates, which proves to be 3 : 5-diphenylpyridazine (Almström, this vol., i, 1240).

By treatment with boiling aniline, α-chlorodiphenacyl yields a *substance* (I.), $C_{22}H_{16}NCl$, m. p. 146—147°, faintly yellow plates, whilst β-chlorodiphenacyl (*trans*-2-chloro-3 : 4-oxido-3 : 5-diphenyltetrahydrofuran) yields a *substance* (II.), $C_{22}H_{17}ON$, m. p. 150°, citron-yellow needles, which forms yellow solutions with bluish-green fluorescence. The constitutions of the substances I. and II. were elucidated after the discovery (compare Almström, *loc. cit.*) that 1 : 3 : 5-triphenylpyrrol-2-one (which is isomeric with II.) is converted by phosphorus trichloride into 2-chloro-1 : 3 : 5-triphenylpyrrole (which is isomeric with I.), and by phosphorus pentachloride into 2 : 4-dichloro-1 : 3 : 5-triphenylpyrrole. Since the last substance is also formed by the action of phosphoric and phosphoryl chlorides on I., it follows that I. must be *4-chloro-1 : 3 : 5-triphenylpyrrole*. Substance II. is then easily proved to be *4-hydroxy-1 : 3 : 5-triphenylpyrrole*, since it forms an *acetyl* derivative, m. p. 132—133°, colourless needles, by treatment with aqueous sodium hydroxide and acetyl chloride in acetone at 0°, and is converted into I. (4-chloro-1 : 3 : 5-triphenylpyrrole) by phosphorus trichloride at 170—190°.

By treatment with warm acetic anhydride and a little concentrated sulphuric acid, 4-hydroxy-1:3:5-triphenylpyrrole or its acetyl derivative yields 4-*acetoxy*-2-*acetyl*-1:3:5-*triphenylpyrrole*,

$$\begin{matrix} OAc \cdot C \!\!-\!\!-\!\! CPh \\ \quad\;\;|| \qquad\qquad \rangle C \cdot COMe, \\ CPh \cdot NPh \end{matrix}$$
m. p. 189—190°, colourless needles, from which 4-*hydroxy*-2-*acetyl*-1:3:5-*triphenylpyrrole*, m. p. 180—181°, is obtained by hydrolysis with alcoholic sodium ethoxide.

4-Chloro-1:3:5-triphenylpyrrole is a very stable substance, and is not attacked by sodium amalgam, boiling alcoholic sodium ethoxide, nitrous acid, or boiling alkaline potassium permanganate. By treatment with boiling acetic anhydride and concentrated sulphuric acid, it yields 4-*chloro*-2-*acetyl*-1:3:5-*triphenylpyrrole*, $C_{24}H_{18}ONCl$, m. p. 136° (*semicarbazone*, m. p. about 236° [decomp.]), which reacts with benzaldehyde (1 mol.), 10% sodium hydroxide, and alcohol at the b. p. to form 4-*chloro*-2-*cinnamoyl*-1:3:5-*triphenylpyrrole*, $C_{31}H_{22}ONCl$, m. p. 197°, stout, yellow needles. By reduction with hydriodic acid, D 1·22, and amorphous phosphorus at 160°, 4-chloro-1:3:5-triphenylpyrrole yields 1:3:5-triphenylpyrrole, m. p. 150—151°, which reacts with boiling acetic anhydride and concentrated sulphuric acid to form 2(?)-*acetyl*-1:3:5-*triphenylpyrrole*, $C_{24}H_{19}ON$, m. p. 165—166°.

By treatment with methylaniline at 130—140°, α- and β chlorodiphenacyls yield, not pyrrole derivatives, but phenacylmethylaniline.

Now that the α- and β-halogendiphenacyls have been proved to be *cis*- and *trans*-2-halogen-3:4-oxido-3:5-diphenyltetrahydrofuran respectively, the nature of their additive compounds with halogen hydrides and acyl haloids (Paal and Stern, A., 1901, i, 154; Paal and Schulze, A., 1902, i, 229) is readily understood, and some inaccuracies in the statements of these investigators are easily detected. *trans*-2-Chloro-3:4-oxido-3:5-diphenyltetrahydrofuran and hydrogen chloride, best in warm glacial acetic acid, yield 2:3-*dichloro*-4-*hydroxy*-3:5-*diphenyltetrahydrofuran*, $O {\Large\langle}{\begin{matrix} CHPh \cdot CH \cdot OH \\ CHCl \cdot CPhCl \end{matrix}}$, m. p. 164° (decomp.), which is converted into 4-hydroxy-1:3:5-triphenylpyrrole and 4-*hydroxy*-3:5-*diphenyl*-1-*p-tolylpyrrole*, m. p. 152°, citron-yellow plates, by aniline and *p*-toluidine respectively on the water-bath. In a similar manner, *trans*-2-chloro-3:4-oxido-3:5-diphenyltetrahydrofuran and 12% hydrogen bromide in glacial acetic acid at about 30° yield 2-*chloro*-3-*bromo*-4-*hydroxy*-3:5-*diphenyltetrahydrofuran*, m. p. 155° (decomp.). The substance is given this constitution, not that of the 4-bromo-3-hydroxy-isomeride, because it loses only hydrogen bromide, not both hydrogen chloride and bromide by treatment with alcoholic sodium ethoxide. Contrary to the statement of Paal and his collaborators (*loc. cit.*), the substance, being a bromohydrin, obviously contains a hydroxyl group; the acetyl derivative, m. p. 89—90°, is obtained by the action of acetic anhydride and two drops of concentrated sulphuric acid. This acetyl derivative is identical with the additive compound (2-chloro-3-bromo-4-acetoxy-3:5-diphenyltetrahydrofuran) of β-chlorodiphenacyl and acetyl bromide described by Paal and his co-workers (*loc. cit.*). In a similar manner, the additive compound of β-bromodiphenacyl and hydrogen chloride (*trans*-3-chloro-2-bromo-4-hydroxy-

3 : 5-diphenyltetrahydrofuran) yields an acetyl derivative, m. p.
89—90°, identical with the additive compound of β-bromodiphenacyl
and acetyl chloride. Knowing the constitutions of β-chloro- and
bromo-diphenacyls, the author is able to assert that the two preceding
acetyl derivatives, in spite of their similarities in appearance and
m. p., are not identical, as stated by Paal (*loc. cit.*). The assertion is
proved, not only by a comparison of the corresponding propionyl and
valeryl derivatives which differ in m. p. (see below), but also by the
fact that by treatment with alcoholic sodium ethoxide, *trans*-3-chloro-2-
bromo-4-acetoxy-3 : 5-diphenyltetrahydrofuran (that is, the additive
compound of β-bromodiphenacyl and acetyl chloride) yields *trans*-3-
chloro-2-bromo-4-hydroxy-3 : 5-diphenyltetrahydrofuran, whilst *trans*-2-
chloro-3-bromo-4-acetoxy-3 : 5-diphenyltetrahydrofuran (the additive
compound of β-chlorodiphenacyl and acetyl bromide) is more exten-
sively changed and yields *cis*-2-chloro-3 : 4-oxido-3 : 5-diphenyltetra-
hydrofuran (α-chlorodiphenacyl). In a similar manner, *trans*-2 : 3-
dichloro-4-acetoxy-3 : 5-diphenyltetrahydrofuran, prepared by the addi-
tion of acetyl chloride to β-chlorodiphenacyl or by treating *trans*-2 : 3-
dichloro-4-hydroxy-3 : 5-diphenyltetrahydrofuran with acetic anhydride
and concentrated sulphuric acid, is converted by alcoholic sodium
ethoxide into *trans*-2 : 3-dichloro-4-hydroxy-3 : 5-diphenyltetrahydro-
furan or *trans*-2-chloro-3 : 4-oxido-3 : 5-diphenyltetrahydrofuran, accord-
ing as 1 or 2 molecules of the ethoxide are used.

trans-3-Chloro-2-bromo-4-hydroxy-3 : 5-diphenyltetrahydrofuran (the
additive compound of β-bromodiphenacyl and hydrogen chloride) yields
the *propionyl* derivative, $C_{19}H_{18}O_3ClBr$, m. p. 106°, and the *valeryl*
derivative, m. p. 104—105°, by treatment with propionic anhydride
and valeric anhydride respectively in the presence of a little con-
centrated sulphuric acid. By similar treatment, *trans*-2-chloro-3-bromo-
4-hydroxy-3 : 5-diphenyltetrahydrofuran (the additive compound of
β-chlorodiphenacyl and hydrogen bromide) yields a *propionyl* derivative,
m. p. 69°, and *valeryl* derivative, m. p. 93°.

As stated by Paal and Schulze (*loc. cit.*), *cis*-2-halogen-3 : 4-oxido-
3 : 5-diphenyltetrahydrofurans (α-halogendiphenacyls) do not react with
halogen hydrides to form additive compounds (*cis*-2 : 3-dihalogen-
4-hydroxy-3 : 5-diphenyltetrahydrofurans) ; moreover, these substances
cannot be prepared by the action of sodium ethoxide on the *cis*-
2 : 3-dihalogen-4-acetoxy-3 : 5-diphenyltetrahydrofurans (additive com-
pounds of α-halogendiphenacyls and acetyl chloride).

Bromodeoxybenzoin, $CHBrPh\cdot COPh$, and bromopropiophenone,
$CHBrMe\cdot COPh$, by treatment with cold alcoholic sodium ethoxide
do not yield analogues of the α- and β-bromophenacyls ; the former is
converted into the benzoin, m. p. 131°, and the latter into an oily
substance which does not contain bromine.   C. S.

Conversion of Quinatoxines into Quinaketones and the
Reduction of these to the Alkaloids of Cinchona Bark. ADOLF
KAUFMANN and MAX HUBER (*Ber.*, 1913, **46**, 2913—2924). Rabe and
collaborators have shown (A., 1910, i, 417) that of the four asym-
metric carbon atoms in the chief cinchona alkaloids, that numbered 3
(*loc. cit.*) is the principal source of the isomerism among the alkaloids,

and have explained the apparent formation of a single ketone from each pair of isomerides (A., 1909, i, 252) by assuming that the ketone is tautomeric in each case. They have also shown (Abstr., 1911, i, 742) that cinchotoxine can be converted into cinchoninone and the latter reduced to cinchonine (A., 1908, i, 100), but the yield of the latter is very small, and no proof has been given that it is optically identical with natural cinchonine. The authors now show that in the conversion of cinchotoxine into cinchonine by Rabe's method, the reactions may be regarded as taking place (1) symmetrically, when two pairs of mirror-image isomerides will be formed in equal quantities, or (2) asymmetrically, when 4 optical isomerides will be formed in unequal quantities. They have applied this method to hydrocinchotoxine, and although the results are not conclusive, they indicate that it is the asymmetric direction which the reactions take, whence they conclude that hydrocinchoninone is not an equivalent mixture of two mirror-image isomerides.

Hydrocinchotoxine (hydrocinchonicine), prepared by von Miller and Rohde's method from hydrocinchonine, itself obtained by the reduction of cinchonine by von Skita's process, is an oil having $[a]_D^{23} + 8 \cdot 8°$ in dry alcohol; it yields a *benzoyl* derivative, m. p. 121—122°, which crystallises from light petroleum in colourless needles, and is sparingly soluble in ether. On treatment in hydrobromic acid with bromine vapour, hydrocinchotoxine yields *bromohydrocinchotoxine dihydrobromide*,

$$C_{19}H_{23}ON_2Br,2HBr,$$
m. p. 198° (approx.), yellow crystals, readily soluble in water but sparingly so in alcohol, and this with sodium in an alcoholic solution of sodium ethoxide yields hydrocinchoninone, m. p. 130°, which shows mutarotation (compare Rabe, A., 1909, i, 253), and on reduction with palladium black in presence of hydrogen yields dihydrocinchonine (cinchotine), $[a]_D^{21} + 203 \cdot 4°$, as chief product with a smaller amount of dihydrocinchonidine, m. p. 231°, $[a]_D^{21} - 94 \cdot 6°$.

In like manner, hydroquinotoxine (hydroquinicine) was converted into *bromohydroquinotoxine dihydrobromide*,

$CH_3 \cdot CH_2 \cdot CH—CH—CH_2$
 |
 CH_2
 |
 CH_2
 |
$CH_2—NH—CHBr \cdot CO \cdot Q$
$C_{20}H_{25}O_2N_2Br,2HBr,H_2O,$

m. p. 178° (annexed formula, in which $Q = 6$-methoxyquinoline), and this into *hydroquininone*,

$$C_{20}H_{24}O_2N_2,$$
m. p. 98—99°, $[a]_D^{21}$, changing from $+83 \cdot 08°$ after twenty-four hours to $+73 \cdot 29°$ as the final value, which forms a mixture of needles, platelets, and crusts of yellow colour, and yields a *picrate*, m. p. 224°.

T. A. H.

Oxycolchicine. SIMON ZEISEL and A. FRIEDRICH (*Monatsh*, 1913, 34, 1181—1186).—*Oxycolchicine*, $C_{22}H_{23}(or_{25})O_7N$, m. p. 266—268°, obtained by oxidising colchicine with potassium pyrochromate and sulphuric acid, crystallises in faintly yellow, microscopic prisms; it is fairly soluble in hot alcohol and readily so in chloroform. Oxycolchicine gives a green colour passing into brown with sulphuric acid,

and with nitric acid a carmine-red changing to violet and brown. With boiling hydrochloric acid it appears to undergo changes quite similar to those given by colchicine. It is insoluble in cold potassium hydroxide solution, but gradually passes into solution on warming, methyl alcohol and acetic acid being split off. Oxycolchicine also reacts with hydroxylamine, but no definite derivative has been obtained. It is probable that in its formation from colchicine a $>CH_2$ group is converted into $>CO$. Formic and acetic acids were found as by-products of the oxidation. Further work on oxycolchicine will be undertaken by Windaus in continuation of his researches on the parent alkaloid (A., 1911, i, 904).   T. A. H.

Preparation of Alcoholic Methyl Ethers. J. D. RIEDEL (D.R.-P. 261588).—The following methyl ethers have been prepared from the corresponding alcohols in alkaline solution by means of methyl sulphate: benzyl methyl ether, methyl *isoamyl* ether, and borneol methyl ether; whilst the employment of methyl iodide gave rise to *γ-methylmorphimethine methyl ether*, leaflets, m. p. 259°; *δ-methylmorphimethine methyl ether*, needles, m. p. 277°; *methylcodeine methiodide*, glistening, colourless rods, decomp. 263°; *α-dimethylmorphimethine methiodide*, needles, decomp. 263°; *β-dimethylmorphimethine methiodide*, needles, m. p. 320—330°, and *cinnamyl methyl ether*, b. p. 115°/15 mm.   F. M. G. M.

Action of Acetal on Tetrahydropapaverine. AMÉ PICTET and STANISLAS MALINOWSKI (*Ber.*, 1913, 46, 2688—2697. Compare Pictet and Gams, A., 1911, i, 807).—The authors have studied the condensation of acetal with tetrahydropapaverine, in the hope that it would proceed on similar lines to the action of methylal on veratrylnorhydrohydrastinine, and thus yield one of the optically inactive corydalines. This does not appear to be the case. Two isomeric substances, which the authors name α- and β-coralydine, are obtained, which have the same composition as the coryladines, but differ from them in their properties.

When acetal is gradually added to a hot solution of tetrahydropaverine hydrochloride in hydrochloric acid, a mixture of hydrochlorides is obtained, which can be separated by cautious washing with water and subsequent fractional crystallisation from dilute hydrochloric acid.

In this manner, *α-coralydine hydrochloride*, m. p. 254°, and *β-coralydine hydrochloride*, m. p. 228—230°, are obtained.
α-Coralydine (annexed formula), prepared by the addition of sodium carbonate to the above hydrochloride, forms colourless, shining leaflets, m. p. 148°. It gives a green coloration with warm, concentrated sulphuric acid. The following salts have been prepared: *sulphate*, m. p. 210°; *nitrate*, m. p. 242°; *picrate*, pale yellow needles, m. p. 134°; *aurichloride*, red crystals, m. p. 154°; *platinichloride*, yellow crystals, m. p. 246—247°. Attempts to resolve the base by quinic acid in alcohol solution and by

o-bromocamphorsulphonic acid in aqueous or alcoholic solution were unsuccessful.

When warmed with alcohol and iodine, α-coralydine yields *dehydro-coralydine*. The *hydriodide*, golden-yellow needles, m. p. 263°; *hydrochloride*, pale yellow needles, m. p. 230°; *nitrate*, yellow needles, m. p. 277—278°, and *aurichloride*, yellowish-brown needles, m. p. 252° (decomp.), of the base have been prepared. These salts differ greatly from the corresponding salts of dehydrocorydaline, from which the conclusion is drawn that the tetrahydro-derivatives, coralydine and corydaline, are structurally isomeric.

Oxidation of α-coralydine by potassium permanganate has been effected according to the directions of Dobbie and Lander for coryladine (T., 1894, **65**, 57; 1895, **67**, 17). The sole product appears to be *m*-hemipinic acid, which was identified by conversion into its ethylimide (Goldschmidt, A., 1889, 167). The latter consists of colourless needles (instead of pale yellow needles described by Goldschmidt), m. p. 229°.

β-Coralydine crystallises in colourless prisms, m. p. 115°. It gives a colourless solution in cold concentrated sulphuric acid, which becomes green when warmed. Oxidation with alcoholic iodine solution converts it into dehydrocoralydine, the identity of which, with the product obtained in a similar manner from α-coralydine, is established by comparison of the hydrochlorides, hydriodides and nitrates obtained from the two substances. From this it follows that α- and β-coralydines must be stereoïsomerides, and probably are related to one another in the same manner as the two inactive corydalines. H. W.

1. Polymeric Tetramethylenecarbamide. 2. Some Derivatives of Pyrrole. EMIL FISCHER (*Ber.*, 1913, **46**, 2504—2510).— In attempting to prepare ornithin by the combination of tetramethylene-diamine and carbon dioxide, it has been found that the base absorbs carbon dioxide with the formation of a substance which is apparently a carbamate; this, when heated for two days in a sealed tube at 230°, undergoes conversion into a colourless, sparingly soluble compound which commences to decompose at 260°. When heated with lime or in a sealed tube with hydrochloric acid, this substance, which is probably a polymeric form of *tetramethylenecarbamide*,

$$\begin{matrix} CH_2 \cdot CH_2 \cdot NH \\ CH_2 \cdot CH_2 \cdot NH \end{matrix} \!\!> CO,$$
regenerates tetramethylenediamine.

Pyrrole-2 : 5-dicarboxylic acid (Ciamician and Silber, A., 1886, 938) in the form of the sodium salt is easily reduced by sodium amalgam with formation of a *pyrroline-2 : 5-dicarboxylic acid*, colourless prisms or needles, which becomes pink in the air and when heated commences to decompose at 235°.

2 : 5-Diacetyl-1-methylpyrrole, m. p. 133—134° (Ciamician and Silber, A., 1887, 843), is more readily obtained by the action of sodium hydroxide and methyl sulphate on 2 : 5-diacetylpyrrole than by the earlier process starting with 1-methylpyrrole. It can be oxidised by potassium permanganate followed by hydrogen peroxide to *1-methyl-pyrrole-2 : 5-dicarboxylic acid*, needles of no definite m. p.; *silver* salt,

colourless needles. This acid is possibly identical with a substance briefly described earlier (Bell, A., 1879, 525).

Pyrrolealdehyde (Bamberger and Djierdjian, A., 1900, i, 309) can be methylated in alkaline solution by methyl sulphate with production of 1-*methylpyrrole-2-aldehyde*, a colourless oil, b. p. 75—76° (corr.) /12—13 mm., which, unlike the inodorous unsubstituted aldehyde, has an odour resembling benzaldehyde; *phenylhydrazone*, an almost colourless, crystalline powder, m. p. 127—128°(corr.). Oxidation by silver oxide converts the aldehyde into 1-methylpyrrole-2-carboxylic acid, agreeing in m. p. with that described by Bell (*loc. cit.*); *silver* salt, sparingly soluble.   D. F. T.

Condensation of Ethyl Oxalate with Acetylpyrroles. Oskar Piloty and H. Will (*Ber.*, 1913, **46**, 2607—2612).—Acetyl-pyrroles condense with ethyl oxalate with elimination of alcohol, giving rise to coloured compounds which are closely related to the phono-pyrrolecarboxylic acids and, therefore, to the blood pigments. The substances are very easily converted into blue, red or green dyes.

3-Acetyl-2 : 4-dimethylpyrrole was condensed with ethyl oxalate in presence of sodium ethoxide, and the product, after evaporating the solvent in vacuum, was acidified with acetic acid, when *ethyl 2 : 4-dimethylpyrryl-3-ethanoneoxalate*, $NH < \begin{matrix} CH=CMe \\ CMe \cdot C \cdot CO \cdot CH_2 \cdot CO \cdot CO_2Et \end{matrix}$ was precipitated. The ester crystallises in lemon-yellow leaflets, m. p. 179·5°, forms a *phenylhydrazone*, $C_{18}H_{21}O_5N_3$, pale yellow, slender needles, m. p. 189°, and yields the *hydrazide* of a *ketazine*, $C_{10}H_{13}ON_5$, in thin, glistening, colourless leaflets, m. p. 235°, when mixed with hydrazine hydrate. When left with 2·5% potassium hydroxide, the ester is hydrolysed to 2 : 4-*dimethylpyrryl-3-ethanoneoxalic acid*,

$$C_{10}H_{11}O_4N,$$
which forms short, golden-yellow, prismatic crystals, decomp. 174°. The ester also dissolves in hot concentrated hydrochloric acid, giving a dark blue solution from which water precipitates the dye in greenish-black masses. On boiling the acid solution for some time, however, the dye separates as an indigo-blue powder. It gives a deep red solution in alkalis.

4-Acetyl-2 : 3-dimethylpyrrole (this vol., i, 196) was also condensed with ethyl oxalate, giving a dark red powder which is insoluble in ether, and also *ethyl 2 : 3-dimethylpyrryl-4-ethanoneoxalate*,

$$NH < \begin{matrix} CMe:CMe \\ CH=C \cdot CO \cdot CH_2 \cdot CO \cdot CO_2Et. \end{matrix}$$
The latter crystallises in long, spindle-like prisms, m. p. 180°, and yields a dark red dye on boiling with concentrated hydrochloric acid.
                                    J. C. W.

Electrolytic Oxidation of Cyclic Ammonium Bases. Otto Fischer and K. Neundlinger (*Ber.*, 1913, **46**, 2544—2546).—The authors required a convenient method of preparation for 1-methyl-2-pyridone from which a ready passage through the corresponding 2-chloro-compound to the 2-amino-compound is available.

The aim is achieved by electrolytic oxidation of 1-methylpyridinium sulphate between iron electrodes with a catholyte and anolyte of sodium hydroxide solution, the latter (D approx. 1·17) containing also some potassium ferricyanide as catalyst (compare Decker and Kaufmann, A., 1911, i, 1023). The yield of 1-methylpyridone (*picrate*, needles, m. p. 145°) is good, both from the point of view of the substance oxidised and the current passed.

By a similar process, 1-methylquinolinium sulphate can be almost quantitatively converted into 1-methyl-2-quinolone.　　D. F. T.

Condensation of Unsaturated Aldehydes with Ammonia and Ethyl Acetoacetate.. II. E. GRISCHKEVITSCH-TROCHIMOVSKI and (Mlle.) I. PAVLOVSKAJA (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 935—946. Compare A., 1911, i, 320).—Ethyl 2 : 6-dimethyl-4-allyldihydropyridine-3 : 5-dicarboxylate, which exhibits the normal molecular weight in freezing benzene or boiling ether, is converted by oxidation with nitrogen trioxide into *ethyl 2 : 6-dimethyl-4-allylpyridine-3 : 5-dicarboxylate*, $C_{16}H_{21}O_4N$, a yellow liquid, b. p. 208·2°/21 mm., $D_4^{16·5}$ 1·0762, $n_D^{16·5}$ 1·5065 ; the corresponding *nitrate*, $C_{16}H_{21}O_4N,HNO_3$, m. p. 85·5°, and the *hydriodide*, $C_{16}H_{21}O_4N,HI$, m. p. 137—140° (decomp.), were prepared (see also *loc. cit.*). The free acid, 2 : 6-*dimethyl-4-allyl-pyridine*-3 : 5-*dicarboxylic acid*, $N{<}{CMe \cdot C(CO_2H) \atop CMe : C(CO_2H)}{>}C \cdot CH : CHMe$, decomposes at about 205° ; its *silver* salt, *hydrochloride*, m. p. about 220° (decomp.), and *platinichloride*, m. p. about 225° (decomp.), were prepared and analysed.

In order to explain the mechanism of the formation of 2 : 4 : 6-trimethylpyridine by the dry distillation of potassium 2 : 6-dimethyl-4-allylpyridine-3 : 5-dicarboxylate (*loc. cit.*), experiments are being made on the condensation of acraldehyde with ethyl acetoacetate and ammonia, which yields ethyl 2 : 6-*dimethyl-4-vinyldihydropyridine-3 : 5-dicarboxylate*, $NH{<}{CMe : C(CO_2Et) \atop CMe : C(CO_2Et)}{>}CH \cdot CH : CH_2$, crystallising in needles, m. p. 86—87°.　　T. H. P.

The Action of 2-Methylindole on Formic Acid. MAX SCHOLTZ (*Ber.*, 1913, **46**, 2539—2542).—Mainly polemical in favour of the views of the author (this vol., i, 895) and König (A., 1911, i, 809) as opposed to those of Ellinger and Flamand (A., 1911, i, 329) concerning the formula of the product of the interaction of 2-methylindole and formic acid.

The *nitrate* of the substance in question has now been prepared in a similar manner to the method recently described (Scholtz, *loc. cit.*) ; it forms ruby-red octahedra, decomp. above 220°, the composition agreeing with the formula $C_{19}H_{16}N_2,HNO_3$, or with the less probable $(C_{28}H_{28}N_3)_2,3HNO_3$.　　D. F. T.

Structure of 3-Nitroso-2-phenylindole. I. and II. LUIGI ALESSANDRI (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 150—155, 227—234. Compare Angeli and Morelli, A., 1908, i, 828).—In this preliminary note the author describes some transformations under-

gone by this substance. The production of the *O*-ether described by Angeli and Spica (A., 1899, i, 938) is confirmed. When nitrosophenylindole is heated, small quantities of 2-benzoylaminobenzonitrile are produced. This compound has m. p. 156°, but is readily converted by dilute acids into the corresponding amide, m. p. 216°. The supposed 2-benzoylaminobenzonitrile of Pinnow and Sämann (A., 1896, i, 368) probably consisted of this amide.

By the action of phosphorus pentachloride, 3-nitroso-2-phenylindole is converted into 2-phenyldihydro-4-quinazolone. When 3-nitroso-2-phenylindole is heated with zinc chloride, an apparently isomeric substance, m. p. about 228°, is formed, together with other products. This substance yields the above-mentioned quinazoline derivative when boiled with dilute acids or alkalis, and the same quinazoline derivative is also produced when the amide of m. p. 216° is heated.

The second paper gives experimental details regarding the results recorded in the first paper. 2-Benzoylaminobenzonitrile, prepared either by heating nitrosophenylindole (*loc. cit.*), or from 2-aminobenzonitrile, crystallises in colourless prisms or in long needles, m. p. 156°.   R. V. S.

Scission of Decahydroquinoline into the Two Optical Antipodes. BRUNO VENEZIANI (*Atti R. Accad. Lincei*, 1913, [v], 22, ii, 155—157).—Synthetical decahydroquinoline can be resolved with the aid of *d*-bromocamphorsulphonic acid. d-*Decahydroquinoline* d-*bromocamphorsulphonate* forms acicular crystals, m. p. about 220°, $[a]_D^{27}$ +64·01° (in 1·117% aqueous solution), and is less soluble than the *l*-salt, which was obtained only in the form of an oil. d-*Decahydroquinoline* has $[a]_D^{27}$ +1·28° (in 4·013% ethereal solution). l-*Decahydroquinoline* has $[a]_D^{27}$ −1·02° (in 14·11% ethereal solution). In consequence of the small quantity of substance available, the author suggests that the rotatory powers of the pure enantiomorphs may be numerically greater than those above recorded.   R. V. S.

Arsenic Compounds of the Quinoline Group. SIGMUND FRÄNKEL and PAUL LÖWY (*Ber.*, 1913, 46, 2546—2550).—The authors have turned their attention to the arsenic compounds of quinoline because both constituents of such molecules would be physiologically active.

Schiff (*Annalen*, 1864, 131, 116) has already given a brief report on certain compounds from quinoline and arsenic trichloride. It is now found that the action of quinoline and analogous bases with arsenic trichloride is an additive one ; the action was effected in ethyl acetate solution with equimolecular quantities of the reagents. *Quinoline arsenotrichloride*, $C_9H_7N,AsCl_3$, is a colourless solid, m. p. 138° ; *tetrahydroquinoline arsenotrichloride*, $C_9H_{11}N,AsCl_3$, is a pink solid, m. p. 134° ; *8-hydroxyquinoline arsenotrichloride*, $C_9H_7ON,AsCl_3$, is a bright yellow substance, m. p. 168°. Even under the influence of aluminium chloride the arsenic atom could not be made to enter the quinoline nucleus, and a similar failure was experienced when quinoline and tetrahydroquinoline were heated with arsenic acid at 200° in a sealed

tube, the products being *quinoline arsenate*, bright yellow leaflets, decomp. at 250°, and *tetrahydroquinoline arsenate*, colourless leaflets, m. p. 123°.

Attempts to synthesise the quinoline nucleus from arsanilic acid by Skraup's method gave merely quinoline, whilst Knorr's process with ethyl acetoacetate left the arsanilic acid unaltered. However, arsanilic acid condenses with acetaldehyde when an intimate mixture is treated with hydrobromic acid (D 1·49) ; the *hydrochloride* of 2-*methylquinoline-arsinic acid*, a yellow, crystalline solid, separates, from which the free acid, decomp. at 140°, can be liberated by washing with distilled water. Reduction of this acid in alcohol by sodium yields the tervalent arsenic compound, 2-*methylquinolinearsenoxide*, decomp. at 120°; the *picrate* was prepared.   D. F. T.

Synthesis of 2-Cyanoquinoline and 1-Cyanoisoquinoline. ADOLF KAUFMANN and PAUL DÄNDLIKER (*Ber.*, 1913, **46**, 2924—2929). —2-Cyanoquinoline, already prepared by Pfitzinger (Abstr., 1902, i, 53), was made by treating Reissert's 2-cyano-1-benzoyl-1 : 2-dihydro-quinoline, dissolved in chloroform, with phosphorus pentachloride. It is readily hydrolysed to quinaldinic acid, which is also formed as a by-product in the preparation of the cyano-base.

1-*Cyanoisoquinoline*, similarly obtained from 1-cyano-2-benzoyl-1 : 2-dihydroisoquinoline (Reissert, Abstr., 1905, i, 926) has m. p. 74°, crystallises from light petroleum, and is very soluble in ether or alcohol, but sparingly in water. On hydrolysis by acids or alkalis, it yields *iso*quinaldinic acid (*iso*quinoline-1-carboxylic acid).   T. A. H.

Preparation of Arylquinolinecarboxylic Acid Esters. FARBENFABRIKEN VORM. FRIEDR. BAYER & Co. (D.R.-P. 261028).— *Salicyl 2-phenylquinoline-4-carboxylate*, colourless leaflets, m. p. 188°, is obtained when a benzene solution of 2-phenylquinoline-4-carboxylic acid is warmed during two hours with thionyl chloride and the solid residue (left after evaporating the solvent) mixed with salicylic acid and benzene and heated during three hours at 80°.

o-*Hydroxytoluoyl* 2 : 3-*diphenylquinoline-4-carboxylate*, colourless needles, m. p. 250°, is prepared in an analogous manner from hydroxy-toluic acid and 2 : 3-diphenylquinoline-4-carboxylic acid. *Salicyl* 2-p-*anisylquinoline-4-carboxylate*, colourless needles, has m. p. 132°, and *salicylglycine 2-phenylquinolinecarboxylate*, m. p. 120°.   F. M. G. M.

Quinolyl Ketones. III. ADOLF KAUFMANN, PAUL DÄNDLIKER and HANS BURKHARDT (*Ber.*, 1913, **46**, 2929—2935. Compare Abstr., 1912, i, 1017 ; this vol., i, 294).—It is now shown that in the pre-paration of these ketones by the use of Grignard reagents with cyanoquinolines, a molecule of the magnesium alkyl iodide is first attached to the cyclic nitrogen and then a second molecule to the cyano-group. The position of the cyano-group has some influence on the reactions; thus 2-cyanoquinoline and 1-cyanoisoquinoline give good yields of the corresponding alkyl ketones, whilst 5-cyanoquinoline does not react with Grignard reagents.

2-*Quinolyl methyl ketone*, $C_9H_6N \cdot COMe$, m. p. 52°, b. p. 146—148°/

13 mm., forms small needles from dilute alcohol, and has a jasmine-like odour. The *phenylhydrazone*, m. p. 154°, crystallises from alcohol in slender, yellow needles. 2-*Quinolyl ethyl ketone*, m. p. 59—60°, distils in steam, forms colourless needles from alcohol, and has a pleasant ketone-like odour. The *phenylhydrazone*, m. p. 106°, forms short, yellow needles. 2-Quinolyl phenyl ketone was also prepared by this means (compare Besthorn, 1908, i, 681). 2-*Quinolyl benzyl ketone*, m. p. 78°, crystallising in flat needles, was prepared by treating 2-cyanoquinoline with magnesium methyl iodide followed by magnesium benzyl chloride, or by the action of ethyl quinaldinate on the sodium derivative of benzyl cyanide, which gave 2-*quinolyl cyanobenzyl ketone*, m. p. 120—121°, long needles, which was then hydrolysed to the corresponding *acid* and the latter heated at 120—130°.

1-iso*Quinolyl methyl ketone*, m. p. 48°, crystallises in colourless needles, is readily soluble in organic solvents, and has only a slight odour. The *phenylhydrazone* decomposes at 160°. 1-iso*Quinolylphenyl ketone*, m. p. 76—77°, b. p. 231°/12 mm., crystallises in highly refractive tablets, is readily soluble in benzene, alcohol or ether, but sparingly in light petroleum. It does not yield a methiodide with methyl iodide at 100° under pressure. T. A. H.

New Synthesis of Carbostyril. HANS MEYER and ROBERT BEER (*Monatsh.*, 1913, **34**, 1173—1179).—When o-chlorocinnamic acid is heated with copper and ammonia solution it is partly converted into carbostyril (2-hydroxyquinoline), the reaction being almost complete when the mixture is heated during thirty hours at 160—170°. At 120—130°, on the contrary, more or less o-aminocinnamic acid is also formed. A process for the isolation of the latter is described. The o-aminocinnamic acid produced in this reaction differs in certain respects from that prepared by reduction of o-nitrocinnamic acid, being (1) more soluble in water ; (2) not readily convertible into coumarin, and (3) of different melting point, namely, 150°. It seems possible that it may be a new *trans*-form of the acid (compare Stoermer and Heymann, Abstr., 1912, i, 974).

When 2-methoxyquinoline is (1) distilled under atmospheric pressure, (2) heated on a water-bath, or (3) kept for some time in diffused light, it passes into the non-volatile isomeride in which the methyl group is attached to the nitrogen, a change analogous with the conversion of a-methoxypyridine into *N*-methylpyridine (compare Abstr., 1901, i, 343).

o-Chlorophenylpropionic acid when heated at 140—160° with copper and ammonia solution during thirty hours is converted quantitatively into hydrocarbostyril. T. A. H.

Nitro-derivatives of Thiodiphenylamine [Phenthiazine]. FRIEDRICH KEHRMANN and OLGA NOSSENKO (*Ber.*, 1913, **46**, 2809—2820).—The nitrophenthiazinesulphoxides obtained by the action of nitric acid on phenthiazine (Bernthsen, A., 1886, 53) are converted into the corresponding nitrophenthiazines by mineral acids in the presence of alcohol or glacial acetic acid ; the most suitable reagent is concentrated hydrochloric and glacial acetic

acids, although it has a tendency to replace nitro-groups by chlorine atoms and to form chlorinated products. Smiles and Barnett (T., 1909, **95**, 1261) and Claasz (A., 1912, i, 513) have examined the action of such reagents on nitrated phenthiazinesulphoxides and have described the products as derivatives of phenazothionium hydroxide. This is incorrect, the products obtained by these investigators being nitrophenthiazines mixed with chlorinated and oxidised by-products.

5-Nitrophenthiazine, $C_6H_4\underset{S}{\overset{NH}{\diagup\diagdown}}C_6H_3 \cdot NO_2$, m. p. 111°, violet-black leaflets, is obtained by condensing *o*-aminophenyl disulphide with 1-chloro-2 : 6-dinitrobenzene (2 mols.) in boiling alcohol in the presence of sodium acetate (2 mols.), and reducing the resulting dinitrodiphenylamine disulphide in boiling alcohol and benzene with concentrated aqueous sodium sulphide; the yield is very unsatisfactory. By reduction with stannous chloride and hydrochloric acid, it is converted into *5-aminophenthiazine hydrochloride,* colourless needles, which is oxidised by aqueous ferric chloride to *5-aminophenazothionium chloride,* $C_6H_4\underset{SCl}{\overset{N}{\diagup\diagdown}}C_6H_3 \cdot NH_2$, which is isolated as the *platini-chloride,* $2C_{12}H_9N_2SPtCl_6$, greyish-green crystals. 5-Aminophenthiazine forms an *acetyl* derivative, m. p. 174°, colourless prisms.

3-Nitrophenthiazine, m. p. 218°, violet-black crystals, is obtained by treating an alcoholic suspension of 3-nitrophenthiazinesulphoxide with 30% sulphuric acid, warming finally on the water-bath. The sulphoxide is converted by hydrochloric and acetic acids into *9(?)-chloro-3-nitrophenthiazine,* $C_6H_3Cl\underset{S}{\overset{NH}{\diagup\diagdown}}C_6H_3 \cdot NO_2$, m. p. about 268°, brownish-black, bronze needles; by reduction, the latter yields the chloroaminophenthiazine by the oxidation of which by ferric chloride the chloroaminophenazothionium chloride is obtained.

The action of hydrochloric and acetic acids on 3 : 9-dinitrophenthiazinesulphoxide yields a mixture of 3 : 9-dinitrothiodiphenylamine and a *tetrachloro*-derivative, m. p. 235°, colourless needles (probably *3 : 5 : 7 : 9-tetrachlorophenthiazine*), which is separated by extracting the latter with chloroform. *3 : 9-Dinitrophenthiazine,*

$$NO_2 \cdot C_6H_3\underset{S}{\overset{NH}{\diagup\diagdown}}C_6H_3 \cdot NO_2,$$
m. p. 276°, dark brownish-red needles, forms solutions with a characteristic brick-red fluorescence and yields by reduction the leuco-derivative of Lauth's violet. It is also the chief product of the action of solid sodium nitrite on a suspension of phenthiazine in glacial acetic acid.

Smiles and Barnett's tetranitrophenthiazinesulphoxide (*loc. cit.*) is, contrary to their statement, practically unchanged by treatment with alcohol and mineral acids. From the by-products in its preparation a *substance,* $C_{12}H_6O_8N_4S$, m. p. 270°, yellow needles, is obtained, which is probably a *hydroxytrinitrophenthiazinesulphoxide.*

Attention is called to the fact that all nitrophenthiazines containing at least one nitro-group in the para-position to the nuclear nitrogen

atom form intensely blue or green alkali salts, which probably have the quinonoid constitution $C_6H_4\!\!<^N_S\!\!>C_6H_3{:}NO{\cdot}OM$.   C. S.

Preparation of Anthraquinonedithiazoles and their Reduced Derivatives. BADISCHE ANILIN- & SODA-FABRIK (D.R.-P. 260905).— 2 : 6-*Diaminoanthraquinone*-1 : 5-*dimercaptol* is obtained by heating 1 : 5-dichloro-2 : 6-diaminoanthraquinone with an aqueous-alcoholic solution of sodium polysulphide under pressure, and it has been employed in the preparation of the following *compounds* : (1) by boiling the foregoing mercaptol (50 parts) with 50 to 100 parts of either benzaldehyde, benzylidene chloride, benzotrichloride, or benzoyl chloride ; (2) in a similar manner with *p*-dimethylaminobenzaldehyde ; (3) with anthraquinone-2-aldehyde.

The tinctorial properties of these compounds are described, also modifications in methods of preparation, whilst the same reaction with other aldehydes and mercaptols is also discussed.   F. M. G. M.

Quinone-benzidine and its Reaction Products. KURT BRASS (*Ber.*, 1913, **46**, 2902—2906).—When the components are brought together in toluene, 2 mols. of benzidine unite with 1 mol. of quinone to form a soluble bluish-black addition product (compare Fecht, A., 1908, ii, 916). On warming in alcohol, an insoluble brown powder is obtained containing benzidine and quinone in molecular proportions.

The bluish-black product crystallises in platelets, m. p. 118°. The brown product does not melt ; it dissolves with a blue coloration in concentrated sulphuric acid, and probably represents a polymeride.

Chloranil and benzidine when warmed together in toluene solution condense to an insoluble brown vat dye, which is regarded as a mixture of dibenzidinodichloroquinone with a little monobenzidinotrichloroquinone.   E. F. A.

Oxidation of Anilinoquinones to Benzidine Derivatives. II. KURT BRASS (*Ber.*, 1913, **46**, 2907—2912. Compare A., 1912, i, 874).—1-Anilinoanthraquinone is readily oxidised by manganese dioxide and sulphuric acid to N : N'-bis*anthraquinonyl-1-benzidine*, a clear violet vat dye, which is composed of microscopic, transparent, violet crystals, m. p. 311°. The solution in concentrated sulphuric acid is olive-green.

In a similar manner, 1-anthra-anilinoanthraquinone may be oxidised to N : N'-*bis-(anthraquinonyl-1)-benzidine*-o-*dicarboxylic acid*, which forms a mass of violet-red needles, m. p. about 360°. On heating in concentrated sulphuric acid at 100—110°, the green solution becomes orange, and *dianthraquinone-2 : 1-acridone*,

$$C_6H_4\!\!<^{CO}_{CO}\!\!>C_6H_2\!\!<^{CO}_{NH}\!\!>C_6H_3{\cdot}C_6H_3\!\!<^{CO}_{NH}\!\!>C_6H_2\!\!<^{CO}_{CO}\!\!>C_6H_4$$
is obtained in the form of a mass of pale violet needles. It does not melt or sublime.

Bis-a-naphthoquinonyl-2-benzidine, obtained on oxidation of anilino-*a*-naphthoquinone, gives a brownish-violet solution in concentrated sulphuric acid.   E. F. A.

Phenylhydrazine. I. Anhydrous Phenylhydrazine as a Cryoscopic Solvent. BERNARDO ODDO (*Gazzetta*, 1913, **43**, ii, 263—274).—The cryoscopic constant of phenylhydrazine is 58·59 (from experiments with naphthalene, diphenyl, dibenzyl, veratrole, and safrole). The molecular weight of hydrocarbons (benzene, toluene, *p*-xylene, and *p*-cymene) dissolved in phenylhydrazine increases with the concentration, and the same phenomenon is observed with alcohols (ethyl alcohol, *iso*butyl alcohol, *iso*amyl alcohol, and ethylene glycol); triphenylcarbinol gives a value below the normal at all concentrations. Phenols (phenol, *p*-cresol, and β-naphthol) have molecular weights below the theoretical value, and they diminish slowly when the concentration is increased. Bases (pyridine, piperidine, aniline, dimethylaniline, and quinoline) behave normally. Acetic acid and butyric acid are almost normal, whilst benzoic acid and salicylic acid have molecular weights much below the calculated values. R. V. S.

Phenylhydrazine. II. The System Phenylhydrazine–Water and the Cryoscopic Constant of Hydrated Phenylhydrazine. BERNARDO ODDO (*Gazzetta*, 1913, **43**, ii, 274—281. Compare preceding abstract).—Phenylhydrazine and phenylhydrazine hydrate show an eutectic point at 16°, and there is a maximum corresponding with the formula $(NHPh\cdot NH_2)_2,H_2O$, which agrees with that of the phenylhydrazine hydrate already known. The cryoscopic constant of phenylhydrazine hydrate is 44·15 (from experiments with diphenyl, veratrole, and naphthalene). R. V. S.

Phenylhydrazine. III. Velocity of Reaction of Aldehydes and Ketones with Phenylhydrazine. BERNARDO ODDO (*Gazzetta*, 1913, **43**, ii, 354—362. Compare preceding abstracts).—Comparative cryoscopic experiments show that the reaction of phenylhydrazine with acetone is complete in forty minutes, that with acetophenone in 162 minutes, whilst that with benzophenone has hardly begun after 225 minutes. Tables are also given showing the cryoscopic behaviour of a number of aldehydes and ketones in phenylhydrazine. R. V. S.

Action of Stannic Chloride on Phenylhydrazine. JITENDRA N. RAKSHIT (*J. Proc. Asiatic Soc., Bengal*, 1913, **9**, 131—135, Reprint).—Pure stannic chloride reacts very vigorously with phenylhydrazine, yielding benzene and nitrogen, whilst phenylhydrazine hydrochloride may be isolated from the product by dissolving it in water, precipitating the tin as the sulphide, and concentrating. A quantitative study of the reaction has shown that two molecules of the base give rise to one molecule of benzene, one of phenylhydrazine hydrochloride, and one of nitrogen. The equation:

$$2NHPh\cdot NH_2 + SnCl_4 = C_6H_6 + N_2 + SnCl_2 + NHPh\cdot NH_2,2HCl$$
agrees with these results, but introduces the anomaly that phenylhydrazine forms a dihydrochloride. Such an easily decomposable compound would be analogous to the dihydrofluoride described by Thieme (A., 1893, i, 155), and since no double salt of the base with a chloride of tin could be detected, its existence must be taken for granted.

The question whether the benzene is formed through the intervention of benzenediazonium chloride remains to be proved.

<div align="right">J. C. W.</div>

Mutual Replacement of Ammonia and Amines in Carbon Compounds. N. CONEV and PAVEL IV. PETRENKO-KRITTSCHENKO (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1092—1098).—In order to throw light on the results obtained by Schöttle and Petrenko-Krittschenko (A., 1911, i, 1020 ; 1912, i, 128 ; this vol., i, 48), the authors have investigated the action of ammonia and amines on acetylphenylmethyl-pyridonone (compare von Pechmann and Neger, A., 1893, i, 398), which differs from benzoyldehydracetic acid in that the two phenyl side-groups are replaced by methyl groups. The substituents have such a considerable influence on the course of the reaction that the latter is of an entirely different character from that previously observed. The ring is here found to exhibit great stability, substitution of oxygen and mutual replacement of ammonia and amines taking place only in the side-chains. Further, heating of acetylphenylmethylpyridonone with hydrochloric acid results in the separation, not of aniline, but of acetic acid.

The action of ammonia on 5-acetyl-1-phenyl-2-methylpyridonone gives a quantitative yield of the *compound,*

$$CMe{<}{CH-CO \atop NPh\cdot CO}{>}C{:}CMe\cdot NH_2,$$
m. p. 247—248°. Similarly, the action of methylamine gives the *compound,* $CMe{<}{CH-CO \atop NPh\cdot CO}{>}C{:}CMe\cdot NHMe$, in colourless, thin needles, m. p. 183°, and that of aniline the *compound,* $C_{19}H_2O_2N{:}CMe\cdot NHPh$, m. p. 154—155°.

When these derivatives are subjected to suitable conditions, the methylamine or aniline residue may be replaced by the amino-group, the latter by the methylamine or aniline residue, or the aniline by the methylamine group.

1-*Phenyl-2-methylpyridonone,* $NPh{<}{CMe{:}CH \atop CO-CH_2}{>}CO$, obtained by heating the acetyl compound with excess of concentrated hydrochloric acid in a sealed tube at 150°, forms transparent, lustrous plates, m. p. 270—271°, and yields an *acetyl* derivative, $NPh{<}{CMe{:}CH \atop CO-CH}{>}C\cdot OAc$, which crystallises in needles, m. p. 146—147°, and is isomeric with von Pechmann and Neger's compound (*vide supra*). With benzaldehyde, it yields 1-*phenyl-5-benzylidene-2-methylpyridonone,*

$$NPh{<}{CMe{=\!=\!=}CH \atop CO\cdot C({:}CHPh)}{>}CO,$$
m. p. 308—309°, which has the normal molecular weight in freezing phenol.

<div align="right">T. H. P.</div>

Synthesis of Aminoacetyl - 8 - methoxyquinoline. SIGMUND FRÄNKEL and OSKAR GRAUER (*Ber.*, 1913, **46**, 2551—2554).—After several fruitless attempts to prepare substances which should constitu-

tionally resemble adrenaline, the authors have obtained the above substance.

8-Methoxyquinoline was prepared by the method of Bedall and Fischer (A., 1882, 412) improved by the replacement of ether by benzene for the purpose of extraction ; the base, needles, b. p. 172°/24 mm., gives a *platinichloride*, and a *picrate*, decomp. at 143°. When treated in light petroleum with chloroacetyl chloride and aluminium chloride, the methoxyquinoline is slowly converted into *chloroacetyl-8-methoxyquinoline*, a volatile, colourless solid, m. p. 58°, b. p. 152°/22 mm., which powerfully attacks the skin and eyes. Although the action of ammonia on this substance caused resinification, a mixture with potassium phthalimide in a sealed tube at 160—170° gave rise to *phthaliminoacetyl-8-methoxyquinoline*, a colourless solid, m. p. 219°, which by hydrolysis with concentrated hydrochloric acid in a sealed tube was converted into *aminoacetyl-8-methoxyquinoline hydrochloride*, $OMe \cdot C_9H_5N \cdot CO \cdot CH_2 \cdot NH_2, 1\frac{1}{2}HCl$, m. p. 198° (decomp.). D. F. T.

Reactivity of the Methyl Group in 3-Amino-2-methylquinoline. OTTO STARK and FELIX HOFFMANN (*Ber.*, 1913, **46**, 2697—2703). —Unsuccessful attempts have been made to involve the methyl group of 2-methyl-3-aminoquinoline in condensations with formaldehyde or carbonyl chloride. Further, ring formation is not observed when 3-amino-2-methylquinoline is diazotised, nor could it be brought about by the elimination of water from 3-acetylamino-2-methylquinoline, although, in the latter case, the basicity of the amino-group is weakened by introduction of the acetyl radicle.

When a solution of 3-amino-2-methylquinoline in hydrochloric acid is warmed with formaldehyde, a salt separates from which sodium hydroxide liberates the *base* (annexed formula), m. p. 204—205°. The *hydrochloride*, yellow, prismatic needles, m. p. 210—211°, and the *platinichloride*, yellow needles, m. p. 234—235°, were analysed. Boiling aqueous hydrochloric acid slowly decomposes the base into aminoquinaldine and formaldehyde.

Di-2-methylquinolinecarbamide, $C_{21}H_{18}ON_4$, m. p. 278°, is obtained when a solution of 3-amino-2-methylquinoline in dry toluene is left in contact with a solution of carbonyl chloride in the same solvent during two days and the product decomposed with $2N$-sodium hydroxide. The *hydrochloride*, $C_{21}H_{18}ON_4, 2HCl$, pale yellow needles, has m. p. 232—233°.

When a diazotised solution of 3-amino-2-methylquinoline is neutralised with sodium hydrogen carbonate and the precipitate dissolved in ether, a red, crystalline *powder* is obtained (after removal of the solvent), which has m. p. 105—115°, from which a definite substance could not be isolated. A solution of aniline hydrochloride, however, yields *2-methylquinolinediazoaminobenzene*, yellow crystals, m. p. 158°, when added to a diazotised solution of 3-amino-2-methylquinoline hydrochloride in the presence of sodium acetate. The corresponding *aminoazo*-compound, reddish-yellow crystals, m. p. 98—99°, is readily obtained by the usual methods. H. W.

Constitution of the Blood and Bile Pigments. II. HANS
FISCHER and ERICH BARTHOLOMÄUS (*Zeitsch. physiol. Chem.*, 1913, **87**,
255—269. Compare this vol., i, 209).—Further examples of the
coupling of pyrrole nuclei in the 2-position to a carbon atom are
described.

Equimolecular quantities of ethyl 2 : 5-dimethylpyrrole-3-carboxylate
and ethyl 2 : 4-dimethylpyrrole-3-carboxylate couple with formaldehyde
to form *ethyl 2 : 5 : 2′ : 4′-tetramethyldipyrrylmethane-3′ : 4-dicarboxylate*,

$$\begin{matrix} C Me{:}C(CO_2Et) \\ NH{-}\!\!-\!\!-CMe \end{matrix} {>} C{\cdot}CH_2{\cdot}C {<} \begin{matrix} NH{-}CMe \\ CMe{\cdot}C{\cdot}CO_2Et{\cdot} \end{matrix}$$

This forms faintly yellow
crystals, m. p. 178—179°. From acetone, it crystallises in long,
colourless needles.

Ethyl   2 : 5′ : 2′ : 5-tetramethyldipyrrylmethane-3 : 3′-dicarboxylate,
formed in a similar manner, separates as a colourless, crystalline
powder, m. p. 231—232°, after previously sintering.

Ethyl   5-acetyl-2 : 4 : 2′ : 4′-tetramethyldipyrrylmethane-3′-carboxylate
crystallises in colourless needles in fan-like aggregates, m. p. 188—189°.

Ethyl   3-acetyl-2 : 4 : 2′ : 4′-tetramethyldipyrrylmethane-3′-carboxylate,
crystallises in yellow prisms belonging to the rhombic system,
m. p. 231—232°.

Ethyl 3 : 3′-diacetyl-2 : 4 : 2′ : 4′-tetramethyl-αα-dipyrrylethane,

$$CHMe \left(C {<} \begin{matrix} CMe{\cdot}C{\cdot}COMe \\ NH{-}CMe \end{matrix} \right)_2,$$

obtained on condensing acetyldimethylpyrrole with acetaldehyde,
crystallises in colourless, rectangular platelets, m. p. 251—252°.

Ethyl   2 : 4 : 2′ : 4′-tetramethyl-αα-dipyrrylethane-3 : 3′-dicarboxylate
separates in well formed, colourless crystals, m. p. 171—172°.

Ethyl 3-acetyl 2 : 4 : 2′ : 4′-tetramethyl-αα-dipyrrylethane-3′-carboxylate,
crystallises in hexagonal tablets; m. p. 202—203°, but giving a clear
flux only at 209°.

5 : 5′-Diacetyl-2 : 4 : 2′ : 4′-tetramethyl-αα-dipyrrylpropylene,

$$CH_3{:}CH{\cdot}OH \left(C {<} \begin{matrix} CMe{:}C Ac \\ CMe{\cdot}NH \end{matrix} \right)_2,$$

formed on condensing acetyldimethylpyrrole with an alcoholic solution
of acraldehyde, was obtained as a yellow, microcrystalline powder.

5-Bromo-3-acetyl-2 : 4-dimethylpyrrole, $NH {<} \begin{matrix} CMe{:}CAc \\ CBr{\cdot}CMe \end{matrix}$, obtained on

brominating acetyldimethylpyrrole in acetic acid, crystallises in faintly
yellow prisms, m. p. 165—166° (decomp.).

Pyrroles couple with diazo-compounds more easily in the 2- than in
the 3-position. Accordingly, in a mixture of 2 : 4-dimethylpyrrole and
2 : 4-dimethyl-5-ethylpyrrole on the cautious addition of diazobenzene-
sulphonic acid the former is completely precipitated. On adding more
of the diazo-compound to the filtrate, the latter (3-position free) is also
completely precipitated as azo-dye.   E. F. A.

New Class of Quinoline Dyes. III. EMIL BESTHORN (*Ber.*,
1913, **46**, 2762—2770).—The dye, $C_{19}H_{12}ON_2$, obtained by the methods

previously described (Besthorn and Ibele, A., 1904, i, 527; 1905, i, 612), probably has the annexed con- constitution; it is certainly not 2 : 2'-di- quinolyl ketone (Gebhard, A., 1909, ii, 284), since its properties are quite different from those of 2-quinolyl phenyl ketone (A., 1908, i, 681).
The asymmetric structure of the dye is proved as follows. If the dye is 2 : 2'-di- quinolyl ketone, it is evident that the sub- stances produced from quinaldinyl chloride and 4-phenylquinoline and from 4-phenylquinaldinyl chloride and quinoline must in each case be be 4-phenyl-2 : 2'-diquinolyl ketone. Actually, the two products are different. 4-*Phenylquinaldinyl chloride*, m. p. 116°, and quinoline in benzene at the ordinary temperature yield a *substance*, $C_{25}H_{16}ON_2$, m. p. above 240°, brownish-red crystals, which is converted into carbostyril and 4-phenylquinaldinic acid by concentrated sulphuric acid at 70—75°. The *substance*, $C_{25}H_{16}ON_2$, produced from quin- aldinyl chloride and 4-phenylquinoline has m. p. above 240°, forms brownish-red crystals, and yields quinaldinic acid and 4-phenylcarbo- styril by treatment with concentrated sulphuric acid at 70°.

In a similar manner, quinaldinyl chloride and ethyl cinchoninate in benzene yield a *substance*, $\begin{matrix} C_6H_4\text{---}N\text{===}C\text{---}CH \\ CH:CH\cdot C\cdot CO\cdot N\cdot C_6H_4 \end{matrix}>C\cdot CO_2Et$, m. p. 238°, brownish-red needles with a green reflex, which resembles other dyes of the same type in forming strongly fluorescent solutions.

These quinoline dyes are more sensitive to sunlight than any other class of organic dyes; a change, however, only occurs in the presence of oxygen. Under such conditions in benzene, the preceding dye is rapidly decolorised, ethyl 2-hydroxycinchoninate being formed, whilst the dye from quinaldinyl chloride and 4-phenylquinoline yields 4-phenylcarbostyril; products corresponding with the other halves of the two molecules cannot be isolated. C. S.

Hydantoins. XXV. The Preparation of Hydantoin from Hippuric Acid. TREAT B. JOHNSON and ROBERT BENGIS (*J. Amer. Chem. Soc.*, 1913, 35, 1605—1606).—When a specimen of hydantoin is required urgently and potassium cyanate is not available, the following method is convenient.

Hippuric acid (or, indeed, any α-acylamino-acid) is first converted into 3-benzoyl-2-thiohydantoin, which is possible with excellent yields (Johnson and Nicolet, A., 1912, i, 53). This substance is then desulphurised by digesting with an aqueous solution of chloroacetic acid when hydrolysis concurrently occurs, the products therefore being benzoic acid and hydantoin. D. F. T.

Hydantoins. XXVI. Syntheses of 4-Hydroxy-3-methoxy- phenylalanine and 3 : 4-Dimethoxyphenylalanine. TREAT B. JOHNSON and ROBERT BENGIS (*J. Amer. Chem. Soc.*, 1913, 35, 1606—1617).—Vanillin condenses with hydantoin when heated

together with anhydrous sodium acetate in acetic acid, the product being 4-p-*hydroxy-m-methoxybenzylidenehydantoin*,

$$\begin{matrix} NH-CO \\ CO\cdot NH \end{matrix}\Big> C\colon CH\cdot C_6H_3(OMe)\cdot OH,$$
a granular solid, m. p. 264—265°; this was reduced by tin and an alcoholic solution of hydrogen chloride with formation of 4-p *hydroxy-m-methoxybenzylhydantoin*, prisms, m. p. 194—195°.

The condensation product of vanillin with 2-thiohydantoin, obtainable under similar conditions to the above, was 2-*thio-4-p-hydroxy-m-methoxybenzylidenehydantoin*, yellow needles, m. p. 232—233°, which gives a blood-red solution in concentrated sulphuric acid and a yellow one in aqueous sodium hydroxide solution. When digested with an aqueous solution of chloroacetic acid, it undergoes desulphurisation to the above 4-p-hydroxy-m-methoxybenzylidenehydantoin, and on reduction in aqueous suspension by sodium amalgam becomes converted into 4-*hydroxy-3-methoxybenzylthiohydantoic acid*,

$$OH\cdot C_6H_3(OMe)\cdot CH_2\cdot CH(CO_2H)\cdot NH\cdot CS\cdot NH_2,$$
yellow prisms from aqueous solution, m. p. 181—182° (decomp.). Reduction of the thiomethoxyhydroxybenzylidenehydantoin by tin or by stannous chloride in each case with an alcoholic solution of hydrogen chloride gave the 4-p-hydroxy-m-methoxybenzylhydantoin described above. The last-named substance when submitted to the action of boiling barium hydroxide solution for many hours evolves ammonia and 4-*hydroxy-3-methoxyphenylalanine*,

$$OH\cdot C_6H_3(OMe)\cdot CH_2\cdot CH(NH_2)\cdot CO_2H,$$
prisms (with $1H_2O$), m. p. 255—256° (decomp.), is simultaneously produced.

Veratraldehyde condenses with 2-thiohydantoin, under the conditions described above, with formation of 2-*thio-4-mp-dimethoxybenzylidenehydantoin*, prisms, m. p. 229—230°, which can be reduced in suspension in water by sodium amalgam to 2-*thio-4-mp-dimethoxybenzylhydantoin*, crystals with $1H_2O$, m. p. 102—103°. When desulphurised by aqueous chloroacetic acid, this gives rise to 4-mp-*dimethoxybenzylhydantoin*, a viscous syrup, from which 3 : 4-*dimethoxyphenylalanine*, hair-like crystals, m. p. 249—250° (decomp.), can be obtained by digestion with barium hydroxide solution.

When 4-p-hydroxy-m-methoxybenzylidenehydantoin is treated with alcoholic potassium hydroxide and methyl iodide, methylation occurs with production of 1-*methyl-4-mp-dimethoxybenzylidenehydantoin*, prismatic crystals, m. p. 218°, together with some 1 : 3-*dimethyl-4-mp-dimethoxybenzylidenehydantoin*, distorted prisms, m. p. 122—124°, which gives a bright red solution in sulphuric acid.   D. F. T.

β-**Naphthalaninehydantoic Acid.** WILHELM TÜRK (*Biochem. Zeitsch.*, 1913, **55**, 477—480).—Kikkoji (Abstr., 1911, ii, 909) has obtained from the urine, after administration of β-naphthalanine to a dog, a substance to which the formula $C_{15}H_{16}O_3N_2$ was assigned. As it is known that amino-acids on evaporation in urine react with the urea to yield uraminic acids, it is conceivable that the above-mentioned substance is a derivative of this character formed from unchanged β-naphthalanine. By the action of urea on β-naphthalanine in the

presence of barium hydroxide, a β-naphthalaninehydantoic acid, $C_{14}H_{14}O_8N$, could be obtained with m. p. 194—195°. Kikkoji's substance melted at 190°, so that the identity of the two products cannot yet be regarded as proved, especially as Kikkoji's analyses are not in strict accordance with those of the synthetic substance.

<div style="text-align:right">S. B. S.</div>

Preparation of a Mercury Derivative of the Pyrazolone Series. LEON GIVAUDAN and EMIL SCHEITLIN (D.R.-P. 261081 and 261082).—When 300 parts of 4-sulphamo-1-phenyl-2 : 3-di-methyl-5-pyrazolone (A., 1908, i, 688) are gently warmed with freshly prepared mercuric oxide (from 270 parts of mercuric chloride) in 10,000 parts of water, it furnishes a colourless, crystalline *compound*, I or II (the latter being considered most probable) ; it contains

OMe   OMe

NMe⟨ ⟩C·NH·SO₃Hg   NMe⟨ ⟩C·N(SO₃H)·HgOH
NPh⌐—⌐CO   NPh⌐—⌐CO
(I.)   (II.)

41% of mercury, and, when treated with dilute alkalis, part of the mercury separates in the mercurous condition, leaving a compound in solution containing 24% of mercury.

II. States that by altering the proportions of reacting material in the foregoing preparation, a *compound*, a greenish-white powder containing 67—68% Hg, is obtained, by treatment with sodium hydroxide part of the mercury is eliminated, and the solution furnishes the previously described compound containing 24% of mercury.

<div style="text-align:right">F. M. G. M.</div>

Antipyrine and Ammonia Compounds of Some Nitrates of the Rare Earths. ADALBERT KOLB (*Zeitsch. anorg. Chem.*, 1913, **83**, 143—148. Compare A., 1909, i, 16).—*Zirconium nitrate antipyrine*, $Zr(NO_3)_4,6C_{11}H_{12}ON_2$, prepared in nitric acid solution, forms colourless tablets, m. p. 217—218° (decomp.), readily soluble in water. *Thorium nitrate antipyrine*, $2Th(NO_3)_4,5C_{11}H_{12}ON_2$, readily forms supersaturated solutions and has m. p. 168—169°. The *lanthanum, cerous*, and *samarium* compounds contain 3 mols. of antipyrine, and have m. p.'s 161—162°, 165°, and ¦177—178° respectively. *Erbium nitrate antipyrine*, $Er(NO_3)_3,4C_{11}H_{12}ON_2$, forms pink tablets, and has m. p. 175—176°, whilst the *yttrium* compound is colourless and has m. p. 176—177°.

Thorium nitrate combines with ammonia, forming compounds, $Th(NO_3)_4,2H_2O,3NH_3$ and $2Th(NO_3)_4,3H_2O,7NH_3$. An anhydrous salt, formed with the development of much heat, proves to be basic, $ThNO_3(OH)_3$. Zirconium also forms a crystalline basic compound, $ZrO(NO_3)_2,2H_2O,2NH_3$.

<div style="text-align:right">C. H. D.</div>

Benzylated Pyrazole Derivatives and a Peculiar Case of Autoalkylation. PAUL JACOBSON and H. JOST (*Annalen*, 1913, **400**, 195—219).—By boiling with about 16% alcoholic potassium hydroxide for one hour, 1-phenyl-2-benzyl-3-methyl-5-pyrazolone decomposes and yields ammonia, 30% of acetoacetanilide, and about 25% of a *substance*,

$C_{24}H_{22}ON_2$, m. p. 152°, colourless leaflets, which proves to be 1-*phenyl-2 : 4-dibenzyl 3-methyl-5-pyrazolone*. The explanation of this curious example of autobenzylation is very probably as follows. The pyrazole nucleus of one molecule of the phenylbenzylmethylpyrazolone is ruptured by the alkali, with the formation of the phenylbenzylhydrazide of acetoacetic acid, $CH_2Ph\cdot NH\cdot NPh\cdot CO\cdot CH\colon CMe\cdot OH$. Since the union of the benzyl group and the nitrogen atom in benzylated hydrazines is easily loosed, the hydrazide benzylates a second molecule of phenylbenzylmethylpyrazolone forming the substance, m. p. 152°, being itself converted into acetoacetanilide, an atom of nitrogen appearing ultimately as ammonia.

The proofs of the constitution of 1 phenyl-2 : 4-dibenzyl-3-methyl-5-pyrazolone are the following. In accordance with Knorr's experience of 1 : 2-disubstituted pyrazolones, it reacts with alkyl iodides to form ψ-alkyliodides, $CH_2Ph\cdot NI{\Large\lessgtr}{\scriptstyle\substack{NPh\cdot C\cdot OR \\ \| \\ CMe\text{-}C\cdot CH_2Ph}}$, which are decomposed by fusion or by aqueous alkalis into the original compound and alkyl iodide. The ψ-*methiodide*, $C_{25}H_{25}ON_2I$, decomp. 234°, pale yellow prisms, prepared at 100°, and the ψ-*ethiodide*, $C_{26}H_{27}ON_2I$, m. p. about 258—260° (decomp.), yellow, crystalline powder, prepared at 120°, are described. The former behaves abnormally with aqueous alcoholic potassium hydroxide in forming, not the original phenyldibenzylmethylpyrazolone, but a *substance*, m. p. 149°, colourless needles (*picrate*, m. p. 176°), the composition of which has not been determined. By heating with 10% sulphuric acid at 130°, 1-phenyl-2 : 4-dibenzyl-3-methyl-5-pyrazolone is decomposed into ammonia, aniline, benzoic acid, and benzylacetone. The authors show that *s*-phenylbenzylhydrazine by similar treatment at 135—140° yields ammonia, aniline, benzaldehyde, and benzoic acid.

In preparing the compound by the benzylation of 1-phenyl-3-methyl-5-pyrazolone, Stolz did not definitely prove the constitution of 1-phenyl-2-benzyl-3-methyl-5-pyrazolone. The authors have now done so, in consequence of the curious behaviour of the substance recorded above. It is converted into benzyl chloride and 5-chloro-1-phenyl-3-methylpyrazole by phosphoryl chloride at 140—150°. By heating in toluene with sodium in an atmosphere of carbon dioxide and subsequent treatment with ice and heating with dilute sulphuric acid, it yields aniline and benzylamine.   C. S.

Derivatives of Pyridazine and of Pyrrole. G. KARL ALMSTRÖM (*Annalen*, 1913, 400, 131—146).—With the exceptions of 4 : 5-diphenylpyridazine and 1 : 3 : 4-triphenylpyrrole, all the unknown diphenylpyridazines and triphenylpyrroles have been prepared.

3 : 5-*Diphenylpyridazin-6-one*, $N{\Large\lessgtr}{\scriptstyle\substack{CPh\cdot CH_2 \\ NH\text{—}CO}}{\Large\rangle}CHPh$, m. p. 154—155°, long needles, prepared by warming β-benzoyl-α-phenylpropionic acid and hydrazine hydrate in water, reacts with bromine in boiling glacial acetic acid to form 6-*hydroxy*-3 : 5-*diphenylpyridazine* $C_{16}H_{12}ON_2$, m. p. 183—184°, small needles. The latter is soluble in sodium hydroxide, and is converted by boiling phosphoryl chloride into 6-*chloro-*

3 : 5-*diphenylpyridazine*, m. p. 86—88°, which is reduced to 3 : 5-diphenylpyridazine, m. p. 139—140° (*platinichloride*,

$$2C_{16}H_{12}N_2,H_2PtCl_6,$$

yellow, crystalline powder; *picrate*, m. p. 137—138°), by hydriodic acid, D 1·22, at 160°.

In a similar manner, β-benzoyl-β-phenylpropionic acid and hydrazine hydrate yield 3 : 4-*diphenylpyridazin-6-one*, $C_{16}H_{14}ON_2$, m. p. 217—218°, from which, by methods similar to the preceding, have been successively prepared 6-*hydroxy*-3 : 4-*diphenylpyridazine*, m. p. 177—178°, 6-*chloro*-3 : 4-*diphenylpyridazine*, m. p. 110—111°, and 3 : 4-*diphenylpyridazine*, m. p. 106—107° (*platinichloride*, $2C_{16}H_{12}N_2,H_2PtCl_6$, dark yellow, microscopic plates; *picrate*, m. p 155—156°, dark yellow, crystalline powder).

β-Benzoyl-α-phenylpropionic acid and boiling aniline yield 1 : 2 : 4-*triphenylpyrrol-5-one*, $NPh{<}^{CPh:CH}_{CO-CHPh}$, m. p. 197—198°, faintly yellow, quadratic prisms. The latter becomes deep green when fused, and almost colourless again after solidification. By treating its solution in acetone and aqueous sodium hydroxide with acetyl chloride at 0°, 5-*acetoxy*-1 : 2 : 4-*triphenylpyrrole*, m. p. 172—173°, almost colourless plates (green when fused), is obtained, whilst phosphorus trichloride at 110—120° converts it into 5-*chloro*-1 : 2 : 4-*triphenylpyrrole*, m. p. 145—146, straw-yellow needles. The latter reacts with phosphoric and phosphoryl chlorides at 140° to form 3 : 5-*dichloro*-1 : 2 : 4-*triphenylpyrrole*, m. p. 152—153°, and is converted by hydriodic acid, D 1·22, and amorphous phosphorus at 150—160° into 1 : 2 : 4-*triphenylpyrrole*, m. p. 151—152°. 5-Chloro-1 : 2 : 4- triphenylpyrrole is converted by hot acetic anhydride and a few drops of concentrated sulphuric acid into 5-*chloro*-3-*acetyl*-1:2:4-*triphenylpyrrole*, $C_{24}H_{18}ONCl$, m. p. 188—189°, colourless plates, the position of the acetyl group being determined by the fact that the substance is converted into 5-*chloro*-3-*cinnamoyl* - 1 : 2 : 4 - *triphenylpyrrole*, $C_{31}H_{22}ONCl$, m. p. 150—151°, by warm alcohol, benzaldehyde, and sodium hydroxide.

β-Benzoyl-β-phenylpropionic acid and boiling aniline readily yield Klingemann's 1 : 2 : 3-triphenylpyrrol-5-one, m. p. 189°, from which 5-*chloro* -1 : 2 : 3 -*triphenylpyrrole*, m. p. 165—166°, and 1 : 2 : 3 -*triphenylpyrrole*, m. p. 176—177°, have been successively prepared. C. S.

Phenazine. FRIEDRICH KEHRMANN and EM. HAVAS (*Ber.*, 1913, **46**, 2820).—Methylphenazonium chloride, bromide, and nitrate can readily be isolated from concentrated aqueous solutions of the methosulphate (compare this vol., i, 298). C. S.

Salts of Azine Dyes. II. FRIEDRICH KEHRMANN, EM. HAVAS, and EUGÈNE GRANDMOUGIN (*Ber.*, 1913, **46**, 2802—2808. Compare this vol., i, 908).—The present results are communicated in consequence of the work of Ehrlich and Benda (this vol., i, 904) and of Pummerer and Gassner (*ibid.*, i, 991).

The colour change observed when many azonium bases are converted into salts is not necessarily indicative of constitutive change; in many cases it is due simply to a change in the auxochromic nature of the

amino-group during salt-formation. A number of dyes, such as *apo*-safranine, methyl*apo*safranine, 1:3-diaminophenylphenazonium bromide, 3:7- and 3:11-diaminophenylphenazonium chlorides, have been separately dissolved in alcohol and the solutions treated with regulated quantities of concentrated sulphuric acid; the amount of acid required for the production of different colours has been measured. The most important deductions made by the authors are as follows. The number of colours, with a given substance, agrees with the number of basic groups present, indicating that the individual basic groups possess different basicities, and that salt-formation proceeds step by step. Extraordinarily slight basicity is exhibited by all the salt-forming groups in a substance with the exception of one, by which the normal colour is conditioned; all other coloured salts exist only in quite strongly acidic solutions, and are immediately hydrolysed by dilution.

The influence of the position of an amino-group on the colour of the salts is also considered. An amino-group in the meta-position to the azine nitrogen is least influenced by hydrolysis. Its basic character is as strong as that of the amino-group in aniline, and a dye containing such a group forms a diacid salt even with only a slight excess of acid. An amino-group in position 11 (that is, in a phenyl nucleus), whether free or in a salt form, has practically no auxochromic influence. Also, such a group plays no part in strengthening the basicity, 3:11-di-aminophenylphenazonium chloride being in this respect similar to *apo*safranine.   C. S.

Action of Nitrous Acid on Ethyl Anilino-oximinoacetate.
LEOPOLD SEMPER and LEO LICHTENSTADT (*Annalen*, 1913, **400**, 302—332).—The substance $C_{10}H_{11}O_4N_3$, m. p. 169°, obtained by Jovitschitsch by the action of nitrous acid on ethyl anilino-oximino-acetate and described by him as ethyl phenyldioxatriazinecarboxylate (A., 1898, i, 93; 1899, i, 239; 1907, i, 98), has the composition $C_{10}H_9O_5N_3$ and m. p. 181·5° when quite pure, and proves to be *ethyl 7-nitro-1 : 2 : 4-benzoxadiazine-3-carboxylate,*

$$NO_2 \cdot C_6H_3 {<}{}^{NH \cdot C \cdot CO_2Et}_{O{-\!-}N} .$$
The yield of the substance is doubled by using 2 mols. of sodium nitrite instead of one (compare Jovitschitsch, *loc. cit.*). It forms a *potassium* derivative, $C_{10}H_8O_5N_3K$, dark red powder, and *benzoyl* derivative, $C_{17}H_{13}O_6N_3$, m. p. 165°, colourless crystals. Although ethyl oxanilate is obtained as a by-product in the formation of ethyl nitrobenzoxa-diazinecarboxylate, an intermediate product cannot be isolated; the same substance is also obtained, more slowly, by the action of nitric acid on ethyl anilino-oximinoacetate in glacial acetic acid.

By precipitating ethyl nitrobenzoxadiazinecarboxylate from acetone by water and treating the finely divided suspension with 0·2*N*-sodium hydroxide at 0°, an orange-yellow mass of the extremely unstable *7-nitro-1 : 2 : 4-benzoxadiazine-3-carboxylic acid,*

$$NO_2 \cdot C_6H_3 {<}{}^{NH \cdot C \cdot CO_2H}_{O{-\!-}N} ,$$
is obtained which can only be examined in the moist state. It decomposes at 118°, yielding nitrobenzoxadiazine, and regenerates the ester by treating its *silver* salt with ethyl iodide. *7-Nitro*-1 : 2 : 4-*benzoxadiazine*, $C_7H_5O_3N_3$, m.p. 240° (Jovitschitsch's phenyldioxatriazine, $C_7H_7O_3N_3$), is obtained from ethyl nitrobenzoxadiazinecarboxylate under the latter's conditions, except that $0.2N$-sodium hydroxide is employed; the *hydrochloride*, $C_7H_5O_3N_3$,HCl, m. p. above 300°, is a moderately stable, white substance.

By boiling for forty minutes with $0.2N$-sodium hydroxide (3 mols.), ethyl nitrobenzoxadiazinecarboxylate or nitrobenzoxadiazine is converted into *4-nitro-2-hydroxyphenylcarbamide*,

$$NO_2 \cdot C_6H_3(OH) \cdot NH \cdot CO \cdot NH_2,$$
m. p. 203° (Jovitschitsch's phenyldihydroxydihydrodioxatriazine, $C_7H_9O_4N_3$ [A., 1907, i, 98]), which develops an olive-green coloration with alcoholic ferric chloride, yields 5-nitro-2-aminophenol and 4-nitrocatechol by prolonged boiling with 10% sodium hydroxide, and is converted at 210° into ammonia and nitrobenzoxazolone (nitrocarbonyl-*o*-aminophenyl), m. p. 241° (St. v. Chelmicky, A., 1891, 52). The preceding transformations suffice to establish the constitution of 4-nitro-2-hydroxyphenylcarbamide. The position of the nitro-group in ethyl 7-nitro-1 : 2 : 4-benzoxadiazine-3-carboxylate is proved by the reduction of the ester to 2 : 5-diaminophenol by boiling alcohol and stannous chloride.

The course of the reaction whereby ethyl anilino-oximinoacetate is converted into ethyl 7-nitro-1 : 2 : 4-benzoxadiazine-3-carboxylate by nitrous acid is readily explained in the light of Stoermer's researches on the simultaneous nitriting and oxidising action of nitrous acid on methylaniline and diphenylamine (A., 1899, i, 42). The nitrous acid attacks the aniline group and forms a substance (annexed formula), which, like other such dinitro-compounds, loses nitrous acid with the production of the nitrobenzoxadiazinecarboxylate.

Reactions similar to that exhibited by ethyl anilino-oximinoacetate and nitrous acid are also shown by substances containing the group $NHPh \cdot C(:NOH) \cdot$ attached to $\cdot COPh$ or $\cdot CO \cdot NH_2$. Thus the action of nitrous acid (2 mols.) on anilino-oximinoacetophenone yields *7-nitro-3-benzoyl*-1 : 2 : 4-*benzoxadiazine*, $NO_2 \cdot C_6H_3 \overset{NH \cdot C Bz}{\underset{O \longrightarrow N}{<}}$, m. p. 178° (decomp.), scarlet needles, which forms a bluish-red solution in alkalis, the solution losing the benzoyl group by long keeping, and yielding 7-nitro-1 : 2 : 4-benzoxadiazine. *Anilino-oximinoacetamide*,

$$NHPh \cdot C(:NOH) \cdot CO \cdot NH_2,$$
decomp. 192°, colourless needles, prepared from concentrated aqueous ammonia and ethereal ethyl anilino-oximinoacetate, reacts with nitrous acid (2 mols.) to form chiefly phenyloxamide; a by-product, however, is *7-nitro*-1 : 2 : 4-*benzoxadiazine-3-carboxylamide*,

$$NO_2 \cdot C_6H_3 \overset{NH \cdot C \cdot CO \cdot NH_2}{\underset{O \longrightarrow N}{<}},$$
decomp. 240°, yellow crystals, the constitution of which follows from

the identity of the substance with the amide produced by the action of ammonia on ethyl 7-nitro-1 : 2 : 4-benzoxadiazine-3-carboxylate.

The action of nitrous acid (2 mols.) on oximinobenzanilide proceeds similarly and yet somewhat differently. Very little benzanilide is produced, the chief product being a *substance*, $C_{13}H_8O_3N_2$, m. p. 177—179°, which is very probably 5-nitro-1-phenylbenzoxazole (Fischer, A., 1906, i, 539); however, a small amount of a benzoxadiazine derivative is probably also formed, because the reaction product develops a deep violet-red coloration with alkalis.   C. S.

Preparation of Alkali Soluble Derivatives of Piaselenols [Benz*iso*selenodiazoles]. FELIX HEINEMANN (D.R.-P. 261412).— Benz*iso*selenodiazole, prepared by the action of selenous acid on *o*-phenylenediamine, is insoluble in water and alkalis, and the following compounds have been prepared with a view to eliminate this drawback.

3-*Hydroxybenzisoselenodiazole*, $C_6H_4ON_2Se$, yellowish-brown needles, is obtained when an aqueous solution of 3 : 4-diaminophenol hydrochloride is treated with sodium hydrogen selenite (1 mol.); it sinters and reddens at 200°, and has m. p. 209° (decomp.).

Benzisoselenodiazole-3-carboxylic acid, $C_7H_4O_2N_2Se$, m. p. 222—223°, a crystalline, rose-coloured powder, is prepared in a similar manner from 2 : 3-diaminobenzoic acid.
Benzisoselenodiazole-4-carboxylic acid is a colourless, crystalline powder with indefinite m. p., darkening at 260°, and decomposing violently at 290°.

(I.)

When 3-*p-nitro-o-sulphobenzeneazotolylene*-2 : 5-*diamine-4-sulphonic acid* is reduced it yields 2 : 3 : 5-*triaminotoluene-4-sulphonic acid*, and this on treatment with sodium hydrogen selenite gives rise to 4-*amino-3-methylbenziso*-selenodiazole-6-*sulphonic acid* (formula I); whilst naphthylene-1 : 2-diamine-5 : 7-disulphonic acid (A., 1906, i, 713) furnishes naphth*iso*selenodiazole-5 : 7-*disulphonic acid* (formula II), which is isolated as its crystalline *barium* salt by the addition of barium chloride to the reaction mixture.   F. M. G. M.

(II.)
Rosinduline Isomerides, Nos. 16 and 17. FRIEDRICH KEHRMANN and MARCELIEN CORDONE (*Ber.*, 1913, 46, 2974—2979. Compare Abstr., 1899, i, 79).—The condensation of 3-acetylamino-1 : 2-naphthaquinone with phenyl-*o*-phenylenediamine has now been improved and much better yields of the two *iso*rosindulines obtained. The methods of preparation and separation of salts of the two acetyl compounds first formed are described.

10-*Acetylaminophenyliso*naphthaphenazonium *chloride*,

$$C_6H_4 \begin{array}{c} N(C_6H_5Cl):C——C_6H_4 \\ \diagdown \quad\quad\quad\quad\quad \diagup \end{array} OH,$$
$$N══════C(NHAc)$$
the form in which the substance is isolated, forms crystalline grains,

with a metallic lustre, is almost black, but yields a reddish-brown solution in water, and in alcohol a solution which is olive-green in thin layers and purplish-violet in thick layers. The *platinichloride* forms brownish-black crystals, and the *nitrate*, dark brown needles. The salts dissolve in sulphuric acid to form a violet solution, which, after heating and dilution with water, yields 10-*aminophenyl*isonaphthaphenazine (isorosinduline, No. 16); the *nitrate* of this forms small, olive-green needles; the *platinichloride* is an olive-green, crystalline precipitate.

5-*Acetylaminophenyl*isonaphthazonium nitrate, the form in which this substance is isolated, is an orange-red, crystalline powder; the *platinichloride* is a brick-red, crystalline precipitate, and the *chloride* crystallises from water in long, brick-red needles on salting-out with sodium chloride. All attempts to eliminate the acetyl group led to further decomposition of the substance. T. A. H.

Constitution of Safranine. EM. HAVAS and R. BERNHARD (*Ber.*, 1913, **46**, 2723—2727).—According to Barbier and Sisley (A., 1908, i, 225), phenosafranine is not a single chemical individual, but consists of a mixture of *indo*safranine (I.) and amino*apo*safranine (II.), commercial phenosafranine containing 85% of the latter compound.
A compound of the constitution (II.) has now been prepared by the successive removal of one amino-group and the acetyl group from Ris's *p*-acetylaminosafranine (III.) (A., 1895, i, 148). It possesses the properties of an *apo*safranine, and, therefore, cannot form the main constituent of commercial phenosafranine.

Taken in conjunction with the work of Hewitt, Newman and Winmill (T., 1909, **95**, 577), the present results conclusively prove that phenosafranine is a single chemical individual and has the constitution represented in (I.).

The substances isolated by Barbier and Sisley are either hydrates or homologues, such as occur even in the purest commercial phenosafranine.

Acetylaminosafranine (III) is best prepared by the oxidation of di-*p*-aminodiphenylamine sulphate and acetyl-*p*-phenylenediamine by sodium dichromate in the presence of hydrochloric acid. It may also be obtained by oxidising a mixture of *p*-phenylenediamine, aniline and acetyl-*p*-phenylenediamine. In its appearance, tinctorial properties and absorption spectrum, it very closely resembles phenosafranine.

Aminosafranine is obtained in the form of its *sulphate* by boiling the preceding acetyl derivative with 10% sulphuric acid; the *platinichloride*, $C_{36}H_{32}N_{10}PtCl_8$, was analysed.

When treated with hydrochloric acid and sodium nitrite in alcoholic

solution, acetylaminosafranine is converted into *aminoaposafranine* (II), which forms a *platinichloride*, $C_{36}H_{30}N_8PtCl_6$, and is very similar to *apo*safranine.   F. B.

The Degradation of Uric Acid by Hydrogen Peroxide and an Iron Salt. KOHSHI OHTA (*Biochem. Zeitsch.*, 1913, **54**, 439—445). —By the treatment of uric acid with a boiling 30% solution of hydrogen peroxide in the presence of a ferric salt until all the uric acid was dissolved, the following products could be isolated. A crystalline substance, $C_3H_6O_3N_4$, which separated on cooling, with m. p. 235°, which is apparently carbonyldicarbamide ; a second crystalline substance separated from the mother liquors, which was not obtained pure and could not be identified. In addition, the following oxidation products were found : carbamide, oxalic acid and ammonia.

S. B. S.

Action of Aniline on Halogenated Phthaleins. VASSILI V. SCHARVIN (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 885—890) —The fact that anthraquinone derivatives containing hydroxyls, halogens, sodium or sulpho-groups in the α-positions are converted by the action of ammonia or primary amines into aminoanthraquinones which contain amino- or substituted amino-groups and act as stable violet-blue, blue or greenish-blue colouring matters, has led the author to apply this reaction to halogenated phthaleins.
Treatment of eosin with excess of freshly-distilled aniline in a sealed tube at 180—200° yields the *hexaanilino-fluoran* (annexed formula), which forms a deep, violet-blue, amorphous powder and yields a bluish-violet alcoholic solution and a pure blue solution in acetic acid. It has no acidic properties, but is faintly basic in character, giving with acids blue salts which exist only in presence of a large excess of acid, and are completely hydolysed on dilution with water. In dilute alcoholic solution it is readily decolorised by hyposulphite, but gradually resumes its original colour in contact with air.

In a similar manner, tetrabromophenolphthalein and aniline yield *hexa-anilinophthalophenone*,
which is almost identical in colour and properties with the product obtained from eosin. This compound is accompanied by a bromo-derivative containing 4·16% of bromine, which would indicate a more complex molecule than that given above, since one bromine atom remaining in the molecule would correspond with 9·74% of bromine.

An analogous colouring matter was obtained by the action of aniline on chlorinated eosin containing halogen in the third benzene nucleus.

All the above compounds act as substantive colouring matters, and dye silk and wool violet-blue in an acid bath. The absence of the connecting oxygen atom between the two benzene nuclei of the substituted hexa-anilinophthalophenone renders the latter a somewhat less fast colouring matter than the fluoran derivative. These colouring matters may be converted into sulpho-salts soluble in water by treatment at 120° with fuming sulphuric acid containing 12% of sulphur trioxide.   T. H. P.

Preparation of Chlorinated Products in the Anthraquinone Series. CHEMISCHE FABRIK GRIESHEIM-ELEKTRON (D.R.-P. 262076). —Chlorinated products are obtained when diazotised aminoanthraquinones are treated with hypochlorites ; the *compound* from anthraquinone-2-diazonium sulphate is a pale yellow powder, decomp. 90°, whilst anthraquinone-2 : 6-bisdiazonium sulphate gives rise to a yellow powder.   F. M. G. M.

Saponification of Ethers of Hydroxyazo-compounds. G. CHARRIER and G. PELLEGRINI (*Atti R. Accad. Sci. Torino*, 1913, **48**, 978—981).—These ethers can be readily saponified by acting on them with anhydrous aluminium chloride. When *o*-anisoleazo-β-naphthol is heated for a short time at 120—130° with four or five times its weight of aluminium chloride and the reaction mixture boiled with dilute sodium hydroxide, the *sodium* salt of phenol-2-azo-β-naphthol, $C_{16}H_{11}O_2N_2Na,3H_2O$, is obtained, and from it *phenol-2-azo-β-naphthol*, m. p. 193°, can be prepared. *o*-Phenetoleazo-β-naphthol behaves similarly.

p-Anisoleazo-β-naphthol yields *phenol-4-azo-β-naphthol*,

$$C_{16}H_{12}O_2N_2,$$

which crystallises in cantharides-green needles, m. p. 194°, and the same substance can be prepared similarly from *p*-phenetoleazo-β-naphthol.   R. V. S.

o-Aminoazobenzene. II. FELIX H. WITT (*Ber.*, 1913, **46**, 2557—2559. Compare A., 1912, i, 921).—As mentioned in the earlier paper, the researches of Gattermann and Wichmann (A., 1888, 829) indicate that the rearrangement of diazoaminobenzene must give rise to some *o*-aminoazobenzene besides the para-isomeride, because phenylazoiminobenzene, a dehydration product of the former, is present in the reaction product.

By maintaining the temperature below 40° during the rearrangement, the subsequent dehydration is checked, and up to 4% of the ortho-isomeride is found in the product and can be separated by recrystallisation of the mixture from benzene, in which the ortho-compound is much more soluble.

In common with other *o*-aminoazo-compounds (Goldschmidt and Rosell, A., 1890, 616; Goldschmidt and Poltzer, A., 1891, 839; Noelting and Wegelin, A., 1897, i, 155), *o*-aminoazobenzene condenses with aldehydes producing triazine compounds ; thus when warmed with

formaldehyde in solution in acetic acid to which a little concentrated hydrochloric acid has been added, it gives 2-*phenyl*-2 : 3-*dihydro*-1 : 2 : 4-*triazine*, $N\underset{\underset{NPh \cdot CH_2}{\diagup}}{\overset{\overset{-C_6H_4-}{\diagdown}}{<}}N$, yellowish-white needles, m. p. 210° (decomp.); a similar reaction with benzaldehyde in place of formaldehyde gives rise to 2 : 3-*diphenyl*-2 : 3-*dihydro*-1 : 2 : 4-*triazine*, $N\underset{\underset{NPh \cdot CHPh}{\diagup}}{\overset{\overset{-C_6H_4-}{\diagdown}}{<}}N$, very pale red crystals, decomp. at 215°.

<div align="right">D. F. T.</div>

Hydrolysis of Proteins with an Alcoholic Solution of Hydrogen Chloride. I. CHARLES WEIZMANN and GANESH SAKHARAM AGASHE (*Biochem. J.*, 1913, 7, 437—440).—The method is an attempt to shorten the usual process, by using a saturated alcoholic solution of hydrogen chloride from the beginning to serve both as a hydrolysing and an esterifying agent. The reagent is not so powerful as an aqueous solution for hydrolysis, as it contains less hydrogen chloride, and cannot be heated to so high a temperature. As expected, therefore, hydrolysis is not so complete. The proteins used, caseinogen and silk fibroin are only partly attacked, and the yield of separate amino-acids is poor.   W. D. H.

Indole Formation in the Hydrolysis of Proteins by Alkalis. E. HERZFELD (*Biochem. Zeitsch.*, 1913, 56, 82—94).—The indole was quantitatively estimated with the use of the colour reaction with the *p*-dimethylaminobenzaldehyde reagent, the spectrophotometric method of Herzfeld and Bauer being employed. It was found that small amounts of indole are obtainable from proteins on gentle warming with water. If proteins are treated with 0·5% sodium carbonate, indole is also produced; addition of hydrogen peroxide diminishes the amount, but addition of copper sulphate increases it. Similar results were obtained with 0·2% sodium hydroxide solution, but barium and calcium hydroxides gave smaller yields. It was found that larger yields were obtainable by increasing the concentration of the alkali hydroxide, the best results being produced with 9% sodium hydroxide; increase of the alkali concentration beyond this limit diminished the yield. One gram of protein was treated with 1000 c.c. of the alkaline solution. Under optimal conditions, tryptophan itself gives about 60% of the theoretical yield of indole. A pancreatic digestion product of caseinogen yielded 6·5% of the theoretical amount of indole, calculated on the assumption that this protein contains 0·8% tryptophan. Experiments were also arrived at with the object of ascertaining whether pyrrole and scatole are produced at the same time. The colour reactions employed for this purpose are described in some detail. No evidence of the production of these substances could be obtained.   S. B. S.

Separation of Proteins. III. Globulins. HENRY C. HASLAM (*Biochem. J.*, 1913, 7, 492—516).—The water-insoluble globulin of serum contains, or is closely associated with, rather more than 0·1

phosphorus %. About half of this belongs to a lecithin-like substance which amounts to 8—10% of the globulin freed from ψ-globulin. ψ-Globulin contains no phosphorus. By fractional salt precipitation, the details of which are given, the true globulin, ψ-globulin, and albumin can be satisfactorily separated.   W. D. H.

Racemisation of Proteins and their Derivatives Resulting from Tautomeric Change. II. The Racemisation of Casein. HENRY D. DAKIN and HAROLD W. DUDLEY (*J. Biol. Chem.*, 1913, 15, 263—269).—It has been shown by Dakin (this vol., i, 208) that the treatment of gelatin by dilute alkalis at low temperatures produces racemisation, which is explained on the assumption of a ketol-enol tautomerism of the CH·CO-group. From the character of the amino-acids obtained by hydrolysis, it is claimed that some conception may be formed as to their position in the protein molecule, the occurrence of optically active amino-acids being taken as evidence of their being terminal groups. The preparation of a "racemised" casein is described, which is in fact a hydrolysis product of caseinogen (scission of phosphoric acid having taken place), which on hydrolysis yields inactive alanine, *d*- and inactive valine, *l*- and inactive leucine, *l*-proline and inactive tyrosine, phenylalanine, aspartic and glutamic acids, arginine, lysine, and histidine. As alkalis are used in the synthesis of polypeptides, it is presumed that with present methods it is not possible to synthesise a naturally-occurring protein.   S. B. S.

The Proline Fraction Obtained by the Hydrolysis of Caseinogen. The Isolation of Aminobutyric Acid. FREDERICK WILLIAM FOREMAN (*Biochem. Zeitsch.*, 1913, 56, 1—10).—From the proline fraction of the hydrolysis products, chloroform extracts a non-crystallisable, coloured substance. The residue after extraction with cold alcohol leaves a product which is aminobutyric acid. Further quantities of this substance can also be isolated from the extract in hot alcohol. The cold alcoholic extract when concentrated and treated with cold alcohol yields a precipitate, which is not entirely soluble in amyl alcohol at 60°. From this insoluble fraction, a glassy substance was obtained, which gives a characteristic copper salt, and contains only half its nitrogen in the form of an amino-group, and apparently a piperidine ring. In the same fraction there is also probably a basic substance. There appear to be also in the proline fraction other substances in which the nitrogen is not in the form of amino-groups. A method is also described for preparing fresh *l*-proline, which consists in treating an alcoholic solution of the proline fraction with freshly precipitated, dried and powdered copper hydroxide. The copper salt of the proline passes into solution.   S. B. S.

Colloidal Properties of Hæmoglobin. FILIPPO BOTTAZZI (*Atti R. Accad. Lincei*, 1913, [v], 22, ii, 141—144).—By dialysis of the colouring matter of blood for four or five months, a pure product is obtained, which is gradually precipitated in the dialyser in very finely-divided form. It consists chiefly of methæmoglobin (95%).

It is almost insoluble in water and in neutral salts, but dissolves on addition of a trace of alkali, yielding a colloidal solution in which the colloid is electronegative. The product also dissolves in presence of a trace of acid, and the colloid in solution is then electropositive.

R. V. S.

The Combinations of Hæmoglobin with Oxygen and Carbon Monoxide. I. ARCHIBALD V. HILL (*Biochem. J.*, 1913, **7**, 471—480). —The oxygen and carbon monoxide dissociation curves of hæmoglobin differ according as salts and carbon dioxide are present or not. This has been explained on the theory that the simple molecules of hæmoglobin are aggregated into clusters. This explains all the facts provided two assumptions are made: (1) that the half-saturated molecules Hb_2O_2 and Hb_2CO are unstable, and change into either Hb_2, or $Hb_2(O_2)_2Hb_2(CO)_2$ or $Hb_2 \cdot CO \cdot O_2$; (2) that the half-saturated molecules combine much more readily with carbon monoxide than with oxygen. The first assumption can be explained as due to the fact that Hb_2 is $Hb \vdots Hb$, whilst Hb_2O_2 is $\vdots Hb \cdot Hb \vdots O_2$ with two unsaturated bonds which tend to combine at once with O_2 to form $O_2 \vdots Hb \cdot Hb \vdots O_2$. If these assumptions are justified, the deduction may be made that since carbon monoxide combines much more readily with $[Hb_2O_2$ than with Hb_2, hæmoglobin will take up more carbon monoxide at a given tension if a little oxygen is present than if it is completely absent. W. D. H.

The Combinations of Hæmoglobin with Oxygen and Carbon Monoxide. II. JOSEPH BARCROFT (*Biochem. J.*, 1913, **7**, 481—491). —The available data for the dissociation curves of blood agree very closely with the theoretical curves deduced from the following physical conceptions: (1) That the reaction is reversible:

$$Hb_n + nO_2 \rightleftharpoons Hb_nO_{2n};$$
(2) that n is the average number of molecules aggregated together, its value depending on the nature and concentration of the electrolytes in solution; (3) that acids change the equilibrium constant of the reaction without altering the degree of aggregation; (4) that the action does not involve the breakdown and reformation of the aggregates; and (5) that unsaturated oxides are unstable and break up into hæmoglobin and saturated oxides. An entirely similar conception of carboxyhæmoglobin is supported by the available data. So far as the curves deduced from Hill's formula, $y/100 = Kx^n/1 + Kx^n$, can be distinguished from those held by Haldane and Douglas's more complex formula, the experimental evidence favours the former.

W. D. H.

Action of Alkyloxides on Hæmin and its Derivatives. II. Conversion of Hæmin into Mesohæmin. HANS FISCHER and HEINRICH RÖSE (*Zeitsch. physiol. Chem.*, 1913, **88**, 9—24. Compare this vol., i, 1006).—By the action either of potassium hydroxide in methyl alcohol or of potassium ethoxide on hæmin, the crystalline iron salt of mesoporphyrin, for which the name mesohæmin is suggested, is obtained. This transformation proves the presence of four pyrrole

nuclei in hæmin. Hæmatoporphyrin likewise yields mesoporphyrin on treatment with alkyloxides, but the quantity is small.

On reducing hæmatoporphyrin solutions with sodium amalgam until they became colourless, crystalline hæmatoporphyrinogen could not be isolated, but the solution of the leuco-base was used for physiological experiments. For two days after injection into rabbits it had no action, on the third day it had a sensibilising action indicating conversion into an active porphyrin. The physiological bearing of the inactivity of the leuco-base is discussed. E. F. A.

Blood Pigments. I. Degradation of Hæmins to the Porphyrins. RICHARD WILLSTÄTTER and MAX FISCHER (*Zeitsch. physiol. Chem.*, 1913, 87, 423—498).—I. *Constitution of Haemin.*—There is a certain resemblance between the porphyrins derived from hæmin and from chlorophyll; hæmatoporphyrin and mesoporphyrin, for example, having many points of similarity with phyllo-, pyrro-, rodo-, erythro- and rubi-porphyrins. On far reaching degradation of both classes of porphyrins by oxidation or reduction, similar simple pyrrole derivatives are obtained.

When hæmin and hæmatoporphyrin are heated with potassium hydroxide in methyl alcohol in presence of much pyridine, they are converted cleanly into crystalline porphyrins. Hæmatoporphyrin yields a product *haemoporphyrin* with four oxygen atoms; hæmin gives the complex iron compound of mesoporphyrin. Brief heating of the magnesium derivative of hæmoporphyrin with soda-lime eliminates the carboxyl groups and yields a substance identical with aetioporphyrin, $C_{31}H_{36}N_4$, from chlorophyll in composition, properties, spectrum and basic character. Accordingly, hæmoporphyrin has the composition $C_{33}H_{36}O_4N_4$, which assigns the formula $C_{33}H_{32}O_4N_4FeCl$ to hæmin instead of that usually adopted with 34 atoms of carbon. The new formula is in agreement with the analyses of hæmin derivatives and also with the older analyses of Küster (A., 1904, i, 357).

The basic skeleton of aetioporphyrin is composed of four pyrrole nuclei so united that eight hydrogen atoms are spared as compared with simple junction of the nuclei. The formulæ proposed by Küster, Piloty and H. Fischer are replaced by the above representation of aetioporphyrin.

Etiophyllin, $C_{31}H_{34}N_4Mg$, contains magnesium, presumably attached to all four nitrogen atoms. It is assumed that a vinyl residue is united

with one of the pyrrole nuclei to a *cyclo*butene ring. The position of this ring and of the substituting methyl groups is uncertain.

It is considered that hæmin contains a bridged ring, such as is known in several alkaloids, in two of the pyrrole nuclei, and it is represented as follows:
When hæmin is converted into hæmatoporphyrin, the two bridged rings are broken, $>$C:C$<$ becoming $>$C·C$<$, and one vinyl residue only becomes coupled with a carbon atom of the pyrrole nucleus. In mesoporphyrin the vinyl group CH:CH is saturated, although analysis does not allow the number of hydrogen atoms in this compound to be settled definitely. This conception is in harmony with the observed unsymmetric way in which the hæmin molecule alters on degradation.

II. *Intermediate products in the formation of hæmatoporphyrin.*—Aqueous hydrogen bromide saturated at 0° converts hæmin into the *dihydrobromide,* $C_{33}H_{84}O_4N_4FeBr_2$, which crystallises similarly to hæmin in large, obliquely-cut prisms of blackish-blue lustre, and forming a dark blue powder. The solution in concentrated sulphuric acid is a bluish-red.

Hydrogen bromide and acetic acid acting on hæmin yield a *trihydro-bromide,* $C_{33}H_{85}O_4N_4FeBr_4$. This forms a brownish-red powder.

When ether is added directly the hæmin has dissolved in the hydrogen bromide-acetic acid mixture; the *salt,* $C_{33}H_{36}O_4N_4Br_2,2HBr$, is obtained in bright red flakes: it is hygroscopic.

When sodium acetate is added to the solution in acetic acid and ether the colour changes from green to brownish-red, and finally the *monoacetate,* $C_{33}H_{36}O_4N_4Br·OAc$, is obtained as a brownish-red powder.

By the action of liquid anhydrous hydrogen bromide on hæmin the iron is eliminated, and a *bromide,* $C_{33}H_{39}O_4N_4Br_5$, obtained in lustrous, violet-red or red, crystalline leaflets.

Liquid hydrogen chloride allowed to act on hæmin for a few minutes only gives rise to a *compound,* $C_{33}H_{36}O_4N_4FeCl_5$, which forms a hygroscopic, lustrous, violet residue. Methyl alcohol converts it into a *dimethyl* ester, crystallising in lustrous, brown, rhombic platelets; it is less basic than any known methyl derivative of hæmatoporphyrin.

By the action of methyl alcohol on the pentabromide a *dimethyl ether dimethyl ester* was obtained, which crystallised in large, lustrous, double pyramids, m. p. 163°.

Hæmin dissolves in liquid hydrogen chloride in sealed tubes with a bluish-red coloration. The product could not be properly purified. Methyl alcohol converted it into a *tetramethyl* compound differing from that above. It crystallises in long, thin, brown, matted needles, m. p. 165°.

III. *Porphyrins with more than four oxygen atoms.*—A convenient method of obtaining hæmin from centrifugalised blood is described.

Hæmatoporphyrin, $C_{33}H_{38}O_6N_4$, previously only known in an amorphous condition, crystallises in lustrous, violet ounded plates, which are reddish-brown by transmitted light. The hydrochloride crystallises in needles which are olive-green under the microscope, but form a red powder. A *dimethyl* ester forms a lustrous, dark red, crystalline crust, m. p. 149°. A second *ester* formed on heating with weaker acid is an intense red powder, m. p. 121°.

The crystalline tetramethyl derivative (Küster and Deihle, this vol., i, 1004) has the molecular weight about 600, agreeing with the formula $C_{37}H_{46}O_6H_4$.

The *dimethyl ether*, $C_{31}H_{34}N_4(OMe)_2(CO_2H)_2$, crystallises in very fine, brownish-red, lustrous, prismatic plates, obliquely-cut and often forming twins resembling a swallow's tail. It sinters on heating, m. p. above 270°.

The *monoacetate*, $OAc \cdot C_{31}H_{34}N_4(OH)(CO_2H)_2$, is a bluish-violet powder.

By the action of liquid hydrogen chloride on hæmin and hydrolysis of the intermediate product, $C_{33}H_{37}O_4N_4Cl_6$, with acids, *hæminoporphyrin* is formed, having the composition $(C_{33}H_{37}O_5;N_4)_2$. When heated in a vacuum at 105° no water is eliminated as is the case with hæmatoporphyrin. It forms a heavy, dark violet powder consisting of metallic, rectangular platelets with rounded corners. The *trihydrochloride* forms bright red needles. The *methyl* ester is an intense red powder. Solution in saturated hydrogen bromide and dilution with water converts hæminoporphyrin into hæmatoporphyrin.

Another compound, *hæmidoporphyrin*, is obtained from hæmin hydrochloride on treatment with sodium acetate in warm acetone solution. It crystallises in very large prisms with a brownish-violet lustre, and behaves as an hydroxy acid.

All these compounds are differentiated by their basic properties as determined by their distribution between hydrochloric acid and ether (compare Willstätter and Mieg, A., 1907, i, 69).

IV. *Porphyrins with four oxygen atoms.*—Hæmoporphyrin is shown to have the formula $C_{33}H_{36}O_4N_4$. It is more strongly basic than the isomeric porphyrins obtained from chlorophyll. The *dimethyl* ester crystallises in obliquely-cut prisms with a number of twin forms.

On heating hæmin with potassium hydroxide in methyl alcohol and pyridine, the compound, $C_{33}H_{32}O_5N_4FeK_3$, is obtained in long, transparent, red prisms. Mesohæmin is obtained from this in lustrous prisms or thin, yellowish-brown plates. The *dimethyl* ester,

$$C_{33}H_{32}N_4(CO_2Me)_2 \cdot FeCl,$$
forms brown needles of metallic lustre.

Aetioporphyrin from hæmoporphyrin crystallises in small, reddish-brown prisms with oblique faces, m. p. 265° (decomp.). Despite minor differences, it is shown to be identical with the product derived from chlorophyll.   E. F. A.

The Saturated Fatty Acid of Kephalin. JAKOB PARNAS (*Biochem. Zeitsch.*, 1913, **56**, 17—20).—The only fatty acid obtained by the hydrolysis of kephalin with barium hydroxide was stearic acid. There is no evidence of the existence of a "palmitylkephalin"

in addition to the "stearylkephalin" as has been assumed by other authors.   S. B. S.

The Nitrogenous Constituent of Kephalin. MONTAGUE H. RENALL (*Biochem. Zeitsch.*, 1913, **55**, 296—300).—An improved process for the preparation of kephalin from ox and sheep brain is described. The disintegrated brain is treated with acetone, then with alcohol, and then with light petroleum. The crude kephalin from the latter extract is precipitated by alcohol, and is purified by precipitating from its solution in ether by alcohol, and from its solution in water by hydrochloric acid. Like the human brain, the brains of ox and sheep contain the nitrogen in the form of a primary base, and in ox brain the presence of aminoethyl alcohol could be detected.   S. B. S.

Phosphatides, particularly those in Egg-Yolk. JULIUS EPPLER (*Zeitsch. physiol. Chem.*, 1913, **87**, 233—254).—The products of hydrolysis of that portion of the phosphatides of egg-lecithin which is not precipitated by cadmium chloride consist of aminoethyl alcohol (compare Trier, A., 1912, i, 233) in addition to choline.

The phosphatide soluble in alcohol after complete extraction of egg-yolk with ether is a monaminomonophosphatide.

Comparison of the organic portion of cadmium chloride compounds with the original phosphatides shows a diminution in the amount of carbon, hydrogen and oxygen. Some elimination of fatty acid molecules has perhaps taken place.   E. F. A.

Plastein Formation. II. P. GLAGOLEV (*Biochem. Zeitsch.*, 1913, **56**, 195—208).—The grade of formation of more complex products, as measured by the Sörensen formaldehyde titration method, from dialysed hydrolysis products of proteins by dialysed ferments is not smaller than in the case of peptones containing the salt content of ordinary undialysed fermentation mixtures. The addition of salts, however, especially of sodium chloride, facilitates the formation of precipitates during plastein formation. The addition of sodium chloride up to 1·84%, and of calcium chloride up to 0·6%, exert no influence on the number of free amino-groups which disappear (as measured by Sörensen's method) during plastein formation; in fact, there is no definite relationship between the amount of precipitate formed during plastein formation and the amount of apparent synthesis, as measured by the diminution of free amino-groups. Plastein formation can also take place in absence of added hydrochloric acid in the presence of dihydrogen potassium phosphate.   S. B. S.

Action of Nuclease. P. DE LA BLANCHARDIÈRE (*Zeitsch. physiol. Chem.*, 1913, **87**, 291—309).—The gradual liquefaction of sodium α-thymus-nucleate is conveniently followed by viscometric methods. In this way nuclease may be identified, and its activity approximately determined. Nuclease has been proved to be present in the liver, thymus, pancreas, and in the seeds of the soja bean (*Glycina hispida*). The amount is largest in the pancreas. Nuclease is soluble in glycerol. It has a smaller affinity for colloids than trypsin, and may be protected

from tryptic digestion by treatment with colloids or animal charcoal. Yeast-nucleic acid, although differing in composition from thymus-nucleic acid, is hydrolysed by the nuclease of the thymus and the liver. Pancreas extract and the pancreatic secretion behave differently in decomposing nucleic acid. The liquefying and hydrolysing activities of nuclease are not parallel, from which it is inferred that two separate enzymes exist, or that the same enzyme contains two different active groups.　　　　　　　　　　　　　　　　　　　　E. F. A.

Studies on Amylases. V. Experiments on the Purification of the Amylase of Malt. HENRY C. SHERMAN and M. D. SCHLESINGER (J. Amer. Chem. Soc., 1913, 35, 1617—1623. Compare A., 1912, i, 815).—By extracting ground malt with two and a-half times its weight of water, dilute alcohol, or very dilute acid phosphate solution at as low a temperature as possible, with subsequent dialysis followed by fractional precipitation by alcohol or acetone, products have been obtained of diastasic power of 1800—2200 (Lintner's scale). The preparations resemble pancreatic amylase in appearance, but are less readily soluble in water; their solutions coagulate at 80°, giving large flocks.
　　　　　　　　　　　　　　　　　　　D. F. T.

The Action of Maltase on Starch. ZENON WIERCHOWSKI (Biochem. Zeitsch., 1913, 56, 209—219).—The saccharification of starch by the maltase of maize yields, in every stage, dextrose and soluble starch as the sole products of hydrolysis. The small amounts of dextrins, which yield a violet or red colour with iodine, owe their existence only to the presence of diastase. Maize diastase causes scission of all three kinds of carbonyl bonds in the starch with equal intensity, so that no dextrins are formed as intermediate products. Maize diastase appears, therefore, to be an ideal enzyme for the complete saccharification of starch.　　　　　　　　　　S. B. S.

Enzymes. Asymmetric Syntheses through the Action of Hydroxynitrilases. I. VERNON K. KRIEBLE (J. Amer. Chem. Soc., 1913, 35, 1643—1647).—The result obtained earlier by the author (A., 1912, i, 482) that a certain sample of emulsin when acting on amygdalin gave a residue of l-mandelonitrile, whilst its action on a mixture of benzaldehyde and hydrocyanic acid effected the formation of d-mandelonitrile can be attributed to the occurrence of varying quantities of two hydroxynitrilases in emulsin, one correlated with the d- and the other with the l-nitrile.

These two enzymes might be expected separately in plants which contain prunasin or amygdalin, and sambunigrin which are glucosides derived from the d- and l-nitrile respectively. An enzyme activating the combination of benzaldehyde and hydrocyanic acid to d-mandelonitrile was actually found in the leaves and bark of Prunus serotina, and in the leaves of the peach tree; the product obtained under its influence was not the pure d-isomeride, but the small quantity of racemic product present may have been due to the spontaneous combination of the constituents. The amount of racemic product given by emulsin cannot be explained in this way, and is probably to be ascribed to the concurrent action of two enzymes.

The leaf extract of the common elder, which contains sambunigrin, did not give rise to the formation of any optically active compound from benzaldehyde and hydrocyanic acid; whether this is to be explained by the presence of two enzymes concurrently producing *d*- and *l*-isomerides has still to be decided. D. F. T.

The Influence of Acids and Alkalis on the Diastatic Ferment during the Stages of Regeneration. M. J. GRAMENITZKI (*Biochem. Zeitsch.*, 1913, **56**, 78—81).—It has been shown by .the author that the properties of the diastatic ferment, which have been lost by heating, can, under certain circumstances, be regenerated on keeping. It is now shown that the regenerative process is inhibited by acid, but accelerated by alkalis in certain low concentrations. This is in direct contrast to the action of acids and alkalis on the extracted ferment, of which the former class of substances function as activators and the latter as inhibitors. S. B. S.
Preparation of Soluble, Stable Derivatives of 3:3'-Di-amino-4:4'-dihydroxyarsenobenzene. ANTON DERING (D.R.-P. 261542).—It is found that 3:3'-diamino-4:4'-dihydroxyarsenobenzene hydrochloride combines with albumin acids to furnish compounds which are soluble in water or alkalis, and are of therapeutic value. The preparation of the following *compounds* is described with .(1) sodium nucleinate; (2) sodium caseinate; (3) sodium protalbinate; (4) sodium. lysalbinate, and (5) from a mixture of sodium protalbinate and lysalbinate; the dry substances are yellow, amorphous masses, the alkali salts greenish-grey lamellæ. F. M. G. M.

Preparation of Nuclear-substituted Mercury Derivatives of Aryloxy-fatty Acids and their Salts. FARBENFABRIKEN VORM. FRIEDR. BAYER & Co. (D.R.-P. 261229).—*Mercurithymolacetic anhydride* (annexed formula), a sand-like powder, is obtained when mercuric acetate and thymolacetic acid are heated together in aqueous-alcoholic solution at 70°.
a-*Guaiacolpropionic acid*, m. p. 55°, is prepared by the action of sodium guaiacol on a-bromo-propionic acid; on heating with mercuric acetate it gives rise to *mercuri-a-guaiacolpropionic acid*. These compounds are of therapeutic value, and others having the general formula

$$CO_2H \cdot R_1O \cdot R \cdot Hg \cdot OH,$$

where R is phenyl, naphthyl or their substituted derivatives, and R_1 alkyl or substituted alkyl groups, are also discussed.

F. M. G. M.

Preparation of Soluble Silver Salts of Mercury Derivatives of Hydrocarbons. FARBENFABRIKEN VORM. FRIEDR. BAYER & Co. (D.R.-P. 261875).—When the insoluble silver salts of the substituted mercury derivatives of hydrocarbons are treated with the alkali salts of amphoteric or faintly acidic substances they furnish soluble additive

compounds, and the following have been prepared: from hydroxy-mercurithymoxyl acetate with sodium diethylbarbiturate and from silver hydroxymercuribenzoate with sodium succinimide.

F. M. G. M.

Physiological Chemistry.

Physiological Observations following Descent from Pike's Peak to Colorado Springs. EDWARD C. SCHNEIDER (*Amer J. Physiol.*, 1913, **32**, 295—308).—The return of the blood to a normal state after descent from a great altitude is very slow. Details regarding the percentage of hæmoglobin, red corpuscles, blood volume, pulse rate, alveolar carbon dioxide pressure, etc., are given. The respiratory capacity is not greater in men who live high up than those of similar physique at sea level. W. D. H.

The Respiration of Pulverised Insects. FRED. BATTELLI and (Mlle.) LINA STERN (*Biochem. Zeitsch.*, 1913, **56**, 35—49).—Pulverised insects exhibit a high respiratory exchange, which in certain cases is as large at 40° as that of the living animals, but in others (flies, silk-worm moths) markedly smaller. The respiratory exchange increases with rising temperature up to 30°, and remains from this point constant until about 55°. A slight alkalinity increases in some cases the respiratory exchange, but higher alkalinities exert an inhibitory action, notably on the carbon dioxide production. In acid media both the oxygen consumption and carbon dioxide production are diminished. The gas-exchange takes place both in hypo- and iso-tonic solutions, and is not affected by addition of disodium hydrogen phosphate. It is not much larger in an atmosphere of oxygen than in one of air, and is not influenced by the addition of mammalian blood or of pnein. The addition of trypsin only depresses the respiratory exchange to a small extent. The alcohol and acetone preparations of pulverised insects also exhibit a distinctly high respiratory exchange. Attention is called by the authors to the differences between the respiratory exchanges of pulverised insects and of mammalian tissue; the former are to be ascribed to the presence of oxydases of unknown character.

S. B. S.

The Intensity of the Respiratory Exchanges of Insects. FRED. BATTELLI and LINA STERN (*Biochem. Zeitsch.*, 1913, **56**, 50—58). —The oxygen consumption, carbon dioxide production, and respiratory quotients of cockroaches, silk-worms, and of flies in various stages of development are tabulated. There is an increased respiratory exchange with increasing temperatures. This is also greater in the fully developed insects than in the larvæ, and the latter are more active than the chrysalis. S. B. S.

The Cholesterol and Cholesterol Ester Content of the Blood of Various Animals. FELIX KAUDERS (*Biochem. Zeitsch.*, 1913, **55**, 96—100).—A series of analytical results obtained by the Windaus digitonin method is tabulated. The cholesterol and cholesterol esters were estimated both in the serum and corpuscles.

S. B. S.

Lactic Acid in Blood. WALTER GRIESBACH and SIEGFRIED OPPENHEIMER (*Biochem. Zeitsch.*, 1913, **55**, 323—334).—The formation of lactic acid from various substances by the action of blood corpuscles was investigated. Dextrose, lævulose, mannose, and galactose were found to be capable of forming this acid, whereas arabinose and glucoheptose were not. Inositol was in the majority of cases found to be inactive, but in two cases a slight increase of lactic acid was found. Alanine was indifferent, and glycerol was also generally indifferent, although in one case it gave rise to a considerable amount of acid. It appears as if the same tissue from different individuals of the same species shows an inconstant behaviour as regards the formation of lactic acid from the same substance.

S. B. S.

Method for Extraction of Amino-acids from Different Constituents of the Blood. A. COSTANTINO (*Biochem. Zeitsch.*, 1913, **55**, 419—424).—One hundred c.c. of the blood or serum are mixed with 500 c.c. of 2% mercuric chloride solution containing 0·8% hydrochloric acid. The proteins are thereby precipitated. An aliquot part of the filtrate, obtained after centrifugalisation, is evaporated in vacuum after addition of magnesium oxide (in order to separate ammonia) to a small bulk, in which the formalin titration process is carried out. This is done after addition of solid barium chloride and hydroxide, filtering off the precipitate, and neutralising the filtrate to azolitmin. Where very small amounts of amino-acids are present, a certain known amount is added before these manipulations, so that larger amounts of alkali are required for titration.

S. B. S.

The Normal Sugar Content of the Blood of Rabbits and Dogs. ADOLF LOEWY and SIEGFRIED ROSENBERG (*Biochem. Zeitsch.*, 1913, **56**, 114—116).—The statement has often been made that the sugar in the blood of rabbits occurs abnormally as a result of the treatment of the animals (binding, exposing the arteries, etc.). The authors now show that a similar phenomenon can be observed in dogs. It was noticed, furthermore, that the blood removed under conditions of local anæsthesia (novocaine) contained less sugar than that removed from the same animals without anæsthesia, and that pain probably has some influence on the abnormally high sugar content in the blood of animals.

S. B. S.

Blood Glycolysis: its Extent and Significance in Carbohydrate Metabolism. The Supposed Existence of "Sucre virtuel" in Freshly Drawn Blood. JOHN J. R. MACLEOD [with A. M. WEDD] (*J. Biol. Chem.*, 1913, **15**, 497—514).—Unclotted

(hirudin) and defibrinated blood have the same glycolytic power, but potassium oxalate has a depressing action. The rate of glycolysis varies greatly, but in the mean about half the sugar disappears, in two and a-half hours at 40°. This is a function of the corpuscles. If much dextrose is added to the blood, the process may be depressed. The rate is the same in diabetic blood. The destruction of sugar in the blood in the intact animal is an almost negligible fraction of the total glycolysis. W. D. H.

Permeability of Blood Corpuscles for Amino-acids. A. COSTANTINO (*Biochem. Zeitsch.*, 1913, **55**, 411—418).—By suspending blood corpuscles in serum in which an excess of amino-acid had been dissolved, and estimating the nitrogenous substances titratable in the presence of formalin, it was found that these diminished in the serum and increased in the corpuscles. From this it follows that the latter are permeable to amino-acids, but, as experiment showed, only up to a certain limit. This corresponded nearly with the amount of amino-acids in the corpuscles of a dog at the time of digestion of food, that is, 45 mg. nitrogen per litre of corpuscles. The amount reached did not differ greatly whether asparagine, the acid hydrolysis products of caseinogen, or glycine was added to the serum. S. B. S.

The Amino-acid Nitrogen, which can be Estimated by the Formalin Method, in the Blood Corpuscles and Serum of Fasting and Fed Animals. A. COSTANTINO (*Biochem. Zeitsch.*, 1913, **55**, 402—417).—The author, by various methods described in some detail, is able to confirm the presence of amino-acids in the blood. The amount in fasting animals is less than that in fed animals, although there is no difference in the amounts in the serum in animals at different stages of nutrition. From this it follows that the excess of amino-acids in the blood of fed animals over that in blood of fasting animals is present in the corpuscles, which must consequently be permeable to these acids. The content of both serum and corpuscles in amino-acids is the same in all parts of the circulation, and this fact negatives the supposition of the deaminisation of the digestion products in the intestinal wall. Lymph contains only a small amount of nitrogen titratable in the presence of formalin. S. B. S.

The Influence of Lipoids on the Coagulation of Blood. FRIEDRICH RUMPF (*Biochem. Zeitsch.*, 1913, **55**, 101—115).—Lipoid emulsions (prepared from ox-brain) hasten the coagulation of oxalate plasma, but only to a slight extent, which is quantitatively far below the action of tissue extracts. There is no species specificity in this action. Plasma which has been deprived of its lipoids by light petroleum will only coagulate after addition of lipoids. This fact does not prove, however, that thrombokinase is a lipoid. The statement of Bordet and Delange, that lipoids, like tissue juices, cause the development of large quantities of thrombin in serum, appears to be incorrect, as the acceleration of clotting

4 *p* 2

caused by the former is insignificant compared with that caused by the latter (30 : 600). Peptone and hirudin bloods can be made to clot by tissue extracts, but not by lipoids. The lipoids, therefore, do not appear to be the actual active agents, although they do play some part in the clotting process. It seems therefore advisable to retain the term thrombokinase for the active substance of tissue juices.   S. B. S.

The Nature of Thrombin and Anti-thrombin. BERTRAM J. COLLINGWOOD and M. T. MACMAHON (*J. Physiol.*, 1913, **47**, 44—53). —Thrombin is destroyed by heat (50—60°), by acid, alkali, and trypsin. After destruction of Gamgee's thrombin, thrombokinase is still present; this preparation also contains fibrinogen. Antithrombin is destroyed by heat (60—65°) and by acid. It will act only in an alkaline medium; neutralisation inhibits, but does not destroy it. The rate of action of antithrombin varies directly with temperature in contrast with thrombin. It is suggested that thrombin is a protein, that antithrombin is a proteolytic enzyme, and that fibrin is a combination of thrombin and fibrinogen.
                                                           W. D. H.

The Properties of Rabbit's Serum after Treatment of the Animals with Emulsin. KOHSHI OHTA (*Biochem. Zeitsch.*, 1913, **54**, 430—438).—When rabbits have been immunised by several injections of emulsin, their serum exerts a greater inhibitory action on the action of the ferment than the serum of normal animals. This difference of action is, however, only marked when the serum is present in sufficient quantities. If d-galactose and dextrose are incubated together in the presence of immune serum, there is evidence of the formation of a disaccharide, of which small quantities of a phenylosazone could be isolated.   S. B. S.

Hæmolytic Action of Cyclamin–Cholesterol Mixtures. ERNST H. RIESENFELD and H. LUMMERZHEIM (*Zeitsch. physiol. Chem.*, 1913, **87**, 270—290).—On mixing equivalent quantities of cyclamin and cholesterol, a mixture is obtained in which the hæmolytic action of cyclamin is only partly suspended. Further addition of cholesterol has the effect of lessening the poisonous action. It is therefore inferred that the cyclamin-cholesterol complex is dissociated in solution. If the hæmolytic action of any cyclamin-cholesterol mixture is regarded as a measure of the amount of free cyclamin, it is possible to determine the dissociation constant K of the cyclamin-cholesteride, provided that the total amount of cyclamin and cholesterol in the mixture is known. Constant values for K are obtained by this method so long as the same blood solution is used, but different values of K are obtained with different blood solutions, owing probably to the presence of the serum. The serum has the property of lowering the hæmolytic activity of cyclamin, but acts quantitatively in a very variable manner.   E. F. A.

The Hæmolytic Lipoids of the Organs and the Influence on them of Administration of Dextrose. ARNO KIRSCHE (*Biochem. Zeitsch.*, 1913, 55, 169—188).—Various investigators have shown that the liver contains hæmolytic lipoids, which appear to have a special pathological significance in certain diseases, such as pernicious anæmia. The conception is now advanced that in fatty degeneration of the liver the lipoids are of two-fold origin, namely, those due to degeneration of the cell material itself, and those due to infiltration. To the former class only is to be ascribed the hæmolytic activity. This hypothesis has been tested in the following way: In a number of rabbits fatty degeneration was produced by the following methods: starvation, phloridzin, acute and chronic poisoning with tolylenediamine, maintenance of the animal at high temperatures, post-mortal autolysis. The lipoids were obtained from the liver by heating this organ with alcohol, then extracting with ether, and precipitating the lecithins from the ethereal extract by acetone; after distillation of the ether–acetone mixture the residue was weighed and used for experiment in methyl-alcoholic solution. The hæmolytic value of this solution was then determined. It was found that in all cases, both the quantity of extract and its hæmolytic value were increased in cases of fatty degeneration, especially in that produced by autolysis. Now it is supposed that administration of dextrose inhibits infiltration. A series of experiments similar to the above was carried out with this addition. If the action of sugar is correctly interpreted, then the lipoids derived from the sugar-fed animals should contain relatively larger amounts of fats derived from the cell degeneration, and consequently a higher hæmolytic value. This was actually found to be the case. Attention is also called to differences in the fatty-degenerated livers produced by different methods. S. B. S.

Digestion and Absorption under Normal and Pathological Conditions. EFIM S. LONDON (*Zeitsch. physiol. Chem.*, 1913, 87, 313—370).—This is a series of short papers on various aspects of the subject carried out on fistula dogs by London's methods.

I. *General Remarks*. E. S. LONDON.—Introductory.

II. *Does Absorption Occur in the Stomach?* J. S. TSCHEKUNÒV. —Many previous authors have stated that absorption occurs in the stomach. In the present experiments finely-divided meat alone or mixed with gliadin was given by the mouth, or solution of dextrose or sodium chloride by the gastric fistula. The material which left the stomach contained the same amount of sugar as given, and protein substances entirely leave the stomach with an accession of nitrogen. In no case was there a deficit in the food material introduced. The proteins were not much broken up in the stomach (amide nitrogen = 11—18%).

III. *Absorption Products of Protein*. N. A. DOBROVOLSKAJA.— Two hundred c.c. of a 5% solution of alanine was placed in the intestine. In five minutes excess of amide nitrogen was found in the blood of the jugular vein. During digestion, the amide

nitrogen rises in the portal blood; the rise in the general blood stream is smaller. In no case did the blood give a biuret reaction.

IV. *The Amount of Amide Nitrogen in the Peripheral Blood during Digestion.* A. D. VOLKOV.—In all stages of digestion the jugular blood contains a small excess of amide nitrogen (almost 4 mg. per 100 c.c. of serum).

V. *The Influence of Surgical Changes in the Stomach on Digestion.* S. F. KAPLAN.—The pyloric section of the stomach plays an important rôle in the proper evacuation of the organ. Hydrochloric acid stimulates the fundus, and inhibits the pylorus. Sodium hydrogen carbonate also stimulates the fundus. Partial extirpation of the fundus hastens the emptying of the stomach. Observations on the rate of emptying an "hour glass" stomach are also given.

VI. *Digestion in Intestinal Resections.* P. P. BRJUCHANOV.— Resection of the jejunum makes no difference on the course of excretion of the constituents of the chyme through a fistula, but the rate of output is raised. The complete compensation for the defect does not, however, occur in the upper section of the digestion canal; the ileum takes no special share in the work of compensation; the main share falls on the large intestine. Opium and tannalbin do not lessen, but increase, the discharge through the fistula. Similar details are given in reference to removal of other parts of the bowel.

VII. *The Course of Digestion of Anomalous Constituents of the Gastric Contents.* R. S. KRYM.—Preliminary digestion of the meat-powder given does not hasten the emptying of the stomach. Excess of hydrochloric acid inhibits it.

VIII. *Digestion of Peptonised Milk.* Z. O. MITSCHNIK.—In vitro, peptonised milk is more rapidly digested by gastric, but not by pancreatic, juice. In dogs it causes an increase in the flow of bile. In weakly children, and certain pathological conditions, its use is advised. Further work is in progress.

IX. *The Physiological Importance of the Omentum.* M. R. GILLELS.—The experiments confirm the conclusion that the omentum is of importance, but compensation by the mesentery takes place. Further work is in progress.

X. *The Digestive Glands in Normal and Defective Digestion.* P. P. BRJUCHANOV.—The injection of an aqueous solution of Witte's peptone into the jejunum increases the excretion of bile; this is not affected by acidification of the solution with hydrochloric acid, but if the solution is made alkaline by sodium hydrogen carbonate, it stops the bile flow. Neutral or alkaline peptone solution has no effect on the pancreas, but hydrochloric acid excites a flow of pancreatic juice.

XI. *Maximal Reduction of the Alimentary Tract.* With S. F. KAPLAN.—Experiments are recorded which show how greatly the canal may be reduced without serious harm in dogs. Large amounts of the small intestine, and the whole colon were removed, and the dogs were in good condition months afterwards.   W. D. H.

Absorption of Yeast-Nucleic Acid after Extensive Resection of the Small Intestine in Dogs. JUNICHI MAYESIMA (*Zeitsch. physiol. Chem.*, 1913, **87**, 418—122).—Removal of the greater part of the small intestine in dogs has no practical effect on the absorption of yeast-nucleic acid. Whether this is due to the remnants of the intestine, or to the activity of micro-organisms, is uncertain.   W. D. H.

The Influence of Chronic Insufficient Nutrition on Metabolism. NATHAN ZUNTZ, S. MORGULIS, and M. DIAKOV (*Biochem. Zeitsch.*, 1913, **55**, 341—354).—A dog was kept over a prolonged period (more than a year) on a diet insufficient for the energy needs of the organism, during which time the weight sank from 10 to 4·19 kilos. The animal then died of inanition. The caloric value of the food administered (rice and meat) was controlled during the whole time, and repeated measurements of the respiratory exchanges were made; the nitrogen excreted was also repeatedly estimated. It was found that the energy consumption per square metre of surface sank during this period from 931 cal. per 10 kilos. of weight to a minimum of 631 for half that body weight, and rose again towards the end of the life of the animal to 921 calories for a weight of 4·1 kilos. There was no indication of a gradual accommodation of the energy consumption to the diminished food supply.   S. B. S.

Metabolism during Pregnancy and Lactation. LUDWIG DIENES (*Biochem. Zeitsch*, 1913, **55**, 124—133).—The gaseous metabolism of a tracheotomised dog during pregnancy and lactation was carried out by a method, described in some detail, based on the Regnault-Reiset principle. The results indicate that there is a large increase in the metabolism during the later stages of pregnancy. During lactation, on the other hand, the increase in the metabolism is relatively small.   S. B. S.

The Carbohydrate Metabolism of the Isolated Heart–Lung Preparation. S. W PATTERSON and ERNEST H. STARLING (*J. Physiol.*, 1913, **47**, 137—148).—Starling and Knowlton stated that the diabatic heart is unable to utilise sugar as well as the normal heart. Furthermore accurate work has shown that this is not the case. The main purport of the present paper is to withdraw the former conclusions, and explain Maclean and Smedley's results, which seemed to confirm it; the glycogen of the heart muscle is a varying and disturbing factor, which may account for certain discrepancies. The view that the primary factor in diabetes is an absence of the power of the tissues to consume sugar is abandoned.   W. D. H.

The Rate of Resorption of Proteins and their Degradation Products from the Small Intestine. HERMANN MESSERLI (*Biochem. Zeitsch.*, 1913, **54**, 446—473).—The experiments were

carried out on a dog with a Thiry-Vella fistula. The various products under investigation were introduced into the fistula, and removed after a definite interval by a method described by the author. The amount of resorption of proteins and degradation products was determined by estimations of nitrogen. All experiments were carried out on the same animal. The amounts of genuine proteins taken up in ten minutes may be represented by the following numbers: Serum, 20; gliadin, 16; caseinogen, 12; hæmoglobin, 8. The less degraded proteins, such as peptones, are resorbed more rapidly than the products of complete acid hydrolysis. This fact indicates that the proteins are not degraded completely in the small intestines. During a diet poor in proteins, the resorbability of various proteins progressively diminished, but increased again when the animal reverted to a protein-rich diet. This phenomenon was observed, however, only in the first experiments. In later experiments the resorption was less during the subsequent period of rich protein diet. This is probably due to the fact that after the various treatments to which the animal had been subjected, the cells of the intestine had lost their physiological functions as regards the resorption of nitrogenous products. Their capacity for taking up sugar remained, however, unimpaired.

S. B. S.

The Pentoses as a Source of Energy in the Animal Organism. P. Schirokich (*Biochem. Zeitsch.*, 1913, **55**, 370—392). —The experiments were carried out with *l*-arabinose prepared from cherry-gum. It was found that the addition of this carbohydrate to a given basal diet caused very little rise in the respiratory quotient, and about half of the amount ingested was excreted unchanged in the urine. When dextrose was given in corresponding quantities, a certain increase in the respiratory quotient could be ascertained. The increased oxygen consumption, which takes place normally after a meal, is slightly diminished by the addition of dextrose to the diet, and largely diminished by arabinose.

S. B. S.

The Biological Significance of Phosphorus for the Growing Organism. I. The Influence of Phosphorus on the Growth of Animals and on the Phosphorus and Nitrogen Metabolism. M. Masslov (*Biochem. Zeitsch.*, 1913, **55**, 45—62).—The rate of growth of puppies from three different litters on diets rich and poor in phosphorus was investigated. As basal diets a gruel containing rice, albumin and sugar, cow's milk alone, cow's milk in which the caseinogen was replaced by egg-albumin, which was therefore poor in phosphorus content, and mixed diets of meat, milk, and porridge were employed. The animals were found to thrive only on the mixed diet. The animal fed on milk lived longer than the other animals, but even in this case it finally died of inanition. Phosphorus was added in other experiments after a period on the phosphorus-poor basal diets, in the form either of lecithin, glycerophosphate, or inorganic phosphate. The addition of

lecithin caused a temporary improvement of condition, but in this, as in all the other cases in which phosphorus was added, the animals finally succumbed. The rate of growth when the animals were transferred from a normal to a special diet was not affected immediately, but loss of weight occurred only when they had been a certain time on the abnormal diet. The experiments here recorded do not show conclusively whether the normal growth is due to phosphorus in any special form of combination, or to some other factor. S. B. S.

The Biological Significance of Phosphorus for the Growing Organism. II. The Content of Phosphorus and Intracellular Ferments in the Various Organs. M. MASSLOV (*Biochem. Zeitsch.*, 1913, **56**, 174—194).—The author gives the content in inorganic, organic, and phosphatide phosphorus of the organs of the animals fed by the methods described in the former paper (preceding abstract). The chief loss of the organs during a period of phosphorus starvation is in the inorganic phosphorus. The least loss is in the "organic" phosphorus (nucleoproteins, etc.). The lipoid phosphorus is less stable. Heart and brain do not under any conditions suffer loss in phosphorus, whereas the liver, intestines, muscles, bone-marrow, and kidneys lose considerable quantities during phosphorus starvation. When this loss attains certain limits, the animals die. The only phosphorus compound which produced, when added to the phosphorus-poor diet, an increase in the phosphorus-content of the organs, was lecithin. As regards the intracellular ferments, it was found that on a mixed milk and meat diet, there was a general increase in the fermentative energy of the organs, especially of the lipolytic, amylolytic, and diastatic energy. The development of the catalytic and nucleolytic energies was less marked. Under the influence of phosphorus starvation, not only is there no increase of fermentative energy of the organs, but in certain cases there is a distinct diminution. S. B. S.

The Soft Roes of Fish as Foodstuff for Man. JOSEF KÖNIG and J. GROSSFELD (*Biochem. Zeitsch.*, 1913, **54**, 333—350).—The soft roes from herring and carp were submitted to chemical examination by methods described in some detail, and found to contain meat bases (xanthine and creatinine) and free amino-acids in addition to the protamines, which exist combined with nucleic acid. The fatty substances consist to a large extent of lecithin (20·2—20·7%) and cholesterol (11·2—17·9%). S. B. S.

The Hard Roes of Fish as Foodstuff for Man. JOSEF KÖNIG and J. GROSSFELD (*Biochem. Zeitsch.*, 1913, **54**, 351—394).—The eggs of fish contain a relatively small amount of water as compared with hen's egg; they contain also meat bases, amino-acids, together with ichthulin, as chief protein (which is insoluble in water), albumin, and quantities of fat, which vary in the different species. All the roes investigated contain xanthine substances and creatinine. Xanthine and hypoxanthine were isolated, and the presence of the

following amino-acids was proved, viz., taurine, *l*-tyrosine, and glycine. The presence of thymine was also determined. The proteins contain relatively large quantities of sulphur and phosphorus. No protamines could be isolated from the ichthulins. These substances, on hydrolysis with sulphuric acid, yield purine bases, as Hammarsten and Levene and Mandel have already shown. The ichthulins and albumins yield, furthermore, on hydrolysis, tyrosine, leucine, arginine, histidine, and small quantities of lysine. The ichthulin of carp yields also glutamic acid. The fats contain large quantities of lecithin (up to nearly 60%), and not inconsiderable amounts of cholesterol (3·9—14%). The roes which are poorest in fats contain the largest amounts of lecithin. Caviare and other roes contain free acids, which increase in amount on putrefaction. Of the mineral matter, the acid ions are in excess of the basic ions, as the sulphur and phosphorus are in organic combination.

S. B. S.

Chemical Differentiation of the Central Nervous System. III. Chemical Differentiation of the Brain of the Albino Rat during Growth. Waldemar Koch and (Miss) Mathilde L. Koch (*J. Biol. Chem.*, 1913, **15**, 423—448).—The principal chemical changes which occur in the rat's brain during growth are: a decrease in water which begins before medullation sets in; a relative fall in protein due to appearance of lipoids. The lipoids which appear with medullation are cerebrosides and sulphatides. The phosphatides increase before medullation, and occur both in cells and sheaths. Organic sulphur compounds diminish relatively with age, whilst the colloidal sulphur rises. The increase of colloidal matter, which is relatively inactive supporting matter, is one factor in the slowing of metabolism which characterises senescence. W. D. H.

The Action of Ions and Lipoids on the Frog's Heart. A. J. Clark (*J. Physiol.*, 1913, **47**, 66—107).—An excised frog's heart after perfusion for a few hours passes into a hypodynamic state, and is more readily affected by ionic changes in the fluid perfused. It is improved by increase in the calcium relative to sodium and potassium, and not much improved by increase in hydroxyl ions. The hypodynamic state is caused by a loss of power to combine with calcium. The hydrogen ion concentration must be within narrow limits ($10^{-6·7}$ and $10^{-8·5}$), and a buffer must be present to stabilise the concentrations. A slight increase of carbon dioxide, amino-acids, glycogen, and sugars to a less extent benefit the hypodynamic heart. But the best of all are soaps of the high aromatic fatty acids higher than decoic acid; these soaps form insoluble calcium compounds, but other substances which form similar compounds injure the heart. Serum (but not the serum proteins) is beneficial; the same is true for serum lipoids, lecithin, and saponified serum lipoids. The loss of lipoids is the chief cause of the hypodynamic state; and the function of calcium is to cause an alteration in the colloidal state of the lipoids at the cell-surface. W. D. H.

The Mucin of the Stomach. J. López-Suárez (*Biochem. Zeitsch.*, 1913, **56**, 167—175).—By extraction of mucin from pig's stomach with 2% potassium hydroxide solution, and addition of acetic acid to the extract, a product was obtained which contained purine bases and also lipoids. By repeated solution in alkali and reprecipitation, a substance free from purine bases could be obtained. This contained (after extraction with alcohol and ether), 53·8% carbon, 7·29% hydrogen, 16·30% nitrogen, 1·47% sulphur, and 4·45% phosphorus. Chondroitinsulphuric acid, prepared from the mucin by Kondo's method, contained 43·3% carbon, 5·47% hydrogen, 5·37% nitrogen, and 4·29% sulphur. The former product contains less oxygen and sulphur than a true mucin, and in other respects differs from it widely in chemical composition. The stomach mucin appears to be a mixture of proteins, in which the chondoprotein is largely replaced by a nucleoprotein.　　S. B. S.

Carbon Dioxide Formation in the Liver. Eduard Freise (*Biochem. Zeitsch.*, 1913, **54**, 474—502).—An apparatus is described for perfusing liver with blood, and for estimating the carbon dioxide formed in the process, for which purpose the blood is treated with a stream of oxygen, and the mixture of gases is then led through a special absorption apparatus containing barium hydroxide solution. By the artificial perfusion of livers of rabbits or dogs with the blood of calf or ox, 54·74—192·48 mg. of carbon dioxide were formed per minute by 1 kilo. of the organ. This amount could be increased up to 50% by the addition of various oxidisable substances, such as dextrose, pyruvic acid, glyceric acid, and lactic acid. The addition to the blood, on the other hand, of galactose, glyoxylic acid, glycollic acid, and acetic acid, exerted no such influence.　　S. B. S.

The Effect of Water Ingestion on the Fatty Changes of the Liver in Fasting Rabbits. M. R. Smirnow (*Amer. J. Physiol.*, 1913, **32**, 309—314).—Fasting causes in rabbits fatty infiltration of the liver; if water is given, however, this as a rule does not occur.　　W. D. H.

Formation of Sugar in the Frog's Liver. Ivar Bang (*Biochem. Zeitsch.*, 1913, **56**, 153—157).—A reply to the criticisms of Lesser (this vol., i, 931).　　S. B. S.

Glyoxalase. III. The Distribution of the Enzyme and its Relation to the Pancreas. Henry D. Dakin and Harold W. Dudley (*J. Biol. Chem.*, 1913, **15**, 463—474).—This enzyme converts α-ketonic aldehydes, such as methyl- and phenyl-glyoxals, into optically active lactic and mandelic acids. It is probably important in carbohydrate metabolism. It is found in all tissues except the pancreas, which tissue contains an anti-glyoxalase, that is very powerful, and thermolabile. The inhibiting action is not limited to glyoxalase derived from the same species. It is present in pancreatic juice, in commercial pancreatic preparations, and in

the dry state lasts indefinitely (eight years in one case). It is destroyed at 85°, and by digestion with weak hydrochloric acid. Weak alkali is less injurious. The inactivation it produces is a function of the time of action. Whether it is an enzyme or not is unsettled. It is not trypsin, lipase, or diastase. The pyloric caeca of the fish (considered to be homologous with the pancreas) contain no anti-glyoxalase. The blood and tissues of diabetic men and dogs contain less glyoxalase than the normal, but this conclusion demands further work.   W. D. H.

Influence of Pancreatic and Duodenal Extracts on the Glycosuria and Respiratory Metabolism of Depancreatised Dogs. JOHN R. MURLIN and B. KRAMER (*J. Biol. Chem.*, 1913, 15, 365—383).—The effect of injecting pancreatic extract by itself and when mixed with duodenal mucosa extract on the dextrose : nitrogen ratio in the urine of a depancreatised dog, was investigated. This ratio was increased in the day following the injection, but a slight fall followed in the hourly elimination shortly after the injection, which was followed by a compensatory increase. In one case, when the mixed extracts were injected, there was for a short interval a complete disappearance of sugar. A similar effect could be produced by making Ringer's solution as alkaline as the extracts, and a marked diminution of sugar output could also be caused temporarily by injection of 2% sodium carbonate solution. The effects of the extracts are to be explained possibly by the alteration of the acidity. It is also possible that pancreatic extracts alter the permeability of the kidneys. The extracts, within the time of maximal glycosuria, produced no effect on the respiratory quotient, and there is therefore no evidence that they increased the combustibility of sugar in the organism.   S. B. S.

The Production and Utilisation of Glycogen in Normal and Diabetic Animals. E. W. H. CRUICKSHANK (*J. Physiol.*, 1913, 47, 1—14).—After extirpation of the pancreas, the liver rapidly and almost completely loses its glycogen, and becomes loaded with fat. Minkowski's statement that feeding diabetic animals on lævulose produces glycogen-storage was not confirmed. The percentage of glycogen in heart muscle varies, but averages 0·5; it is increased by copious carbohydrate food, and lessened by a diet devoid of protein and carbohydrate. During great activity, the heart may use all its stored glycogen in a few hours. In pancreatic diabetes, the cardiac glycogen rises, and may be entirely consumed if great activity of the heart occurs, as, for instance, after adrenaline. After death, both normal and diabetic hearts contain a glycogeno-lytic enzyme, so that the glycogen rapidly disappears if the heart is kept warm after the incubation has ceased.   W. D. H.

Influence of Extirpation of the Pancreas on the Endo-cellular Activity of the Liver Diastase. I. ERNST J. LESSER (*Biochem. Z-itsch.*, 1913, 55, 355—356).—The extirpation of the pancreas from frogs causes changes in the organism in many

respects analogous to those produced by diabetes in the human subject. It was shown that whereas the post-mortem diminution of the liver glycogen in frogs with intact pancreas was 4·2% in three and a-half hours at 22°, that of the depancreatised animals was 15·5%. The difference is explained, as the result of the author's previous experiments (this vol., i, 1129), by the assumption that the inhibition of the diffusion of the diastase to the glycogen which exists in the intact frogs has been removed. The experiments were carried out by the method already described, care being taken to keep the livers as free from damage as possible after removal from the body.   S. B. S.

The Physiology of the Glands. XIV. The Function of the Spleen as an Organ of Protein Metabolism, and the Compensatory Processes after Splenectomy. LEON ASHER and HANS SOLLBERGER (*Biochem. Zeitsch.*, 1913, 55, 13—44).—Immediately after the extirpation of the spleen of a normal rabbit on an iron-rich diet, there is an increase in the hæmoglobin content, and the number of red corpuscles in the blood, which may be explained by diminution of hæmolysis in the absence of the spleen and possibly an increased functioning capacity of the bone-marrow. The withdrawal of a small quantity of blood from the splenectomised animal causes a smaller diminution of hæmoglobin and of blood corpuscles than in a normal animal, and in the former case the blood much more rapidly attains its normal, or even hypernormal, condition. This fact indicates increased functional capacity of the bone-marrow when the spleen is absent. A similar difference between the splenectomised and normal animals was observed when larger amounts of blood were withdrawn. A difference was also observed when the organism was deprived of oxygen by the administration of hydrocyanic acid administered subcutaneously in the form of *aqua amygdalarum amarum.* In the splenectomised animal the treatment resulted ·again in a smaller diminution of hæmoglobin and red corpuscles, and the reversion to the normal condition of the blood was also more rapid. The extirpation of the thyroids had no specific effect on the hæmoglobin formation in splenectomised animals, or on the effect of hydrocyanic acid on either the splenectomised or normal animals. The general conclusion from the experiments seems to be that on iron-rich diet the functions of the bone-marrow are increased in the absence of the spleen.
                                                S. B. S.

The Intra-renal Resorption of Chlorides in Different Conditions of the Kidney. RAPHAEL LÉPINE and RAYMOND BOULUD (*Compt. rend.*, 1913, 157, 487—490. Compare *ibid.*, 1913, 156, 1958).—The resorption of chlorides by the kidneys, on exercising a contra-pressure by means of a canula inserted in the urether and connected to a vessel of water, is reduced to an almost negligible quantity if the water is replaced by a solution of quinine sulphate (1 in 250), or by solutions of numerous toxic substances, or by the use of water after previous section of the splanchnic nerve.
                                                W. G.

The Iodine Content of Fish Thyroids. ALEXANDER T. CAMERON (*Biochem. J.*, 1913, **7**, 466—470).—Although iodine has been found in many marine animals, no estimations have hitherto been made for the thyroids of fishes; the percentage in the thyroids of the ray and dogfish averages 1·16%. The highest figure previously obtained in mammals is 0·7 in the dog.   W. D. H.

The Carbon Dioxide Formation in Surviving Perfused Muscles. HERBERT ELIAS (*Biochem. Zeitsch.*, 1913, **55**, 153—168).— The hinder extremities of dogs were employed, and they were perfused with ox-blood by the apparatus described by Freise (this vol., i, 1267), whose method of estimating the amount of carbon dioxide formed, was employed. At rest, the muscles produce about 7 mg. of carbon dioxide per kilo. per minute, which quantity can be largely increased by tetanisation (up to fifteen times the amount).   S. B. S.

Glycolysis by Muscular Tissue. ALFRED GIGON and MAX MASSINI (*Biochem. Zeitsch.*, 1913, **55**, 189—194).—This work was undertaken with the object of reinvestigating the statement of Cohnheim, that sugar is destroyed by incubation with muscular tissue, only in presence of pancreatic substances, as this result has not been confirmed by subsequent observers. A method is described for removal from rabbits of muscular tissue under aseptic conditions. This was disintegrated by freezing with solid carbon dioxide in sterile leather bags and breaking up in the frozen state. It was found that muscular tissue alone, in the absence of pancreas or liver powder, was capable of destroying 85% of the added sugar within twenty-four hours. Salts appear to be necessary for the process, and the best results were obtained when the sugar was incubated with the tissue in Ringer's fluid in the presence of small quantities of sodium hydrogen carbonate. The addition of pancreas, liver, or suprarenal tissue did not appear to increase the amount of sugar destruction.   S. B. S.

Pigments. A New Method for the Preparation and a Comparison of the Various Hair Pigments. HUGO FASAL (*Biochem. Zeitsch.*, 1913, **55**, 393—401).—The method of preparation consisted in treating the hair or other keratinous material with twenty-five times the weight of cold saturated potassium hydroxide solution. The protein is thereby dissolved, and the pigment separates; it is purified by dissolving in hot 5% potassium hydroxide solution, in which it dissolves; the solution is filtered off from any undissolved inorganic matter when cold, and the pigment is then precipitated by addition of acid. The examination of hair of different colours indicated that the difference in colour is due to the differences in the amount of pigment, and dark hair which has been deprived of its colour by hydrogen peroxide is nearly free from pigment. White hair contains but very small quantities. The ratio of the amount of pigment in the most strongly coloured hair to that in the least coloured was found to be 30 : 1.   S. B. S.

Investigations on Cell Proteins by means of Addition of Formalin. HUGO WIENER (*Biochem. Zeitsch.*, 1913, **56**, 122—152).— The cells of organs of different animals contain soluble proteins, which can be divided into two classes. The chief difference between these is that one class is precipitated by formalin, whereas the other is not. The proteins, which are precipitable by formalin, are considered by the author to belong to the tissue proteins. On washing out the organs in situ, the soluble proteins do not go entirely into the saline solution, owing, apparently, to the semipermeability of the cell-walls. They are only extractible when the cells are destroyed, either by grinding to a paste, or better still, by drying to a powder by Wiechowski's method. If, however, formalin (2%) is added to the saline perfusion liquid, the cell walls are injured, and the semipermeability is destroyed. The soluble proteins can ·then be readily washed out. In this case, only the soluble proteins which are not precipitated by formalin are obtained. By long perfusion with saline, the walls are also slightly injured, and a small amount of soluble proteins will pass out, so that it is difficult to obtain a perfusion liquid protein-free. Formalin can be used to separate three kinds of protein in the cell, namely, the insoluble proteins, the soluble proteins precipitable by formalin, and the soluble proteins not precipitable by formalin. From a comparison of the amounts obtained from the livers of fed and fasting dogs (the latter, for example, contains small quantities of soluble protein not precipitable by formalin), the conclusion is drawn that the three classes represent stages in the conversion of the protein of the food into the protein of the organ; there is, that is to say, no hard and fast line between the fixed and circulating proteins.

S. B. S.

The Distribution of a Keto-reductase in Tissues. L. VON LAGERMARK (*Biochem. Zeitsch.*, 1913, **55**, 458—462).—Friedmann and Maase have shown that the liver contains a ferment capable of reducing acetoacetic acid to *l*-β-hydroxybutyric acid. It is now shown that this ferment exists also in the muscles and in the kidneys, but not in blood, lungs, the pancreas, or the spleen. The organs investigated were removed from fasting dogs. S. B. S.

Changes in the Reaction of Growing Organisms to Narcotics. HORACE M. VERNON (*J. Physiol.*, 1913, **47**, 15—29).— As tadpoles grow, the narcotising concentration of methyl and ethyl alcohol falls, but that of propyl alcohol remains constant, and of higher alcohols increases; the quotients between the narcotising concentration of successive alcohols vary. The effect of ethyl acetate, propionate, butyrate, and valerate does not alter with age; that of three ketones diminished during growth. The fatal concentrations of monohydric alcohols vary greatly with age. These changes are attributed in most part to changes in the composition of cell-lipoids. W. D. H.

The Function of the Ferments in the Animal Body after Introduction of Killed Tubercle Bacilli. Nina Kotschnev (*Biochem. Zeitsch.*, 1913, 55, 481—494).—The introduction of killed tubercle bacilli into rabbits and guinea-pigs caused a diminution of the lipoclastic properties of the serum and organs, and an increase in their antitrypsin and nuclease content. The catalase of the serum and organs was diminished in energy in the case of guinea-pigs only. There was a slight diminution of the amylase and diastase content of serum and organs.   S. B. S.

The Presence of Adenase in the Human Body. Esmond R. Long (*J. Biol. Chem.*, 1913, 15, 449—462).—Aderase could not be found in human adult liver, the placenta or fœtal liver, brain, bone, thymus, stomach, intestine, pancreas, lungs, and spleen. It is, however, present somewhere in the fœtus, for if the entire fœtal material is mixed with adenine, hypoxanthine is formed. Hypoxanthine is always formed in the autolysis of human tissues, and in the absence of adenase is probably due to the action of adenosine deamidase and inosine hydrolase.   W. D. H.

The Tyrosineoxydase, Polyphenoloxydase, and Oxydones of Insects. Fred. Battelli and Lina Stern (*Biochem. Zeitsch.*, 1913, 56, 59—77).—All the above ferments are contained in the insects investigated. The fully developed insect contains less polyphenol oxydase than the larva and chrysalis of the same species. p-Phenylenediamine is oxidised less energetically than quinol and pyrogallol by pulverised insects, which is in marked contrast to the action of vertebrate tissue. There is no parallelism between the polyphenoloxydase content of insects and the respiratory exchange of the living insect. As a rule, those insects which have the largest content in polyphenoloxydase have also the largest amount of tyrosineoxydase. Both ferments can be obtained in powder form by treatment of an insect paste with acetone or alcohol. Tyrosine is oxidised with evolution of carbon dioxide. Insects contain no uricoxydase. There is no alcohol oxydase in silk-worms. Insects contain a succino-oxydone, but the oxidation of succinic acid is much weaker than that of the polyphenols and tyrosine. This oxidation is also weaker in the case of insects than in the case of muscular or liver tissue of mammals. There is a rough parallelism between the oxidation of succinic acid by pulverised insects and the oxidation energy of the living animals. Citric acid is not oxidised by insect paste, and the intensity of the oxidation by pulverised insects is uninfluenced by the addition of sodium acetate, sodium lactate, or dextrose.   S. B. S.

Physical Properties and Chemical Composition of Frog's Urine. Shozo Toda and Katsuta Taguchi (*Zeitsch. physiol. Chem.*, 1913, 87, 371—378).—The reaction of frog's urine is usually feebly acid to litmus paper; D 1·0009 to 1·0018; $\Delta = 0·106$. The electrical conductivity in reciprocal ohms is $0·78 \cdot 10^{-3}$. In summer frogs, the urine contains 0·193 of organic and 0·053 of inorganic con-

stituents %; of the latter 0 0467 are salts soluble in water. There
is a relative large amount of phosphoric acid and sodium. The
proportion of sodium to potassium is 1·7 : 1.   W. D. H.

The Chemistry of Cancerous Tumours. B. WOLTER (*Biochem.
Zeitsch.*, 1913, **55**, 260—265).—Analyses of the total phosphorus and
its distribution as inorganic, phosphatide and protein phosphorus
from a liver sarcoma, from the surrounding liver tissue, and from
the tissue of normal liver, are given. The most marked difference
in the analyses of the tumour and other tissues was the somewhat
smaller percentage (both relative and absolute) of the phosphatide
phosphorus in the former. The amount of cholesterol in the
tumour was 0·25% of the fresh tissue.   S. B. S.

Disturbances in the Protein Metabolism in Cancer. (The
Excretion of Thiocyanates.) PAUL SAXL (*Biochem. Zeitsch.*,
1913, **55**, 224—244).—It has been found that the urine in cases
of cancer generally contains excess of nitrogen, but the amount of
urea is less than the normal, whereas the quantities of oxyproteic
acid and ammonia are greater. The urine of cancer patients is
also characterised by containing a certain amount of sulphur in a
form in which it is readily oxidised to sulphuric acid. These
results suggest the presence of thiocyanates, due to hydrogen
cyanide, split from proteins, and not completely oxidised. Similar
urines were obtained from normal individuals after administration
of thiocyanates. It is now directly shown that, in the majority
of cancer cases, the urine contains abnormally large amounts of
thiocyanate, which is the source of the easily oxidised sulphur.
Other pathological urines also yield abnormally large amounts, but
not to quite the same extent as those from cancer patients. The
thiocyanate was estimated by precipitation with silver nitrate in
acid solution; the silver salt was then dissolved in sodium hydrogen
carbonate, and treated with excess of $N/10$-iodine solution and
potassium iodide. After four hours, hydrochloric acid is added,
and the excess of iodine estimated by titration. The amount of
thiocyanate can be calculated from the equation :

$$CNSK + 3I_2 + 4H_2O = H_2SO_4 + 5HI + KI + HCN.$$
S. B. S.

Protozoan Protoplasm as an Indicator of Pathological
Change. II. In Carcinoma. FRANK P. UNDERHILL and LORANDE
LOSS WOODRUFF (*J. Biol. Chem.*, 1913, **15**, 401—414).—Extracts of
breast cancer depress the division rate of *Paramœcium*, and kill
the protozoon. Extracts of normal mammary tissue do not possess
this property. Weak concentrations of the abnormal extracts may
stimulate the *Paramœcium*.   W. D. H.

The Tryptophan Content of Normal and Pathological
Cutaneous Tissues, and of Malignant Tumours. HUGO FASAL
(*Biochem. Zeitsch.*, 1913, **55**, 88—95).—By means of the author's
colorimetric method, the tryptophan content in various normal

and pathological tissues was estimated. The epidermis is relatively rich in this substance, as are certain tumours, such as carcinoma of the liver. Mammary tumours, on the other hand, do not contain a trace.   S. B. S.

A Case of Pentosuria. PHŒBUS A. LEVENE and FREDERICK B. LAFORGE (*J. Biol. Chem.*, 1913, **15**, 481—486).—Neuberg states that the usual pentose in cases of pentosuria is *dl*-arabinose. Elliott and Raper described a case in which it was probably ribose. In the present case much of the pentose was lost in the methods adopted for its separation, and the identification of the sugar was not complete, but it was probably *l*-ribose.   W. D. H.

The Origin of the Sugar Secreted in Phloridzin Glycosuria. RAPHAEL LÉPINE and RAYMOND BOULUD (*Compt. rend.*, 1913, **157**, 530—532. Compare A., 1904, ii, 753).—The authors quote experiments which, they maintain, contradict the generally accepted hypothesis that the sugar eliminated in phloridzin glycosuria comes from the renal cells. They consider that the point of attack of the phloridzin in the kidney is the vascular endothelium.   W. G.

The Production of Fever. MAX CLOETTA and ERNST WASER (*Arch. expt. Path. Pharm.*, 1913, **73**, 436—456).—By subcutaneous and intravenous injection of the monomethyl derivative of alicyclic tetrahydro-β-naphthylamine, the body temperature is raised in a few minutes. This rise occurs in the region of the cerebral ventricles within twenty seconds, and in the fore-brain in about forty to sixty seconds; the intestinal temperature rises next, and finally that of the skin (which falls during the first half minute). If death occurs, the intestine and skin remain warm after the temperature falls in the central nervous system.   W. D. H.

Protozoan Protoplasm as an Indicator of Pathological Changes. I. In Nephritis. LORANDE LOSS WOODRUFF and FRANK P. UNDERHILL (*J. Biol. Chem.*, 1913, **15**, 385—400).—Extracts of normal kidneys from well-fed and starving animals exert no effect on the division rate of *Paramœcium*; but extracts of nephritic kidneys depress it. This is not due to accumulation of tartrate which was given to induce nephritis. The experiments were made on rabbits.   W. D. H.

The Chemistry of the Leucocytozoon Syphilidis and of the Hirt's Protecting Cells. JAMES E. R. MCDONAGH and R. L. MACKENZIE WALLIS (*Biochem. J.*, 1913, **7**, 517—543).—Much of the work recorded relates to the properties of the colloidal dyes used for micro-chemically investigating the syphilis parasite. Basic stains are most suitable for work in vivo, and of these borax-methylene-blue is the best. The parasite has a lecithin-globulin envelope which stands out more clearly by adding dextrose to the stain. The varied affinity shown for methylene-violet and methylene-red is due to the prevalence of a substance which has

strong reducing properties (lecithin-globulin), and not to a change in the reaction. Details are given of the staining reactions of different parts of the parasite, but the whole subject is at present of subsidiary chemical interest.   W. D. H.

(Pharmacological) Action of Bromine Salts. E. BERNOULLI (*Arch. expt. Path. Pharm.*, 1913, 73, 355—397).—The theory of chlorine poverty is insufficient to explain the action of alkali bromides. For the neutralisation of the bromine action, the administration of chlorides is not necessary, but other salts (sodium sulphate and nitrate) act in the same way. Bromine salts cause changes in the colloidal material of the central nervous system. The bromine ions which take the place of chlorine ions alter the aggregation state of the cell-colloids, probably in the direction of greater swelling, and thus is produced a functional change in the nerve-cells.   W. D. H.

The Action of Leucocytes and Other Tissues on *dl*-Alanine. PHŒBUS A. LEVENE and GUSTAV M. MEYER (*J. Biol. Chem.*, 1913, 15, 475—480).—Leucocytes under aseptic conditions form *d*-lactic acid from hexoses, regardless of the configuration of the hexose. The conversion of amino-acids into hydroxy-acids is analogous to the change of methyl-glyoxal into lactic acid; thus, alanine is transformed into lactic acid through the stage of pyruvic acid. Dakin, Dudley and Ringer found in diabetic dogs fed on pyruvic acid that the yield of sugar was smaller than from either alanine or lactic acid. Hence in the present research the action of leucocytes was tested on various forms of alanine. The unexpected result obtained was that neither leucocytes nor kidney tissue had any effect at all on *dl*-alanine.   W. D. H.

The Behaviour of Pyruvic Acid in the Animal Body. II. GUSTAV EMBDEN and MAX OPPENHEIMER (*Biochem. Zeitsch.*, 1913, 55, 334—340. Compare A., 1912, ii, 1075).—As pyruvic acid is a possible intermediate product in the conversion of alanine into lactic acid, it was of interest to ascertain whether the latter acid could be obtained directly from the former in the animal body. It was found that this change could be accomplished when pyruvic acid was perfused through a glycogen-poor liver of a dog which had been starved for four days. It was obtained in the *d*-form.
                                                       S. B. S.

The Behaviour of Pyruvic Acid in the Animal Body. III. The Formation of Sugar and Lactic Acid from Pyruvic Acid. PAUL MAYER (*Biochem. Zeitsch.*, 1913, 55, 1—3).—The author recapitulates his former results, which indicate that pyruvic acid, on administration to rabits and dogs, causes hyperglycæmia and glycosuria, but that on administration to animals treated with phloridzin, it causes a diminution of the sugar and nitrogen output in the urine, owing apparently to a toxic action on the kidneys. He is not able to explain the difference between his results and those obtained by A. J. Ringer and by Dakin and Janney (this vol.,

i, 937), but rejects the explanation offered by the former. Animals to which pyruvic acid has been administered excrete in the urine both dl- and d-lactic acids.   S. B. S.

The Degradation of Carboxylic Acids in the Animal Body. XV. The Behaviour of Benzaldehyde in the Animal Body. ERNST FRIEDMANN and WILHELM TÜRK (*Biochem. Zeitsch.*, 1913, 55, 425—431).—After administration of benzaldehyde to dogs, only hippuric acid and small quantities of benzoic acid, but no cinnamic acid, could be isolated in the urine. The cinnamic acid found by Dakin after administration of phenylpropionic and phenylvaleric acid must be due therefore to degradation, and not to synthesis by condensation of an aldehyde with acetic acid.   S. B. S.

The Degradation of Carboxylic Acids in the Animal Body. XVI. Behaviour of a-Phenylbutyric Acid in the Animal Body. ERNST FRIEDMANN and WILHELM TÜRK (*Biochem. Zeitsch.*, 1913, 55, 432—435).—As γ-phenylbutyric acid undergoes in the animal body oxidation in the β-position to yield a keto-acid and finally phenyl-acetic acid, it was of interest to ascertain how the a-acid $CH_3 \cdot CH_2 \cdot CHPh \cdot CO_2H$ would behave. If oxidation were to take place in the β-position, phenylacetic and acetic acid should be expected as final products, according to the equations given by the authors. As a matter of fact, only unchanged a-phenylbutyric acid, and a neutral substance, which was not further investigated, could be isolated in the urine of dogs, to which this substance had been administered.   S. B. S.

The Degradation of Carboxylic Acids in the Animal Body. XVII. Formation of Acetoacetic Acid from Acetic Acid in the Perfusion through the Liver. ERNST FRIEDMANN (*Biochem. Zeitsch.*, 1913, 55, 436—442).—Adam Loeb has shown that the addition of sodium acetate to the blood perfused through the surviving liver of a dog causes a marked increase in the amount of acetoacetic acid formed. This is in contrast to the author's own results, where no such increase was found. It is now shown that this increase only results when the liver is poor in glycogen, as, for example, in the livers of animals which have been starved and tetanised by strychnine. In this case increase of acetoacetic acid only follows when acetate is added to the perfusing blood. Such an addition causes no increase when the livers used for experiment are rich in glycogen and taken from a well-fed animal. The mechanism of the formation of acetoacetic acid from acetic acid is discussed, and it is suggested that acetaldehyde is an intermediate product, which condenses with acetic acid to form crotonic acid, from which, by addition of water and oxidation, acetoacetic acid is formed. It is further suggested that in presence of carbo-hydrates, acetic acid is condensed in some other way. From the fact that acetoacetic acid is only formed from fatty acids with an even number of carbon atoms, the conclusion is drawn that acids do not always form β-keto-acids as intermediary oxidation products,

as in this case acetic acid should always be formed, and this is, as the experiment shows, an acetoacetic acid former. S. B. S.

The Degradation of Carboxylic Acids in the Animal Body. XVIII. Behaviour of Glycollic and Glyoxylic Acids in Perfusion through the Liver. JUNICHI MOCHIZUKI (*Biochem. Zeitsch.*, 1913, **55**, 443—445).—Friedmann has suggested (see preceding communication) that acetoacetic acid is formed from acetic acid in perfusion experiments by condensation of the latter with acetaldehyde to yield crotonic acid as an intermediate product. It follows, if this suggestion is correct, that no acetoacetic acid should be formed if the methyl group of acetic acid should have a hydrogen replaced by hydroxyl. As a matter of fact, it was found that neither from glycollic nor glyoxylic acid is acetoacetic acid formed.

S. B. S.

The Degradation of Carboxylic Acids in the Animal Body. XIX. Acetoacetic Acid Formation in the Perfusion of Livers Rich in Glycogen. JUNICHI MOCHIZUKI (*Biochem. Zeitsch.*, 1913, **55**, 446—449).—It has been shown by Friedmann (this vol., i, 1276) that acetoacetic acid is formed from acetic acid only when perfused through livers poor in glycogen. It is now shown that butyric acid, β-hydroxybutyric acid, crotonic acid, and *iso*valeric acid yield acetoacetic acid when perfused through livers rich in glycogen, whence the conclusion is drawn that acetic acid is not an intermediary product of reaction. S. B. S.

The Degradation of Carboxylic Acids in the Animal Body. XX. Conversion of Crotonic Acid into *l*-β-Hydroxybutyric Acid by Liver Pulp. ERNST FRIEDMANN and C. MAASE (*Biochem. Zeitsch.*, 1913, **55**, 450—457).—Crotonic acid is converted into *l*-β-hydroxybutyric acid in the presence of liver pulp obtained from a fasting dog. Carbon dioxide inhibits the reaction. S. B. S.

The Fixation of the Digitalis Substances in the Animal Organism, Considered more Especially with Reference to their Behaviour in the Blood. ERNST OPPENHEIMER (*Biochem. Zeitsch.*, 1913, **55**, 134—152).—Various investigators have failed to detect these substances in the tissues after injection into animals, and researches were undertaken to ascertain the cause of this failure. It was found that the slightly soluble digitoxin is only slowly precipitated from its alcoholic solution. The solutions of both amorphous, slightly insoluble, digitalis glucosides are dialysable, and behave in this respect like the easily soluble crystalline glucosides, strophanthin and antiarin. As precipitation in the blood-stream does not account for the apparent absence of the substances in the blood-stream, the effect on their toxic action due to the admixture with serum was determined, Straub's method for estimating the toxicity (action on frog's heart) being employed. It was found that serum could diminish or destroy the toxicity of the following substances: digitoxin, gitalin, digitalin, oleandrin,

saponin, and methyl-violet. It increased the toxicity, on the other hand, of strophanthin and antiarin. This action of the serum cannot be replaced by either cholesterol, egg-white, or lecithin in Ringer's fluid. These experiments indicate that the failure to detect digitalis alkaloids after injection into the organism is not due to its fixation by cells of the tissues.   S. B. S.

Action of Enzymes on Racemised Proteins and their Fate in the Animal Body. HENRY D. DAKIN and HAROLD W. DUDLEY (*J. Biol. Chem.*, 1913, 15, 271—276).—" Racemised" casein and caseose are resistant to the action of pepsin, trypsin, and erepsin. On feeding the substances to a dog *per os*, they were excreted unchanged in the fæces, no absorption having taken place in the intestine. It appears as if this organ can take up only comparatively simple substances. Racemised caseose, when administered subcutaneously to a dog, produced no symptoms, and was excreted unchanged in the urine. "Racemised" casein remained unchanged in the presence of bacteria, but the caseose was slowly attacked, yielding indole and other products.   S. B. S.

The Behaviour of Iodoprotein in the Organism. JULIUS WOHLGEMUTH and BRUNO REWALD (*Biochem. Zeitsch.*, 1913, 55, 7—12).—The preparation of an iodine derivative from coagulated blood by means of an alcoholic solution of iodine is described, which contains about 15% of iodine and 0·25% of iron. Preliminary therapeutic experiments indicate that this preparation is well tolerated in relatively large doses by rabbits, dogs, and man. In the experiments on rabbits, it was shown that the iron accumulates in the liver. The preparation is readily absorbed, and about 70% of the iodine is excreted in the urine between the third and forty-eighth hours after administration. Little or no iodine is found in the fæces.   S. B. S.

Degradation of the Naphthalene Ring in the Animal Body. ERNST FRIEDMANN and WILHELM TÜRK (*Biochem. Zeitsch.*, 1913, 55, 463—476).—β-Naphthylalanine and β-naphthylpyruvic acid are degraded in the organism to benzoic acid. In order to study the influence of the side-chains on the degradation of the naphthalene nucleus, the degradation of the following products was studied: β-naphthoic acid, β-naphthylacetic acid, and (in greater detail) β-naphthylpyruvic acid. The former results with the last-named were confirmed, in that in the urine of dogs to which it had been administered an excess of hippuric acid was found. This did not happen in the case of either the naphthoic or naphthylacetic acids. The pyruvic acid derivative, however, yielded hippuric acid only when administered *per os*, but not when subcutaneously applied, and the conversion into benzoic acid is therefore possibly a putrefactive process in the intestines. After administration of β-naphthoic acid, in addition to unchanged product, naphthuric acid was found in the urine both after administration *per os* and after injection under the skin. A conjugation with glycine had

therefore taken place. After administration of β-naphthylacetic acid, a considerable amount of unchanged product was found in the urine. The fate of the remainder is still unknown. S. B. S.

The Influence of the Subsidiary Alkaloids of Opium on the Action of Morphine. RICHARD MEISSNER (*Biochem. Zeitsch.*, 1913, **54**, 395—429).—The experiments were carried out with a view to demonstrate the potentialising capacity of other alkaloids on the pharmacological action of morphine, as shown by Straub. The action on the respiratory centre of rabbits, the narcotic action on cats, and the action on the isolated intestine of rabbits were investigated. A larger diminution in the respiratory volume was produced by narcophine, but apart from this, no essential difference was found in the actions of narcophine, pantopone, or laudenone. The investigations appear to negative the conception of a potentialising action of narcotine on morphine. Nevertheless, the results must be accepted with some caution, in view of some quoted experiments of Zehbe on the action of various preparations on the human intestine. S. B. S.

Degradation of Phenylalanine in the Animal Organism. GUSTAV EMBDEN and KARL BALDES (*Biochem. Zeitsch*, 1913, **55**, 301—322).—The general theory as to the relationship between the combustibility of amino-acids in the normal organism, their convertibility into homogentisic acid in alcaptonuric individuals, and their conversion into acetoacetic acid when perfused through the liver is discussed. Phenylpyruvic acid, a conceivable first oxidation product of phenylalanine, both of which substances are burnt up in the organism and converted into homogentisic acid in alcaptonuric cases, might be expected, like substances generally with this behaviour, to be convertible into acetoacetic acid by perfusion through the liver, especially as phenyl-lactic acid, and the keto-acid corresponding with tyrosine, undergo this change. This was found, however, not to be the case; on the contrary, phenylpyruvic acid even inhibits the acetoacetic acid formation from phenylalanine, tyrosine, leucine, and p-hydroxyphenylpyruvic acid when these are perfused in its presence. On the other hand, it does not inhibit acetoacetic acid formation from *iso*valeric or n-hexoic acids, and does not therefore act as a general inhibitor of oxidation processes in the liver. It possibly combines with the side-chains in the cell to which the amino-acids are normally attached when converted into acetoacetic acid. These facts suggest that phenylpyruvic acid is not the first oxidation product of phenylalanine, but oxidation takes place, probably, first in the benzene nucleus. It was found, in fact, that dl-phenylalanine, when perfused through the liver, gives rise to the normal l-tyrosine. From this, p-hydroxyphenylpyruvic acid could be formed, which is an acetoacetic acid former. It is suggested that when phenylpyruvic acid is burnt in the organism, it is converted first into phenylalanine, as it is known that the change of amino- into keto-acids in the body is a reversible one. S. B. S.

The Relations between Constitution and [Physiological] Action in Alicyclic Tetrahydro-β-naphthylamine and its Derivatives. Max Cloetta and Ernst Waser(*Arch. expt. Path. Pharm.*, 1913, 73, 398—435).—From the substance mentioned, optically active *d*- and *l*-bases can be isolated, which resemble the racemic base in their action. From the latter a series of salts can be prepared with differing dissociation capacities, but no relation was found between this property and toxicity. The monomethyl derivative, like the original base, dilates the pupil, and raises body temperature and blood-pressure; the corresponding monoethyl compound acts in the same way, but is more toxic. If, however, the nitrogen is replaced by an acid residue (acetyl, formyl), the actions are reversed, the pupil is narrowed, and body temperature and blood-pressure fall. If an acid and alkyl group are both introduced there is a double action; for instance, in the frog, myosis is produced by the acid group, and in the rabbit, mydriasis by the alkyl group. In the case of derivatives that raise the blood-pressure, a second injection is not effective in the same way.   W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

The Fermentation of Pyruvic Acid by Bacteria. László Karczag and L. Móczár (*Biochem. Zeitsch.*, 1913, 55, 79–87).—The bacteria which are capable of fermenting dextrose with evolution of gas are also able to ferment pyruvic acid. Amongst such bacteria are *B. coli*, *B. paratyphi-B.*, and Gaertner's bacillus. The gas evolution with bacteria follows more rapidly than with yeast, but there is a marked difference between the two classes of fermentations, for whereas with yeast the gas evolved is carbon dioxide, the pyruvic acid yielding this gas and formaldehyde, the gas evolved by bacteria consists for the most part of hydrogen.   S. B. S.

Formation of Hydrogen Cyanide from Proteins. H. W. Emerson, Hamilton P. Cady, and E. H. S. Bailey (*J. Biol. Chem.*, 1913, 15, 415—418).—Certain micro-organisms (*B. pyocyaneus*) evolve hydrogen cyanide when grown on protein media, especially if the medium is slightly acid to litmus and phenolphthalein. This is absent when free mineral acid is present.   W. D. H.

Formation of Hydrogen Cyanide from Proteins. B. J. Clawson and C. C. Young, (*J. Biol. Chem.*, 1913, 15, 419—422).—*B. pyocyaneus, B. fluorescens, B. violaceus*, and other bacteria the nature of which is still uncertain, produce hydrogen cyanide from protein material.   W. D. H.

Chemistry of Bacteria. Sakae Tamura (*Zeitsch. physiol. Chem.*, 1913, 87, 85—114).—Chemical investigations were made on large

quantities of the cells of *Bacillus tuberculosis* and *Mycobacterium lacticola perrugosum.* Extraction with ether failed to give any phosphatides, but treatment with warm alcohol showed the presence of a diaminomonophosphatide in each species of bacteria. Both cultures were found to contain an alcohol ($C_{29}H_{56}O$), for which the name *mycol* is suggested. This alcohol is present in the bacterial cell partly as an ester of a higher fatty acid, and it is to the alcohol or its ester that the acid- and alkali-resistance and gram-positiveness of the organisms are due. Adenine and hypoxanthine were present in each case, in addition to arginine, histidine, lysine, phenylalanine, proline, valine, tyrosine, and tryptophan. Bacterio-proteins are characterised by a high phenylalanine content.

H. B. H.

Fermentation of Cellulose by Thermophilic Bacteria. HANS PRINGSHEIM (*Centr. Bakt. Par.*, 1913, ii, 38, 513—516).—Impure cultures of anaerobic, thermophilic, cellulose-decomposing bacteria were obtained from soil and horse manure. By means of a special apparatus the cultures were maintained at 55—60°, and samples of the decomposition gases were withdrawn from time to time. These were found to consist of 22—49% carbon dioxide, and the residue in all cases proved to be hydrogen.

Examination of the residual liquid cultures showed the presence of formic and acetic acids, but no butyric acid. This is significant, as the latter is the chief product of anaerobic cellulose decomposition at normal temperatures. Three grams of cellulose led to the production of 0·2125 gram of formic acid, 1·15 gram of acetic acid, a trace of lactic acid, and a mixture of carbon dioxide and hydrogen in the above proportions.

H. B. H.

The Enrichment of the Invertase Content of Living Yeasts. LEOPOLD LICHTWITZ (*Biochem. Zeitsch.*, 1913, 56, 160—162).—The author replies to certain criticisms of Meisenheimer, Gambarjan, and Semper (this vol., i, 1139), who found that the invertase con-tent of yeast increases when the organism is kept in sugar solution. This is the direct contrary of what was found by the author. He calls attention to the fact, however, that yeast sown in large quantities in sugar solution, as was done by Meisenheimer and his collaborators, does not increase; on the contrary, it probably autolyses. This did not happen in the author's own experiments; hence, probably, the difference in the results.

S. B. S.

Catalysts of Alcoholic Fermentation. HANS VON EULER (*Zeitsch. physiol. Chem.*, 1913, 87, 142—144).—Earlier work has shown that the rapidity of fermentation by living yeasts is accelerated by the addition of alkali salts of organic and especially fatty acids, and dried yeast or yeast juice is not affected in a similar manner. Of the two possible interpretations of the results, particular attention has been paid to that which assumes that the activation is not directly connected with enzymes in the yeast cell, and experiments have been made to determine an alteration

of the protoplasmic layer of the cell or of the cell wall generally by the salts, with adsorption and an alteration of surface tension.

Preliminary experiments with sodium and ammonium salts of the acids having given negative results, an attempt was made to determine the action of various dye salts on the living cell. According to their behaviour towards the yeast cell, it was possible to divide the dye salts into three classes, namely, those without action on the cell, those which are clearly adsorbed, and others the entrance of which into the cell depends on the fermentative activity of the latter. These phenomena and the part played by an alteration of the surface tension are being further investigated.

<div align="right">H. B. H.</div>

Influence of Certain Inorganic Salts, particularly Stannous Chloride and Bismuth Subnitrate, on Fermentation. GILBERT GIMEL (*Bull. Assoc. chim. Sucr. Dist.*, 1913, 31, 128—129).—Results of further experiments confirm those obtained previously by the author (A., 1909, ii, 171). The activity of various yeasts in sweet worts is increased when the latter contain from 50 to 100 mg. of stannous chloride per litre. Bismuth subnitrate is soluble in acid liquids, such as musts, etc., and has a decided influence on the fermentation; it appears to inhibit acetic fermentation. The use of pure yeast cultures and different conditions of fermentation are probably the reason of the opposite opinion arrived at by Pozzi-Escot (this vol., i, 1139).

<div align="right">W. P. S.</div>

Protein Degradation in Yeast. I. The Influence of Sugar Fermentation on the Protein Degradation of Yeast. W. ZALESKI and W. SCHATALOV (*Biochem. Zeitsch.*, 1913, 55, 63—71).— Various views have been expressed to explain the fact that proteolysis is less in yeast that has been used for sugar fermentation than in unused yeast, the Ivanov has stated that acetaldehyde is the fermentation product which is responsible for the antiproteolytic action. This statement the authors have been unable to confirm, for they find that an appreciable inhibition of yeast autolysis only takes place in concentrations of this aldehyde which are far higher than those found in fermentation liquors. The same is also true for furfuraldehyde and for formaldehyde, which latter, however, has a much stronger inhibitory action than acetaldehyde. Although the distillates from fermentations possess antiproteolytic properties, the actual antiproteolytic substance has not been isolated. The conditions of nutrition of the yeast exert some action on the subsequent proteolysis. The addition of amino-acids to yeasts increases the autolytic degradation of their proteins; it cannot be claimed, however, that they antagonise the antiproteolytic properties of the fermentation products.

<div align="right">S. B. S.</div>

Biochemical Conversion of Betaine into Glycollic Acid. FELIX EHRLICH and FRITZ LANGE (*B.r.*, 1913, 46, 2746—2752).—In the course of their experiments on the behaviour of amino-acids towards micro-organisms, the authors have examined betaine, which is remarkably stable, not only to concentrated sulphuric acid or

aqua regia at high temperatures, but also during passage through the bodies of most animals except the ruminants. They find that betaine is not assimilated by brewers' and distillers' yeasts or by various kinds of *Saccharomyces*, but is extensively degraded by *Willia anomala, Pichia farinosa, Pichia membranefaciens*, and other yeasts rich in oxydases; also many moulds, such as *Penicillium, Aspergillus, Monilia, Oidium*, and *Dematium*, are able to employ betaine for the formation of their albumin. In most cases characteristic degradation products of betaine cannot be isolated, partly because the decomposition is too extensive, partly owing to the difficulty of separating the decomposition products of the sugar added as a source of carbon. In experiments on solutions containing betaine, nutrient salts, and ethyl alcohol as a source of carbon, the authors find that after the addition of a pure culture of *Willia anomala* and keeping for eight weeks, glycollic acid is present in quantity sufficient for isolation; the amount is small, because the acid is an intermediate, not the final, product of the assimilation of the betaine. This is proved by the fact that *Willia anomala* grows extensively in a solution containing nutrient salts, and glycollic acid and carbamide as the only sources of carbon, the glycollic acid disappearing completely after four months; in a similar experiment, in which carbamide is the only source of carbon, growth of the yeast cannot be detected.

In the preceding experiments with betaine, not a trace of trimethylamine can be detected. Probably it is converted into methyl alcohol and ammonia, the latter, which also cannot be detected, being utilised by the organism in the formation of albumin.

In conclusion, the authors reply to Stoltzenberg (this vol., i, 345; compare also Ehrlich, A., 1912, i, 835; Stoltzenberg, *ibid.*, i, 680) concerning the isolation of betaine from molasses residue.

C. S.

Protein Synthesis in Plants. I. Protein Synthesis in the Bulbs of Allium cepa. W. ZALESKI and W. SHATKIN (*Biochem. Zeitsch.*, 1913, 55, 72—78).—Experiments confirm a former statement of Zaleski, that the proteins increase in quantity in the injured bulbs when left in a moist atmosphere or in intact bulbs when allowed to grow in the dark. Estimations were of the total nitrogen, proteins, peptones, ammonia, acid amides, organic bases, and mono-amino-acids. It was found, as a result, that the proteins are formed at the expense of the monoamino-acids. The mono- and di-amino-acids and ammonia were also estimated in the various specimens after hydrolysis with acids. The results obtained indicate that the monoamino-acids pre-existing combine with the pre-existing proteins. There is no evidence that the acid amides, without further change, take any direct part in the protein synthesis. S. B. S.

The Inulin Metabolism of Cichorium intybus (Chicory). III. VIKTOR GRAFE and VALENTIN VOUK (*Biochem. Zeitsch.*, 1913, 56, 249—257. Compare A., 1912, ii, 977; this vol., i, 148).—It is shown

that by the freezing of the roots, the amount of inulin decreases, whereas the amount of reducing sugar increases; the amount of the latter returns to normal when the frozen roots are afterwards kept at normal temperature, whereas the amount of inulin remains unchanged. These results confirm the theory of Molisch, that the dissolved inulin acts as a "thermically active" protector against cold. The changes in the inulin and reducing sugar distribution in the roots which had wintered in a normal manner were also investigated. It was found that a hydrolysis of inulin takes place before new parts of the plants are visible; the reserve substances appear to be converted into building material, and this allows the further hydrolysis of the inulin reserves. A résumé of the results obtained by the authors up to the date of publication is also given.   S. B. S.

The Colorimetric Method for Determining Hydrocyanic Acid in Plants with Special Reference to Kafir Corn. C. K. FRANCIS and W. B. CONNELL (*J. Amer. Chem. Soc.*, 1913, 35, 1624—1628).—After examining the various methods for the estimation of small quantities of hydrocyanic acid, the authors decide in favour of a colorimetric process depending on the formation of ferric thiocyanate. This method indicates that Kafir corn contains minute quantities of combined hydrocyanic acid, the quantity apparently being greater in frost-bitten or stunted plants than in normal ones.

It is difficult to decide from the results whether the quantity of hydrocyanic present could prove fatal to an animal fed with this material.   D. F. T.

Antitoxic Action of Chloral Hydrate on Copper Sulphate for Pisum sativum. R. P. HIBBARD (*Centr. Bakt. Par.*, 1913, ii, 38, 302—308).—Water culture experiments in which garden peas were supplied with solutions of copper sulphate in concentrations varying from $M3 \times 10^{-4}$ to $M2\cdot5 \times 10^{-6}$, and with chloral hydrate, $M/165\cdot5$ to $M/16,550$, both together and separately. After forty-eight hours the roots of the plants were measured. Whilst in the single solutions growth was very slight, when both substances were supplied simultaneously the growth was distinctly better, especially when both substances are present in about equal amounts. The action of chloral hydrate in diminishing the toxicity of copper sulphate is similar, although less marked, to the influence of calcium over magnesium salts.

Several explanations are suggested, the most important of which is perhaps connected with the extent of ionisation which may be retarded when both substances are present. Or, changes may be brought about in the plasma membrane which will modify the permeability of the limiting layer. Then, again, the effect may be the result of changes in the cell itself.   N. H. J. M.

Organic Chemistry.

Separation of Mixtures of a Saturated with an Unsaturated Hydrocarbon by means of Permanganate. S. S. NAMETKIN (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1423—1429).—Attempts to determine the proportions of the constituents of mixtures of (1) *cyclo*hexane and *cyclo*hexene, and (2) *n*-hexane and hexylene by oxidising the unsaturated hydrocarbon by means of permanganate were unsuccessful, owing to the saturated constituent reacting to some extent with the oxidising agent.

A similar method was then applied to analogous mixtures of gaseous hydrocarbons. For this purpose a special gas pipette was devised which permits the gaseous mixture to be passed repeatedly in small bubbles through the reagent, and in which the latter does not come into contact with mercury. After the reaction with saturated permanganate solution, the excess of oxidising agent was destroyed by means of saturated bisulphite solution, both this and the permanganate solution having been previously saturated with the saturated constituent of the gaseous mixture. With various mixtures of propane and ethylene, propane and propylene, and *cyclo*propane and propylene, the greatest error in the volume of the gas remaining after treatment with permanganate was 0·27%.

The unsatisfactory results obtained by Kishner (this vol., i, 153) are largely explained by the fact that, in most cases, the reaction was completed at 100°, and hence under conditions which should lead to attack of the saturated hydrocarbon. T. H. P.

Investigations on Polymerisation. I. Diethylene Hydrocarbons. SERGEI V. LEBEDEV and (in part) B. K. MERESHKOVSKI (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1249—1388. Compare A., 1911, i, 26, 774, 959; 1912, i, 173).—The vast majority of organic compounds are essentially unstable, and their great variety owes its existence to what the author terms passive resistance. It is quite conceivable that polymerisation, as a process directing molecules into more stable forms, is very widespread, and that most unsaturated organic compounds are able to polymerise under suitable conditions. No sharp line can be drawn between association and polymerisation, although with typical association no difference can be found between the chemical reactions of the monomeride and of the polymeride; it may be that, owing to ready dissociation of the latter, only the former reacts or that no sufficiently sensitive reagent for the polymeride has been discovered. The stability of the complex molecule depends on the particular type of polymerisation occurring, in addition to the properties of the individual compound.

In the great majority of cases polymerisation occurs with formation of a ring system, the ring having in all cases an even number of atoms. In studying polymeric changes, account must be taken of the isomerisa-

tion so common with unsaturated compounds, especially with rise of temperature.

Among the hydrocarbons the principal well-defined types of polymerisation are : (1) the styrene type, peculiar to ethylenic hydrocarbons with unsymmetrical substitution of the hydrogen atoms by definite groups (phenyl), and yielding polymerides of high molecular weight and structures not yet definitely established; (2) the stilbene type, exhibited by ethylene derivatives with symmetrical replacement of the hydrogen atoms by certain groups (phenyl); (3) the acetylene type, giving benzene derivatives; (4) the allene type, yielding *cyclo*butane derivatives; (5) the divinyl [$\Delta^{\alpha\gamma}$-butadiene] type, which forms *cyclo*hexane derivatives and polymerides of uncertain constitution. If it can be shown that stilbene forms a polymeride and styrene a dimeride of closed-chain structure, types (1) and (2) may have to be regarded as a single type; and, further, the resemblance between polymerides of the styrene and divinyl types (compare Ostromisslenski, A., 1912, i, 280) may lead to the fusion of these two types. Most cases of polymerisation of unsaturated compounds containing halogen, nitrogen, oxygen, or sulphur may be referred to one of the above types.

Polymerisation of the divinyl or $\Delta^{\alpha\gamma}$-butadiene type is first considered, an account being given of all such hydrocarbons studied in this respect. Experiments with isoprene and with di*iso*propenyl [$\beta\gamma$-dimethyl-$\Delta^{\alpha\gamma}$-butadiene] show that : (1) the relative proportions of dimeride and polymeride formed increase and diminish respectively as the temperature is raised; (2) at constant temperature, the ratio between the proportions of dimeride and polymeride does not change during the heating ; (3) the reaction of polymerisation is sensitive to catalytic action, since replacement of the air in the tube by nitrogen results (with $\beta\gamma$ dimethyl-$\Delta^{\alpha\gamma}$-butadiene) in a fall of the relative amount of polymeride from 23% to 16·4%. It is further found that symmetrical hydrocarbons of this type, such as $\Delta^{\alpha\gamma}$-butadiene and its $\beta\gamma$-dimethyl derivative, yield a single dimeride, whereas the unsymmetrical isoprene gives two dimerides. In contradiction to the statement of Kondakov ("Synthetic Caoutchouc, its Homologues and Analogues," Yuriev, 1912, p. 101) and of Harries (A., 1911, i, 798), it is found that polymerisation of the pure hydrocarbons, without catalyst, yields no open-chain dimeride.

In general, it seems that no such equilibrium as that represented by dimeride ⇌ monomeride ⇌ polymeride exists, but that the processes of polymerisation are irreversible and proceed simultaneously in two directions, yielding dimeride and polymeride respectively. The existence of reversible processes of formation of dimeric and of polymeric forms renders it probable that such equilibria may yet be realised.

The possible methods of formation and structures of dimerides and polymerides are discussed in detail.

The dimeride of di*iso*propenyl [$\beta\gamma$-dimethyl-$\Delta^{\alpha\gamma}$-butadiene] is 4 : 6-dimethyldipentene or 4 : 6-dimethyl-$\Delta^{6,8(9)}$-menthadiene,

$$CMe\!<\!\substack{CMe\cdot CH_2\\CH_2\cdot CH_2}\!>\!CMe\cdot CMe\!:\!CH_2,$$
which is a colourless liquid with an aromatic odour, b. p. 85°/13 mm.,

$205°/750$ mm., $D_4^0\ 0.8741$, $D_0^{20}\ 0.8597$, $n_C^{197}\ 1.47716$, $n_D\ 1.48074$, $n_F\ 1.48796$, $n_G\ 1.49491$ (compare Richard, A., 1911, i, 733). Treatment with ozone in chloroform solution at $-20°$ yields the *ozonide*, $C_{12}H_{20}O_6$, which is a froth-like, amorphous compound, exploding violently on heating, but failing to yield the triketone on decomposition with water. Oxidation of the dimeride in aqueous acetone by means of permanganate yields: (1) δ-*Methyl-δ-isopropenyl-$\beta\eta$-octandione*,

$$CH_3\cdot CO\cdot CH_2\cdot CMe(\cdot CMe\dot{:}CH_2)\cdot CH_2\cdot CH_2\cdot CO\cdot CH_8,$$
which is a viscous liquid, b. p. $132—133°/8.5$ mm., and yields the *semicarbazone*, $C_{14}H_{26}O_2N_6$, m. p. $228°$; hydrogenation of the diketone at the ordinary temperature in presence of platinum black gives δ-*methyl-δ-isopropyl-$\beta\eta$-octandione*, $CH_3\cdot CO\cdot CH_2\cdot CMePr^\beta\cdot CH_2\cdot CH_2\cdot CO\cdot CH_3$, as a colourless, viscous liquid, b. p. $133—135°/8$ mm., $D_4^{20}\ 0.9934$, the corresponding *semicarbazone*, m. p. $202°$, being also prepared. (2) A small proportion of an acid, m. p. $164—166°$, containing 63.2% of carbon and 8.88% of hydrogen.

Oxidation of the dimeride of $\beta\gamma$-dimethyl-$\Delta^{\alpha\gamma}$-butadiene by means of benzoylhydroperoxide in ethereal solution (compare Prileschaev, A., 1911, i, 255) yields (1) a small proportion of the *monoxide*,

$$OMe\!<^{OMe\cdot CH_2}_{CH_2\cdot CH_2}\!>\!OMe\cdot OMe\!<^{CH_2}_{O},$$
b. p. $94—95°/10$ mm., and (2) the *dioxide*, $C_{12}H_{20}O_2$, b. p. $110—112°/10$ mm., which when heated in a sealed tube at $115°$ with water acidified with benzoic acid gives the tetrahydric alcohol (4:6-*limonetritol*), $OH\cdot \dot{O}Me\!<^{OMe(OH)\cdot CH_2}_{CH_2———CH_2}\!>\!OMe\cdot OMe(OH)\cdot CH_2\cdot OH$, as a highly viscous liquid; oxidation of this by means of aqueous permanganate gave a small yield of the *keto-glycol*,

$$OH\cdot OMe\!<^{OMe(OH)\cdot CH_2}_{CH_2———CH_2}\!>\!OMe\cdot COMe,$$
m. p. $155—165°$.

The action of dry hydrogen chloride on the dimeride in carbon disulphide yields $1:2:4$-*trimethyl-4-chloroisopropyl-Δ^1-cyclohexene*, $OMe\!<^{OMe\cdot CH_2}_{CH_2\cdot CH_2}\!>\!OMe\cdot OMe_2Cl$, which is a colourless liquid, b. p. $122—124°/17$ mm.

The polymeride of diisopropenyl is shown by means of its ozonide to have the structure $(\cdot CH_2\cdot OMe\dot{:}OMe\cdot CH_2\cdot CH_2\cdot OMe\dot{:}OMe\cdot CH_2\cdot)_x$. The *ozonide*, $C_6H_{10}O_8$, separates partly in a gelatinous form and yields acetonylacetone when heated with water (compare Harries, A., 1911, i, 798).

Further details are given of the results obtained with isoprene (compare A., 1911, i, 26). For obtaining pure isoprene use was made of the following method elaborated in Favorski's laboratory and not yet published. Crude isoprene, b. p. $30—40°$, obtained by decomposition of turpentine, is poured into a cooled solution of hydrogen bromide in acetic acid, and the precipitated mixture of bromides washed and dried. Amyl bromide is distilled off at $52—53°$ under 100 mm. pressure, and the residual $\alpha\gamma$-dibromo-γ-methylbutane, after distillation at $80—82°$ under 23 mm. pressure, heated at $150°$ with a large excess

of pounded potassium hydroxide in a flask provided with a dephlegmator and condenser ; the dibromide and monobromide formed from it are arrested by the dephlegmator and fall back into the flask, whilst the isoprene passes over and is condensed.   The isoprene thus obtained, distilled over sodium, has b. p. 34·5—35°, D_0^{20} 0·6803, n_D^{20} 1·42207, n_C 1·41787, n_F 1·43307, n_G 1·44280, optical exaltation (D) 1·07 (compare Harries and Neresheimer, A., 1911, i, 798).

Two dimerides of isoprene were obtained : (1) Dipentene, b. p. 58°/9·5 mm., 174—175°/760 mm., D_0^0 0·8607, D_0^{20} 0·8454, $n_D^{19\cdot7}$ 1·47428, n_C 1·47069, n_F 1·48211, n_G 1·48887.   (2) 1 : 3-Dimethyl-3-ethenyl-Δ^6-*cyclo*hexene (*loc. cit.*), D_0^0 0·8481, $n_D^{19\cdot7}$ 1·46581, n_C 1·46230, n_F 1·47204, n_G 1·47964, which yields a liquid tetrabromide, not obtained pure, and combines with 2HBr in acetic acid solution, giving the *compound*, $C_{10}H_{18}Br_2$, softening at 25° and melting at 34—35°.   1 : 3-Dimethyl-3-ethyl*cyclo*hexane (*loc. cit.*), obtained by hydrogenation of this dimeride in presence of platinum black and under a pressure of 70 atmospheres, has D_4^0 0·8132, D_4^{20} 0·7990, n_D^{20} 1·44112.   The *ozonide*, $C_{10}H_{16}O_6$, of this dimeride resembles those of di*iso*propenyl and dipentene and, on decomposition, gives an oil resolved on boiling into the *ketodialdehyde*, $COMe \cdot CH_2 \cdot CMe(CHO) \cdot CH_2 \cdot CH_2 \cdot CHO$, which yields α-methyl-α-acetonylglutaric acid on oxidation.   Treatment of the dimeride with benzoylhydroperoxide yields (1) the monoxide, which is a liquid, b. p. 68—70°/15 mm., with a camphor-like odour, and (2) the *dioxide*,

$$O<^{CMe——CH_2}_{CH \cdot CH_2 \cdot CH_2}>CMe \cdot CH<^O_{CH_2}$$, which is a liquid with an aromatic

odour, b. p. 108—109°/15 mm., and yields the *compound*, $C_{10}H_{20}O_4$, on hydration.

Two isomeric polymerides of isoprene are possible theoretically, and should give ozonides of the structures :

$$(1) \qquad [\cdot CH_2 \cdot CMe \cdot CH \cdot CH_2 \cdot CH_2 \cdot CMe \cdot CH \cdot CH_2 \cdot]_x$$
$$\diagdown O_3 \qquad\qquad \diagdown O_3$$

$$and \cdot (II) \qquad [\cdot CH_2 \cdot CMe \cdot CH \cdot CH_2 \cdot CH_2 \cdot CH \cdot CMe \cdot CH_2 \cdot]_x$$
$$\diagdown O_3 \qquad\qquad \diagdown O_3$$
Of these, (I) corresponds with natural caoutchouc and should give, on decomposition, lævulinaldehyde and its peroxide, and lævulic acid ; all these products were actually observed.   Similarly, (II) should give succindialdehyde, succinic acid and acetonylacetone, none of which could be detected.   Hence, only the former polymeride is formed ; its *ozonide*, $C_5H_8O_3$, is an extremely viscous liquid, exploding when heated.

Piperylene should yield, not a dimeride of the structure,

$$CMe<^{CH—CH_2}_{CH_2 \cdot CH_2}>CH \cdot CH:CHMe$$
(compare Harries, this vol., i, 284), but two dimerides, formed thus :

$$(1) \; CH_2 \cdot CH \cdot CH \cdot CH \cdot CH_2 \cdot \; \rightarrow \; CH<^{CH—CH_2}_{CHMe \cdot CH_2}>CH \cdot CH:CHMe,$$

$$and \; (2) \; {^{CH_2}_{CH \cdot CH \cdot CH \cdot CH_2}} \; \rightarrow \; CH<^{CH—CHMe}_{CH_2 \cdot CHMe}>CH \cdot CH:CH_2;$$
the former should have the higher boiling point.

According to a private communication from Favorski, di*iso*crotyl [$\beta\epsilon$-dimethyl-$\Delta^{\alpha\delta}$-hexadiene] undergoes spontaneous change into a waxy substance, but this was not observed by the author. This hydrocarbon undergoes polymerisation with great difficulty, only 50% of it being transformed after being maintained at 290° for ten days. The employment of such a high temperature causes partial isomerisation of the dimeride, of which only a single one should be formed from a symmetrical molecule, and also results in decomposition of the polymeride. The dimeride is 3:3:5:5:6:6-*hexamethyl*-4-*iso*crotyl-Δ^1-cyclo*hexene*, $CH{<}{CH-CMe_2 \atop CMe_2 \cdot CMe_2}{>}CH \cdot CH{:}CMe_2$, b. p. 130—132°/ 24 mm., D_4^0 0·8634, D_4^{20} 0·8491, n_D^{20} 1·47751, n_C 1·47452, n_F 1·48757, n_G 1·49120. The polymeride was obtained only as an impure, yellow, viscous liquid containing decomposition products.

Myrcene, which probably consists of a mixture of two or more isomerides, was found to have the constants: b. p. 56—57°/12 mm., D_4^{20} 0·7982, n_D^{20} 1·47065, n_C 1·46675, n_F 1·48055, n_G 1·48905. When heated for twelve days at 150°, it yields (1) two cyclic isomerides of myrcene, (a) b. p. 60—61·5°/16 mm., D_4^{20} 0·8392, n_D^{20} 1·46611, n_C 1·46270, n_F 1·47334, n_G 1·47974, and (b) b. p. 65—65·5°/16 mm., D_4^{20} 0·8340, n_D^{20} 1·47133, n_C 1·46774, n_F 1·47922, n_G 1·48613; (2) a dimeride, b. p. 183—184°/10 mm., D_4^{20} 0·8763, $n_D^{20\cdot1}$ 1·49859, n_C 1·49568, n_F 1·50668, n_G 1·51606; (3) a viscous polymeride yielding a mixture of products when treated with ozone (compare Harries, A., 1902, i, 811).

a-Phenyl-$\Delta^{\alpha\gamma}$-butadiene polymerises with great ease. The dimeride was investigated by Riiber (A., 1904, i, 569), who suggested formulæ for it and for the tribasic acid yielded on oxidising it with permanganate. The author regards these formulæ as inaccurate, since, according to his scheme, the dimeride should have the structure

$$CH{<}{CH-CH_2 \atop CHPh \cdot CH_2}{>}CH \cdot CH{:}CHPh,$$
and the tribasic acid, $CO_2H \cdot CHPh \cdot CH_2 \cdot CH(CO_2H) \cdot CH_2 \cdot CO_2H$, the latter agreeing better with the analytical data than that proposed by Riiber.
As was shown by Stobbe and Reuss (A., 1912, i, 842), *cyclo*pentadiene polymerises so rapidly that intense cooling is necessary in order to obtain it in the monomeric form. If the type of polymerisation exhibited by openchain hydrocarbons holds also for cyclic compounds, the dimeride should have the annexed structure (compare Kraemer and Spilker, A., 1896, i, 289). This case is under investigation.

Allene hydrocarbons polymerise with great ease and, unlike those of the divinyl type, with velocities varying only within narrow limits. The character of the polymerisation is also different, the polymerides being *cyclo*butane derivatives and forming an uninterrupted series from di- to hexa-merides. Actually, however, the polymerisation of allene hydrocarbons is complicated by transformation to the type shown by those of the divinyl series. This occurs in two ways: (1) the allene hydrocarbons undergo isomeric change into divinyl derivatives with

comparative ease, and (2) the dimerides are cyclic derivatives of divinyl ; thus, that of allene has the structure

$$CH_2:C{<}{\stackrel{CH_2}{\underset{C(:CH_2)}{\frown}}}{>}CH_2,$$
and readily polymerises giving a di-dimeride and a polymeride. At the ordinary temperature allene hydrocarbons polymerise so slowly that years elapse before the formation of an appreciable proportion of polymeride. But the temperature-coefficient of the velocity of the change is far greater than with divinyl derivatives, and at 150° the velocity is approximately the same as with isoprene and di*iso*propenyl. The author elaborates a scheme to explain the mechanism of the process, starting from the assumptions that the molecules combine initially at a single point and that the union is directed by two causes : the magnitude of the affinity with the unsaturated atoms and the polarity. The construction of models of the polymeric forms shows that two types of arrangement in space are possible : (1) the cyclic type, in which the central carbon atoms of allene are arranged in a ring in one plane, with the four-membered rings alternately on either side of this basal plane ; and (2) the spiral type, in which the central atoms of the allene groups are arranged in a spiral so that the first, fourth, and seventh carbon atoms occupy analogous positions on the spiral, and so on ; the four-membered rings lie in three mutually-perpendicular planes, the first, fourth, and seventh rings also taking up similar positions on the spiral. The dimerides of the two types are identical, as also are the trimerides. Stereoisomerism is possible, beginning with the tetrameride, and assuming the formation of polymeric forms according to both types, two stereoisomerides may be expected for the tetra-, penta-, and hexa-meride. Higher degrees of polymerisation are possible only with the spiral type.

When heated to 130—140°, *as*-dimethylallene gives 3% of dimeride, b. p. 140—141°, 18% of dimeride, b. p. 149—150°, 40% of dimeride, b. p. 179—181°, 33% of trimeride, b. p. 100°/8 mm., and 60% of vaseline-like residue. The three dimerides, which are the only possible ones, have been already described (A., 1912, i, 173). The *trimeride*,

$$CMe_2{<}{\stackrel{CH_2}{\underset{C(:CH_2)}{\frown}}}{>}C{<}{\stackrel{C(:CMe_2)}{\underset{CMe_2}{\frown}}}{>}CH_2,$$
is a colourless, odourless liquid, b. p. 100°/8 mm., D_4^0 0·8723, D_4^{20} 0·8578, n_D^{20} 1·48724, n_C 1·48395, n_F 1·50260, n_G 1·51398, optical exaltation 2·28, and has the normal molecular weight in freezing benzene. Hydrogenation of the trimeride in presence of platinum black yields the *compound*, $CMe_2{<}{\stackrel{CH_2}{\underset{CHMe}{\frown}}}{>}C{<}{\stackrel{CHPr^a}{\underset{CMe_2}{\frown}}}{>}CH_2$, b. p. 116—118°/ 23 mm., D_4^0 0·8521, D_4^{20} 0·8380, $n_D^{19\cdot9}$ 1·46362, n_C 1·46101, n_F 1·47274, n_G 1·47827, optical exaltation 1·50. The ozonide of the trimeride is unstable, and was not obtained pure. Oxidation by means of benzoylhydroperoxide yields the *dioxide* (annexed formula), m. p. 49°, b. p. 137°/16 mm., which undergoes partial hydration to the *compound*, $C_{15}H_{26}O_3$, m. p. 136·5°,
$$CMe_2{<}{\stackrel{CH_2}{\underset{C}{\frown}}}{>}C{<}{\stackrel{\stackrel{O—CMe_2}{\diagdown}}{\underset{OMe_2}{C}}}{>}CH_2$$

probably a glyco-oxide. Attempts to complete the hydration by heating with water containing a trace of acid resulted in the formation of a *diketone*, $C_{15}H_{24}O_2$, m. p. 86°, which yields a *semicarbazone*,

$$C_{17}H_{30}O_3N_6,$$

m. p. 170° (decomp.), but was not obtained in sufficient quantity to admit of the determination of its structure.

[With B. K. MERESHKOVSKI.]—When heated in a sealed tube at 150°, trimethylallene undergoes polymerisation and isomerisation, the mixture of dimerides consisting principally of 1 : 2-*dimethyl*-3 : 4-*di-isopropylidene*cyclo*butane*, $\begin{array}{c} \text{CHMe·C:CMe}_2 \\ | \\ \text{CHMe·C:CMe}_2 \end{array}$, which is a colourless liquid with the odour of kerosene, b. p. 69—70°/11 mm., 190—191°/754 mm., D_4^{20} 0·8247, n_D^{20} 1·48337, n_C 1·47946, n_F 1·49282, n_G 1·50297. The ozonide is unstable, and on distilling in a current of steam is decomposed into dimethylsuccinic acid, acetone peroxide, and 1 : 2-*dimethyl*-3 isopropylidene cyclo*butan*-4-*one*, $\begin{array}{c} \text{CHMe·C:CMe}_2 \\ | \\ \text{CHMe·CO} \end{array}$, which is a colourless liquid with the characteristic quinone-like odour common to all unsaturated ketones obtained from dimerides of allene hydrocarbons, b. p. 83—86°/20 mm., and was not obtained free from traces of the original dimeride; its *semicarbazone*, $C_{10}H_{17}ON_3$, m. p. 200—201° (decomp.), contained a small proportion of another semicarbazone, m. p. about 180°; oxidation of the ketone with permanganate yields the maleinoid form of dimethylsuccinic acid. Products of higher polymerisation are formed to the extent of 10%, but no individual compounds were isolated.

[With B. K. MERESHKOVSKI.]—At 150°, polymerisation of s-dimethylallene is complete in four to five days. The products contain (1) about 90% of the dimeride, 1 : 2-*dimethyl*-3 : 4-*diethylidene*cyclo*butane*, $\begin{array}{c} \text{CHMe:C·CHMe} \\ | \\ \text{CHMe:C·CHMe} \end{array}$, which is a colourless liquid, b. p. 65°/22 mm.; 163°/762 mm., D_4^{20} 0·8113, n_D^{20} 1·47850, n_C 1·47423, n_F 1·48913, n_G 1·49838, optical exaltation 2·25. When oxidised with permanganate, this dimeride yields the maleinoid form of s-dimethylsuccinic acid and acetic acid (?), whilst hydrogenation at ordinary temperature in presence of platinum black yields 1 : 2-*dimethyl*-3 : 4-*diethyl*cyclo*butane*, $\begin{array}{c} \text{CHEt·CHMe} \\ | \\ \text{CHEt·CHMe} \end{array}$, b. p. 155—156°/760 mm., D_4^{20} 0·7729, n_D^{20} 1·42447, n_C 1·42193, n_F 1·42950, n_G 1·43377, optical exaltation 0·24; (2) about 5% of the *trimeride*, $\text{CHMe} \big\langle {}^{\text{CHMe}}_{\text{C(:CHMe)}} \big\rangle \text{C} \big\langle {}^{\text{C(:CHMe)}}_{\text{CHMe}} \big\rangle \text{CHMe}$ (?), which is a colourless, odourless liquid, b. p. 108—110°/17 mm.

When heated at 140° for three and a-half days, allene yields 5% of dimeride, 15% of trimeride, 5% and 22% of tetramerides I and II, 18% of pentameride, 10% of hexameride, and 25% of residual polymeride. With the exception of the dimeride and tetrameride I, these polymeric forms all rapidly absorb atmospheric oxygen, and all without exception yield formic, oxalic, and succinic acids on oxidation, and give a dark brown coloration with tetranitromethane. The viscosity increases with the degree of polymerisation, the hexameride being somewhat more

liquid than glycerol. (1) The dimeride, 1 : 2-*dimethylenecyclobutane*, $\begin{smallmatrix}CH_2 \cdot C:CH_2\\ CH_2 \cdot C:CH_2\end{smallmatrix}$ is a colourless liquid, b. p. 63—65°, D_4^{20} 0·7698,

n_D^{20} 1·42317. (2) The *trimeride*, $CH_2{<}{\begin{smallmatrix}CH_2-\\ C(:CH_2)\end{smallmatrix}}{>}C{<}{\begin{smallmatrix}C(:CH_2)\\ -CH_2\end{smallmatrix}}{>}CH_2$, is a liquid with a peculiar odour, b. p. 135°/774 mm., 70·5°/90 mm., 38°/21 mm., D_4^{20} 0·8624, n_D^{20} 1·48064, n_C 1·47677, n_F 1·48922, n_G 1·49694, optical exaltation 1·04. It readily absorbs hydrogen in presence of platinum-black giving the *compound*,

$$CH_2{<}{\begin{smallmatrix}CH_2\\ CHMe\end{smallmatrix}}{>}C{<}{\begin{smallmatrix}CHMe\\ CH_2\end{smallmatrix}}{>}CH_2,$$
which is a colourless, almost odourless liquid, b. p. 132°/756 mm., D_4^{20} 0·7972, n_D^{20} 1·43459, n_C 1·43159, n_F 1·43950, n_G 1·44410, optical exaltation 1·23. (3) Tetrameride I is a *dimeride of the dimeride*, $\begin{smallmatrix}CH_2 \cdot C \cdot CH_2 \cdot CH_2\\ CH_2 \cdot C——CH_2\end{smallmatrix}{>}C{<}{\begin{smallmatrix}CH_2-\\ C(:CH_2)\end{smallmatrix}}{>}CH_2$, and forms a colourless liquid with an odour of turpentine, b. p. 72—74°/9 mm., D_4^{20} 0·8955, n_D^{20} 1·50301, n_C 1·49905, n_F 1·51204, n_G 1·51999, optical exaltation 2·58. On prolonged heating in a sealed tube at 150°, it thickens and deposits an insoluble polymeride, which was obtained only in small amount. With hydrogen in presence of platinum-black, it gives the *compound*, $\begin{smallmatrix}CH_2 \cdot CH \cdot CH_2 \cdot CH_2\\ CH_2 \cdot CH——CH_2\end{smallmatrix}{>}C{<}{\begin{smallmatrix}CH_2\\ CHMe\end{smallmatrix}}{>}CH_2$, as a colourless liquid with a faint odour, b. p. 77—78°/13·5 mm., D_4^{20} 0·8679, n_D^{20} 1·46809, n_C 1·46448, n_F 1·47305, exaltation 1·51. (4) *Tetra-*

(I.) $\begin{smallmatrix}CH_2 \cdot CH_2 \;\; CH_2 \cdot CH_2\\ C——C——C——C\\ CH_2 \;\; CH_2 \cdot CH_2 \;\; CH_2\end{smallmatrix}$

(II.) $\begin{smallmatrix}CH_2——CH_2 \;\; CH_2 \cdot CH_2\\ CHMe \cdot C——C——CHMe\\ CH_2 \cdot CH_2\end{smallmatrix}$
meride II (I.) is a colourless liquid with an odour of kerosene, b. p. 101°/10 mm., D_4^{20} 0·9346, n_D^{20} 1·52624, n_C 1·52210, n_F 1·53579, n_G 1·54396, exaltation 2·33, and has the normal molecular weight in freezing benzene. On hydrogenation it yields the *compound* (II.), b. p. 95°/13·5 mm., D_4^{20} 0·8827, n_D 1·48289, n_C 1·47950, n_F 1·48941, n_G 1·49528, exaltation 2·02. On oxidation it yields formic, oxalic, and succinic-acids. (5) The *pentameride* (annexed formula) is a viscous, almost odourless liquid, b. p. 131—132°/10·5 mm., D_4^{20} 0·9498, n_D^{20} 1·52814, n_C 1·52422, n_F 1·53765, n_G 1·54591, exalta-tion 2·90. On hydrogenation it takes up sufficient hydrogen to saturate two double linkings, giving the *compound*, $C_{15}H_{24}$, as a colourless liquid with a faint odour, b. p. 123·5—124·5°/8 mm., D_4^{2} 0·9152, n_D^{20} 1·49623, n_C 1·49265, n_F 1·50241, n_G 1·50810, exaltation 2·40, and exhibits normal cryoscopic behaviour in benzene. (6) The *hexameride*, $C_{18}H_{24}$, of similar structure to the foregoing, is a viscous, almost odourless liquid, b. p. 170°/10 mm., D_4^{20} 0·9721, n_D^{20} 1·53869, n_C 1·53426, n_F 1·54817, n_G 1·55648, exaltation 3·64. Oxalic and succinic acids were found among its products of oxidation.

$\begin{smallmatrix}CH_2 \cdot CH_2 \;\; CH_2 \cdot CH_2 \;\; CH_2\\ C——C——C——C——C\\ CH_2 \;\; CH_2 \cdot CH_2 \;\; CH_2 \cdot CH_2\end{smallmatrix}$

It has been shown by Favorski (A., 1891, 1330) that, when heated with alcoholic alkali hydroxide, hydrocarbons of the diallyl series undergo isomeric change to divinyl derivatives: $C:C\cdot C\cdot C:C:C \longrightarrow$ $C\cdot C:C:C\cdot C:C\cdot C$; thus diallyl yields $\Delta^{\beta\delta}$-hexadiene. When heated at 250° for ten days, diallyl begins to isomerise, 10% of the monomeride boiling at a higher temperature than diallyl. The crude polymeride consists of (1) about 15% of a liquid of peculiar odour, b. p. 97—98°/20 mm., consisting of mixed dimerides, and (2) about 85% of colourless, insoluble, caoutchouc-like polymeride, which is converted into ozonide only with difficulty. At 150°, $\Delta^{\beta\delta}$-hexadiene yields a dimeride, b. p. 88—90°/20 mm., quite different from that of diallyl, but at 250° it gives a considerable proportion of the dimeride, b. p. 96—98°/20 mm.

The author has devised a method for determining the velocity at which polymerisation occurs. From 2 to 10 grams of the hydrocarbon were sealed in tubes and heated in a perfectly dark thermostat at $159\pm0\cdot1°$. After definite intervals of time, the tubes were cooled and their contents introduced into tared distilling flasks connected with small condensers and tared receivers. Liquids with low boiling points were distilled at ordinary pressure and those with high boiling points under diminished pressure. A bath of Wood's metal was used. for the heating, its temperature being at first below the boiling point of the monomeride, and finally about the boiling point of the dimeride. The monomeride, the residual polymeride, and sometimes also the dimeride were weighed to within $0\cdot02$ gram. In general, all the polymerised products were taken into account in calculating the velocity. The results obtained in this way were corrected for several errors inherent in the method. The numbers obtained with twelve hydrocarbons of the $\Delta^{\alpha\gamma}$-butadiene series show that: (1) With isomerides, the transference of a substituent from the extreme atom of a conjugated system of atoms to the middle atom is accompanied by increase in the velocity of polymerisation, and conversely. (2) The formation of a ring from a chain containing a conjugated system increases the velocity of polymerisation. (3) In homologous series, increase of the mass of a substituent at the middle (or extreme) atoms of a conjugated system increases (or lowers) the velocity of polymerisation, assuming that the heating occurs at corresponding temperatures. The results given by the four allene derivatives lead to the following conclusions: (1) The velocity of polymerisation of isomeric hydrocarbons of the allene series does not depend on the positions of the substituent groups. (2) In an homologous series of allene hydrocarbons, increase of the mass of the substituent results in increased velocity of polymerisation, the heating being at corresponding temperatures. T. H. P.

Polymerisation as a Method of Detecting the Allene Group, $C:C:C$. Sergei V. Lebedev (*J. Russ. Phys. Chem. Soc.*, 1913, 45, 1390—1391).—The polymerisation of allene hydrocarbons affords a simple and easy method of distinguishing them from diethylenic hydrocarbons of other types. At 150° allene hydrocarbons are polymerised almost completely in one to two days, part undergoing isomeric change to $\Delta^{\alpha\gamma}$-butadiene derivative. The crude polymeride consists principally

of dimeride or, with unsymmetrical allene hydrocarbons, of dimerides. The dimeride is separated by distillation; when several are present, the predominating one is obtained by fractionation.   The dimeride is

of the type $\begin{smallmatrix} C \cdot C \vdots C \\ C \cdot C \vdots C \end{smallmatrix}$, and, on oxidation by means of permanganate in

acetone solution, gives a good yield of succinic acid or one of its substituted derivatives, these being well crystallised and readily transformed into anhydrides. Further, the dimerides of allene hydrocarbons exhibit marked optical exaltation, which is usually about, and greater than, 2; dimerides from diethylene hydrocarbons of other types are optically normal.   T. H. P.

Isomeric Transformations of Diethylenic Hydrocarbons. I. Isomeric Transformation of Dimethylallene. [γ-Methyl-Δ-ᵃ·ᵝ-butadiene] into Isoprene. L. M. KUTSCHEROV (*J. Russ. Phys. Chem. Soc.*, 1913, 45, 1634—1654).—When heated with quinoline hydrobromide (compare Favorski and Borgmann, A., 1908, i, 15), γ-methyl-Δ-ᵃ·ᵝ-butadiene readily undergoes isomeric change into isoprene (50—55% yield) and a small proportion of *iso*propylacetylene [γ-methyl-Δ-ᵃ-butinene].   The reaction is irreversible, neither isoprene nor γ-methyl-Δ-ᵃ-butinene undergoing isomerisation under the above conditions; isoprene yields condensation products and combines with the pyridine, whilst γ-methyl-Δ-ᵃ-butinene partly remains unchanged and partly undergoes conversion into an unsaturated derivative according to the equation: $C_5H_8 + C_9H_7N,HX = C_5H_9X + C_9H_7N$.   The formation from γ-methyl-Δ-ᵃ·ᵝ-butadiene of isoprene is represented by the scheme: $CMe_2\!:\!C\!:\!CH_2 + C_9H_7N,HX \rightarrow CMe_2X\cdot CH\!:\!CH_2 + C_9H_7N \rightarrow CH_2\!:\!CMe\cdot CH\!:\!CH_2 + C_9H_7N,HX$, and that of γ-methyl-Δ-ᵃ-butinene by: $CMe_2\!:\!C\!:\!CH_2 + C_9H_7N,HX \rightarrow CHMe_2\cdot CX\!:\!CH_2 + C_9H_7N \rightarrow CHMe_2\cdot C\!:\!CH$; in the former case, the compound $CMe_2X\cdot CH_2\cdot CH_2X$ may also be formed as an intermediate product.

β-Bromo-γ-methyl-Δ-ᵃ-butene, $CH_2\!:\!CBr\cdot CHMe_2$, formed by treating γ-methyl-Δ-ᵃ-butinene either with hot quinoline hydrobromide or with hydrogen bromide in the cold, is a liquid, b. p. 100·5°/758 mm., D^{20} 1·2381 (1·2320), n_D^{20} 1·45093 (1·45033), and is reconverted into γ-methyl-Δ-ᵃ-butinene when heated in a sealed tube with alcoholic potassium hydroxide at 138°.   When treated with aqueous hydrobromic acid it yields: (1) γδ-dibromo-β-methylbutane, b. p. 61—62°/12 mm.; (2) *γγ-dibromo-β-methylbutane*, $CMeBr_2\cdot CHMe_2$, m. p. 13—15°, b. p. 53·5—54°/12 mm., 44—45°/8 mm., D_4^2 1·6987, D_4^{20} 1·6695, n_D^{20} 1·50468, which is converted into methyl *iso*propyl ketone when heated in a sealed tube with water and lead hydroxide.

γγδ-Tribromo-β-methylbutane, $CH_2Br\cdot CBr_2\cdot CHMe_2$, obtained by the action of bromine on β-bromo-γ-methyl-Δ-ᵃ-butene, is a hygroscopic liquid, b. p. 100—101·5°/12·5 mm., D_4^{20} 2·07112, n_D^{20} 1·55448.
                                                                   T. H. P.

Pyrogenic Acetylene Condensations. RICHARD MEYER and AUGUST TANZEN (*Ber.*, 1913, 46, 3183—3199. Compare A., 1912, i, 525).—The previous experiments in which nine hydrocarbons present in coal tar were obtained synthetically by the condensation of acetylene

have been repeated in an enlarged apparatus which enabled 6000 grams of tar to be obtained, which has been completely investigated. Phenanthrene and acenaphthene and also, in small quantities, styrene and hexylene were identified. The last has previously only been found in boghead coal and in bituminous shale.

On heating acetylene diluted with coal gas with hydrogen cyanide, pyridine and its homologues were obtained. Mixtures of ammonia and benzene yield aniline when heated, the reaction being reversible. Further condensation of the aniline leads to carbazole and to benzonitrile, the latter being formed by the action of hydrogen cyanide on aniline.

In all, therefore, seventeen constituents of coal tar have been identified as formed by the pyrogenetic condensation of acetylene. The hexylene formed is n-hexylene, identical with that from mannitol.

The formation of pyridine requires a temperature of 800°, at which the mixture of acetylene, hydrogen, and hydrogen cyanide can be heated without catching fire. Apparently the hydrogen cyanide acts as a poison towards the catalytic changes which bring about the sudden decomposition of acetylene and cause a mixture of acetylene and hydrogen to catch fire much below 800°.

The apparatus used is figured and described in detail.   E. F. A.

Improvements in the Preparation of Dichlorinated Hydrocarbons in which the Chlorine is Combined with Different Carbon Atoms. WILLIAM H. PERKIN, CHARLES WEIZMANN, and HAROLD DAVIES (Fr. Pat. 452503, and 1st Addition).—If vaporised hydrocarbons or chlorohydrocarbons are treated with the required halogen with or without the addition of a catalyst or in the presence of light with subsequent fractionation under diminished pressure definite products are obtained, and the preparation of the following compounds as chief products of the reaction is described.

From *isoamyl* chloride : *δ-dichloro-β-methylbutane* (b. p. 142°), *γδ-dichloro-β-methylbutane* (b. p. 150°), and *ββ-dichloro-β-methylbutane* (b. p. 170—172°).

From α-chlorobutane : tetrachlorobutane : from n-heptane : chloroheptane, and from *isoamyl* bromide : *ββ-dichloro-β-methylbutane* (b. p. 72—75°/5 mm.).

Monochloroacetic acid can also be prepared from acetic acid in a similar manner.   F. M. G. M.

Compounds of Aluminium Bromide with Hydrogen Sulphide and Organic Bromides. Synthesis of Mercaptans. VLADIMIR A. PLOTNIKOV (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1162—1173. Compare A., 1907, i, 580).—The following compounds have been prepared : $AlBr_3,H_2S$, obtained by passing hydrogen sulphide through aluminium bromide, either in a fused condition or in solution in carbon disulphide, forms colourless crystals, m. p. about 84°, and is decomposed immediately by the moisture of the air with liberation of hydrogen bromide and hydrogen sulphide.

$AlBr_3,EtBr,H_2S$, obtained by passing hydrogen sulphide through a solution of aluminium bromide in ethyl bromide, forms snow-white

crystals, m. p. (in sealed capillary) about 81°, is readily decomposed by water with formation of mercaptan (90% yield) : $AlBr_3,EtBr,H_2S +$ aq. $= AlBr_3,$aq. $+ EtHS + HBr,$ and in solution attacks aluminium or zinc with liberation of hydrogen. Electrolysis of a solution of the compound in ethyl bromide with platinum electrodes results in the development of hydrogen at the cathode and bromine at the anode.

$AlBr_3,CH_2Br\cdot CH_2Br,H_2S$ forms a pale yellow, crystalline powder decomposing at about 200°, and is also decomposed by the moisture of the air with formation of an oil with a garlic-like odour.

$AlBr_3,CHBr_3,H_2S$ is decomposed by water, apparently with formation of thioformic acid, which then undergoes condensation.

The structures of these compounds are considered in the light of Werner's co-ordination system.   T. H. P.

Dipropyl*iso*amylcarbinol and the Action of Nickel Carbonate on its Chlorohydrin. IVAN VANIN (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1155—1162).—Zaicev (A., 1912, i, 777) has shown that the action of silver carbonate on 1-chloro-1-allyl*cyclo*hexane yields an unsaturated hydrocarbon, C_9H_{14}. The author finds that a similar change is effected by the action of nickel carbonate on ε-chloro-β-methyl-ε-propyloctane.

Dipropyl*iso*amylcarbinol (β-methyl-ε-propyloctan-ε-ol), obtained by the action of magnesium *iso*amyl bromide on butyrone, has properties agreeing well with those given by Murat and Amouroux (A., 1912, i, 527).

ε-*Chloro-β-methyl-ε-propyloctane*, $CPr_2Cl\cdot CH_2\cdot CH_2\cdot CHMe_2$, is a colourless, mobile liquid, b. p. 115—117°/30 mm., D_0^0 0·8901, D_0^{20} 0·8748. When heated with excess of nickel carbonate in a reflux apparatus in an oil-bath at 135—145° for four to five hours, it is converted into a *methylpropyloctene*, $CHEt:CPr\cdot CH_2\cdot CH_2\cdot CHMe_2$ or $CPr_2:CH\cdot CH_2\cdot CHMe_2$, b. p. 89—91°/20 mm., 189—191°/756·5 mm., D_0^0 0·7773, D_0^{20} 0·7610, which may be identical or isomeric with that obtained by Murat and Amouroux (*loc. cit.*) by catalytic dehydration of dipropyl*iso*amylcarbinol with alumina.   T. H. P.

Transformation of *iso*Nitro-compounds into Ketones. S. S. NAMETKIN and (Mlle.) E. I. POZDNJAKOVA (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1420—1422).—Three methods exist for converting secondary nitro-compounds into ketones : (1) Reduction of nascent *iso*nitro-compounds by means of stannous chloride (compare Konovalov, A., 1899, i, 733) ; (2) action of acids on aqueous solutions of salts of *iso*nitro-compounds (compare Nef, A., 1895, i, 3) ; (3) heating of halogen-substituted nitro-compounds (compare Wislicenus and his collaborators, A., 1908, i, 973 ; 1909, i, 99 ; 1910, i, 621 ; 1912, i, 52). The last two methods are, however, only of theoretical interest. Nef's method yields, besides the ketone (or aldehyde), more or less free nitro-compound, which renders purification difficult, whilst method (3) is applicable only to those cases in which aggregation of several electro-negative groups to one carbon atom renders the halogen-

substituted nitro-compound unstable. Konovalov's method gives excellent results.

Investigation of the action of permanganate on nitro-compounds (compare A., 1910, i, 830; Konovalov, A., 1904, i, 499; 1905, i, 762) shows that, under the following conditions, almost quantitative yields of the corresponding ketones are obtained. A solution of the nitro-compound in potassium hydroxide solution (1 part to 2 of water) is mixed with five to six times its volume of water, and in the event of separation of insoluble nitro-compound, the latter is extracted by means of light petroleum. To the aqueous solution, mixed with pieces of ice in a large flask, is gradually added the theoretical quantity of $1\cdot5\%$ potassium permanganate solution, the ketone being subsequently distilled in a current of steam.

In this way, nitro*cyclo*hexane gave a 97% yield of *cyclo*hexanone, and nitrofluorene, a 96% yield of fluorenone.　　　　T. H. P.

Structure of *iso*Nitro-compounds. S. S. NAMETKIN (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1414—1420).—The author criticises the arguments advanced by Steinkopf and Jürgens (A., 1912, i, 152) in support of Hantzsch's formula for *iso*nitro-compounds.

Stress is laid on the unsaturated character of these compounds, which react with halogens and halogen hydracids, and in alkaline solution, even in the cold, instantly reduce 1—2% potassium permanganate solution, the nitro-compounds being converted almost quantitatively into ketones (compare preceding abstract). Such ready oxidisability is difficult to explain according to Hantzsch's ring constitution, but is easily understood if the presence of a double linking is assumed as is the case in the structure proposed by Michael and Nef. If oxidation at a double linking between carbon and nitrogen follows the same course as at one between two carbon atoms, the initial product of the reaction should be a compound exhibiting an accumulation of hydroxyl groups and hence possessing but slight stability; loss of the elements of water from this compound would yield ketone and a nitrite: $=C{:}NO{\cdot}OK \longrightarrow =C(OH){\cdot}NO(OH)(OK) \longrightarrow =CO + KNO_2 + H_2O$.

The behaviour of salts of primary nitro-paraffins on acidification, which yields transitory nitroso-compounds, and finally hydroxamic acids, is also readily accounted for on the basis of Michael and Nef's formula: $CHR{:}NO{\cdot}OH \longrightarrow CHR{:}O + {:}NOH \longrightarrow CHR(OH){\cdot}NO \longrightarrow CR(OH){:}NOH$. When, however, the nitro-group is accompanied by a more or less electronegative group, this intermediate formation of nitroso-compound does not take place, as no blue or green coloration then makes its appearance. Such an essential variation in one and the same reaction leads the author to suggest that the first stage in the action of dry hydrogen chloride is most probably a direct combination, the unstable compound thus formed subsequently undergoing intramolecular rearrangement and loss of water: $CHR{:}NO{\cdot}OH + HCl \longrightarrow CHRCl{\cdot}NH(OH){:}O \longrightarrow CHRCl{\cdot}N(OH)_2 \longrightarrow CRCl{:}NOH$. In those cases where the *iso*nitro-compound and the product of its union with the hydrogen haloid exhibit particularly slight stability,

the loss of water may partly precede the rearrangement ; a nitroso-compound would then be formed as intermediate product :

$$CHR\dot{:}NO\cdot OH \longrightarrow CHRCl\cdot NH(OH)\dot{:}O \longrightarrow CHRCl\cdot NO \longrightarrow CRCl\dot{:}NOH.$$

Analogous interpretations suggest themselves for the formation of halogen-substituted nitro-products, nitrolic acids and ψ-nitroles. Further, Nef's reaction does not necessitate the intermediate formation of a ring compound, as it is expressed in all probability by the scheme:

$$:C:NO\cdot OH + H_2O \longrightarrow :C(OH)\cdot NH(OH)\dot{:}O + H_2O \longrightarrow :C(OH)_2 +$$
$$:NOH + H_2O. \hspace{4cm} T. H. P.$$

Nitrosites of the Aliphatic Series. K. V. SIDORENKO (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1585—1604).—The author has devised an improved method for preparing ethylene nitrosite (compare Demjanov, A., 1899, i, 845), a number of reactions of this compound being studied.

When heated in a sealed tube with dilute hydrochloric acid (1 : 1), it yields hydroxylamine, apparently according to the equation :

$$(C_2H_4O_3N_2)_2 + 4H_2O + 4HCl = 2CHO\cdot CO_2H + 4NH_2\cdot OH,HCl.$$
At the ordinary temperature it is dissolved by concentrated sulphuric acid, from which it is precipitated unchanged on dilution. Nitric acid seems to be without action on it in the cold, but in the hot yields oxalic acid.

With aniline in absolute alcoholic solution, it gives a basic compound, and this, with hydrochloric acid, yields a crystalline substance, which is difficult to purify and gives poor results on analysis. Under similar conditions, p-nitroaniline acts on it apparently as a catalyst, being obtainable unchanged from the products of the reaction.

With benzylamine it reacts in accordance with the equation :

$$(C_2H_4O_3N_2)_2 + NH_2\cdot CH_2Ph = (C_2H_4O_2N_2)_2\cdot N\cdot CH_2Ph + N_2O + H_2O,$$

the unstable *compound* thus obtained crystallising in long, colourless, silky prisms and exhibiting normal cryoscopic behaviour in benzene.

With dibenzylamine it reacts thus : $(C_2H_4O_3N_2)_2 + 2NH(CH_2Ph)_2 = 2C_2H_4O_2N\cdot N(CH_2Ph)_2 + N_2O + H_2O$, the compound formed crystallising in long prisms, m. p. $74\cdot6$—$75\cdot2°$, and possessing the normal molecular weight in freezing benzene. This compound exhibits feeble basic properties ; it exerts a scarcely perceptible alkaline reaction on litmus, and yields no salts, even with strong acids. When reduced with tin and hydrochloric acid, it yields a sparingly soluble hydrochloride, which forms a platinichloride insoluble in alcohol. Accompanying the dibenzylamine derivative is a small quantity of a compound which separates in crystalline granules and possibly represents the result of combination between the amine and the nitrosite after the latter is resolved into two separate molecules.

From these results the conclusion is drawn that ethylene nitrosite has the structure $N_2O_2(CH_2\cdot CH_2\cdot NO_2)_2$, and thus belongs to the class of ψ-nitrosites (compare Wieland, A., 1904, i, 54). T. H. P.

The History of Alcohol. EDMUND O. VON LIPPMANN (*Chem. Zeit.*, 1913, **37**, 1313—1315, 1346—1347, 1358—1361, 1419—1422, 1428—1429. Compare A., 1912, i, 824 ; ii, 897).—A reply, with

historical quotations, to criticism by Diels of the author's view that alcohol and the process of distillation of readily volatile substances were unknown before the eleventh century. H. W.

Vapour Pressure of Glyceryl Trinitrate at the Ordinary Temperature. D. CHIARAVIGLIO and O. M. CORBINO (*Gazzetta*, 1913, 43, ii, 390—398).—In certain circumstances the rate of cooling of a warm substance situated in a closed space containing a very attenuated gas or vapour is proportional to the concentration of the molecules of the gas or vapour. Applying this method, the authors find that at about 21° the vapour pressure of glyceryl trinitrate is less than 0·0001 mm., so that it is beyond the limits of measurement or even detection. The value for the vapour pressure given by Marshall (*J. Soc. Chem. Ind.*, 1904, 23, 157; compare P., 1913, 29, 157) they regard as untrustworthy, because it is based on the assumption that, since the vapour pressures of glyceryl trinitrate and mercury are equal at 70°, they are also equal at the ordinary temperature. R. V. S.

Preparation of Aluminium Ethoxide. CLÉMENT BERGER (*Compt. rend.*, 1913, 157, 717—718).—Aluminium amalgam acts but slowly on absolute alcohol, but if, prior to the addition of the amalgam, a little sodium is dissolved in the alcohol, then, on warming the mixture under a reflux condenser, a rapid action takes place. When a considerable precipitate has formed, it is filtered off rapidly, and the filtrate evaporated to dryness in a vacuum. The solid residue is *aluminium ethoxide*, Al(OEt)$_3$. It is readily decomposed in the solid state or in solution by water, giving alcohol and aluminium, the presence of small quantities of water stopping its preparation. In the solid state it is decomposed by heat. W. G.

Preparation of Epichlorohydrin. JEAN NIVIERE (*Bull. Soc. chim.*, 1913, [iv], 13, 969—971).—A detailed account of a method already mentioned (compare this vol., i, 697) for the preparation of epichlorohydrin by the interaction of αγ-dichlorohydrin and potassium hydroxide in the presence of small quantities of water. W. G.

Catalytic Preparation and Decomposition of Esters. ALPHONSE MAILHE (*Chem. Zeit.*, 1913, 37, 777—778, 806—807).— The first paper contains a historical account of the work done on the catalytic preparation and decomposition of esters with particular reference to the more recent experiments of Sabatier and Mailhe on the use of metallic oxides. The second paper is a discussion of the behaviour of esters of aliphatic acids towards metallic oxide catalysts with special reference to formic acid and its esters. H. W.

Preparation of Sparingly Soluble Salts of Aluminium with Formic Acid Alone or with Formic together with Acetic Acid. ALBERT FRIEDLÄNDER (D.R.-P. 263865).—*Aluminium formate*, Al(OH)(HCO$_2$)$_2$, and *aluminium formoacetate*,
$$\text{HCO}_2 \cdot \text{Al(C}_2\text{H}_3\text{O}_2)\text{OH,2H}_2\text{O,}$$

are respectively prepared by heating aluminium hydroxide with anhydrous formic acid or with a mixture of formic and acetic acids ; they are of therapeutic value.   F. M. G. M.

Ferri- and Chromi-formates. RUDOLF F. WEINLAND and HANS REIHLEN (*Ber.*, 1913, **46**, 3144—3150).—The compounds formed when a ferric salt is treated with sodium formate have been studied.   In the deep red solution which results when equivalent quantities are mixed there is present the cation $[Fe_3(H \cdot CO_2)_6]$ of the hexaformato-triferri-base, of which only the monoformate has yet been isolated (Belloni, A., 1909, i, 283 ; Tower, 1910, ii, 900). By the addition of solid sodium formate to such a solution, the red colour gradually becomes pale, and *trisodium hexaformatoferrate*, $[Fe(H \cdot CO_2)_6]Na_3$, separates in pale green, microscopic, rectangular tablets. Thus, in presence of much sodium formate the anion $[Fe(H \cdot CO_2)_6]$ of hexaformatoferric acid is formed. This recalls the deep green of the trioxalatoferri-anion. By the action of water, the pale green solution or salt becomes red, the complex ions being in equilibrium.

The composition of the red formates, which are formed when ferric salts are mixed with sodium formate, varies, and the formic acid content rises with the concentration of that acid in the solution.   It is therefore probable that in these substances there may be present salts of the hexaformatoferri-base with the hexaformatoferric acid Brick-red, microcrystalline *compounds* which agree with the formulæ $[Fe(H \cdot CO_2)_6][Fe_3(H \cdot CO_2)_6],8H_2O$ and

$$\left[Fe(H \cdot CO_2)_6\right]\left[Fe_3 {(H \cdot CO_2)_6 \atop (OH)_2}\right]_3,14H_2O$$
have been prepared.

Similar phenomena occur in the case of chromium salts. From a solution containing 30 mols. of sodium formate to one of chromium nitrate, *trisodium hexaformatochromate*, $[Cr(H \cdot CO_2)_6]Na_3.4 \cdot 5H_2O$, crystallises in greenish-violet rhombohedra, which are only decomposed by ammonia after prolonged boiling.   J. C. W.

Two Isomeric Forms of Anhydrous Sodium Acetate. DANIEL VORLÄNDER and OTTO NOLTE (*Ber.*, 1913, **46**, 3199—3212).—An anhydrous form of sodium acetate is obtained on fusing sodium acetate trihydrate below 100°, and it also crystallises from fused sodium acetate. Intermediate hydrates do not exist. This modification is isomeric with that obtained on cooling the amorphous flux prepared by dehydrating above 200°. The new low temperature modification crystallises in the rhombic system and passes into the isomeride at 198°. The change is enantiotropic, the reverse change taking place so slowly that the two forms can exist side by side for months. The decomposition temperature of the trihydrate into water and anhydride is 58·2°.

Both anhydrous forms when crystallised from absolute ethyl or methyl alcohol yield the new rhombic form. This is an excellent condensation-agent, absorbing water much more quickly than the ordinary fused form. For such purposes the trihydrate is best dehydrated at 120—160°.

The phenomena of polymorphism are explained on the assumption that within the molecule as a whole there is a difference in the intensity of the energy between the different parts. Further, in consequence of these intramolecular differences there are variable external differences in intensity between similar molecules, so that the molecules become united in different ways. Thus two sodium acetate molecules may be united.

$$\begin{array}{ccc} \text{MeCO·ONa} & \text{MeCO—ONa} & \text{CH}_3\text{·CO·ONa} \\ \vdots & \vdots & \diagdown \\ \text{MeCO·ONa} & \text{CH}_3\text{·CO·ONa} & \text{NaO·CO·CH}_3. \end{array}$$
Such differences will explain the different crystalline structure of the polymorphic forms.　　　　　　　　　　　　　　　E. F. A.

The Solidifying- and Melting-points of Mixtures of Stearic and Oleic Acids. ROBERT MELDRUM (*Chem. News*, 1913, **108**, 199—201).—The investigation was undertaken to confirm the degree of accuracy of Dalican's method of determining the solidifying point and the thermometer bulb method of determining the melting point of mixtures of fatty acids.

In the first series of experiments, the solidifying points were taken in a test-tube 7 inches by 1 inch filled three parts full, which was suspended in a glass jar. The mixtures of acids were melted and cooled to within 10° of their solidifying point. The thermometer was inserted and when crystallisation had commenced the whole was very slowly stirred until the thermometer ceased to fall, when the latter was fixed in the centre, $1\frac{1}{2}$ inches from the bottom, and the readings completed. The point at which the thermometer rose and remained stationary was taken as the solidifying point. The method yields very concordant results for any given mixture and, contrary to the general belief, indicates the composition of the mixture more accurately when the solidifying point is low than when it is high.

A second series of experiments was performed in the same apparatus, but without stirring. The results are concordant among themselves, but both rise and solidifying point are lower than indicated by the first method. The rise appears to be rather erratic, and is apparently governed by the amount of matter crystallised per given interval of time. When working with large quantities, it appears to be eliminated.

A series of determinations of m. p. has also been made (1) by covering the thermometer bulb with a thin layer of substance, and suspending it inside a test-tube which is gradually heated in a beaker of water; (2) by the closed capillary tube method; (3) with an open capillary, and (4) with a capillary U-tube both limbs of which are left open. One limb contains a column of solid fat 4 cm. long. The tube is heated in a water-bath, the thermometer being placed between the limbs. The temperature at which both columns of fat are at equal height is taken as the m. p. The conclusion is drawn that the bulb method is the most accurate, the chief difficulty in it lying in obtaining a uniform coating of the fat. In the methods which depend on the displacement of the column of solid (Nos. 3 and 4), movement occurs before the latter is completely molten.　　　　　　　　H. W.

The Reaction between Acetoacetic Esters and Phenyl Iododichloride. GEORG SACHS (*Monatsh.*, 1913, **34**, 1409—1415).— The application of phenyl iododichloride as a chlorinating agent has been studied in the case of methyl and ethyl acetoacetates. Reaction with the methyl ester commenced at 34—35° and slackened after slightly more than one molecular proportion of phenyl iododichloride had been added at 60°. On distillation, a constant boiling, inseparable mixture of approximately two molecules of iodobenzene with one molecule of the expected methyl α-chloroacetoacetate, b. p. 84°/30 mm., was obtained. When ethyl acetoacetate was warmed at 60—80° with two molecules of the agent, however, iodobenzene, b. p. 79°/23 mm., and ethyl α-dichloroacetoacetate, b. p. 99°/21 mm., 207°/753 mm., were obtained.   J. C. W.

Optically Active Dimethylsuccinic Acid. ALFRED WERNER and M. BASYRIN (*Ber.*, 1913, **46**, 3229—3232).—It is shown that dimethylsuccinic acid may be resolved by means of optically active triethylenediaminecobaltic bromide. The modification of dimethylsuccinic acid, m. p. 195°, could not be resolved, and accordingly it represents the *meso*-form. The form m. p. 127° gives rise to d-*triethylenediaminecobaltic bromide* l-*dimethylsuccinate*, which is sparingly soluble, whereas the mother liquors contain the corresponding d-*dimethylsuccinate*. The optically active dimethylsuccinic acids have m. p. 135° and $[\alpha]_D$ +7·8° and −8·0.°   E. F. A.

Ketonic Decomposition of β-Lactones and its Application to the Synthesis of Ketens. ERWIN OTT (*Annalen*, 1913, **401**, 159—177).—Somewhat similar to the behaviour of dialkylmalonic anhydrides by heating, whereby dialkylketens are formed (Staudinger and Ott, A., 1908, i, 602), is the behaviour of derivatives of Meldrum's β-lactone of β-hydroxy*iso*propylmalonic acid (T., 1908, **93**, 601). In these also, by heating, the 4-ring is broken and acetone and ketens are obtained. The β-lactone of β-hydroxy*iso*-propylmalonic acid decomposes by heating into carbon dioxide, carbon suboxide, acetone, and acetic acid.

The β-*lactone* of β-*hydroxy-α-methyliso-propylmalonic acid*,

$$\begin{array}{c} O\!\!-\!\!CMe_2 \\ CO\cdot CMe\cdot CO_2H \end{array}'$$
decomp. 110—113°, colourless leaflets, is obtained by treating methylmalonic acid with acetic anhydride and a little concentrated sulphuric acid, and keeping the product for many days with the calculated amount of acetone. The lactonic acid decomposes by heating into carbon dioxide, acetone, and viscous substances. It cannot be esterified directly, but the *methyl* ester, $C_8H_{12}O_4$, m. p. 59·5°, b. p. 71°/0·1 mm., is obtained, together with the β-lactones of β-hydroxy*iso*propylmalonic acid and of β-hydroxy-α-methyl*iso*propylmalonic acid, in a remarkable reaction between methyl iodide and the β-lactone of silver β-hydroxy*iso*propylmalonate. The methyl ester, which is remarkably stable and distils at 213°/723·4 mm., with only slight decomposition, yields, by heating in a current of hydrogen, carbon dioxide, acetone, and about 50% of dimethylketen.

The *β-lactone* of *a-bromo-β-hydroxyisopropylmalonic acid*,

$$\begin{array}{c} O—CMe_2 \\ | \\ CO \cdot CBr \cdot CO_2H \end{array}'$$
decomp. 87—92°, colourless needles, is prepared by exactly neutralising the β-lactone of β-hydroxy*iso*propylmalonic acid with 2N-sodium hydroxide in the cold and treating the solution slowly with the calculated amount of bromine. At 130° the brominated lactonic acid decomposes into acetone, carbon dioxide, and hydrogen bromide.

The *methyl* ester, $C_7H_9O_4Br$, m. p. 87°, colourless prisms, prepared from the silver salt and methyl iodide in benzene, is decomposed by slow distillation at 95° over a faintly glowing platinum spiral in a vacuum, whereby carbon dioxide, acetone, and *bromomethylketen*, $CBrMe:CO$, are obtained. Bromomethylketen is being fully examined; it polymerises with great readiness to a faintly yellow, resinous *substance*, $(C_3H_3OBr)_3$, m. p. 60—70°, and differs from all other ketens in not reacting with aniline.

Malonic acid and acetic anhydride in the presence of a little concentrated sulphuric acid yield, after removal of the excess of the anhydride and the acetic acid at 30—40°/1—2 mm., an extremely hygroscopic oil which is presumably the mixed malonic acetic anhydride, since it contains for each molecule of malonic acid, one acetyl group which cannot be removed without decomposition. The substance yields carbon suboxide by warming on the water-bath, and reacts with acetone to give an 87% yield of the β-lactone of β-hydroxy*iso*propylmalonic acid. Dimethylmalonic anhydride is obtained in 96% yield by treating dimethylmalonic acid with acetic anhydride and a little concentrated sulphuric acid, and removing by-products at 40°/1—2 mm., the operations being once repeated on the product. *Diethylmalonic anhydride*, prepared in a similar manner, is a liquid.   C. S.

Synthesis of Formaldehyde from Carbon Dioxide and Water by Inorganic Colloids acting as Transformers of Light Energy. BENJAMIN MOORE and T. ARTHUR WEBSTER (*Proc. Roy. Soc.*, 1913, [B], 87, 163—176).—The experiments of Bach, Euler, Usher, and Priestley (compare A., 1906, ii, 299, 881) have been confirmed and extended to show that formaldehyde is synthesised from carbon dioxide by means of inorganic colloidal uranic and ferric hydroxides in very dilute solution. The colloids act as catalysts for light energy, positive results being obtained only in strong, direct sunlight and in a "uviol" mercury arc. Under similar conditions, crystalloid uranium nitrate does not cause synthesis. The uranium catalyst is more powerful than the ferric catalyst. It is claimed that such a process occurring in nature forms the first step in the origin of life.
                                                    E. F. A.

Condensation of Aldol with Formaldehyde. V. P. KRAVEC (*J. Russ. Phys. Chem. Soc.*, 1913, 45, 1451—1453).—With the object of obtaining derivatives of pentaerythritol, from which the hydrocarbon, C_5H_8, regarded by Gustavson (A., 1896, i, 669) as vinyltrimethylene, has been obtained (compare Zelinski, this vol., i, 254), the author has investigated the condensation of aldol with formaldehyde under the

conditions laid down by Tollens and Wigand (A., 1892, 127); this reaction may be expected to give methylpentaerythritol.

Aldol may be readily prepared in good yield (30 grams) by a method devised by Zelinski and Volkonski, but not yet published. It consists in mixing acetaldehyde (100 grams), dissolved in an equal weight of water, with freshly precipitated, alkali-free lead hydroxide (30 grams) at a temperature not exceeding 5°, the mixture being left at the ordinary temperature for two hours and then gradually heated on the water-bath at 25°, 30°, and 35° during eighteen hours.

In presence of lead hydroxide, aldol and formaldehyde give pentaerythritol, so that resolution of the aldol molecule into 2 mols. of acetaldehyde precedes condensation with formaldehyde. The action of lead hydroxide on aldol is hence a typical, reversible reaction (compare de Bruyn and Alberda van Ekenstein, A., 1899, i, 850; Löb, A., 1909, i, 767; Löb and Pulvermacher, A., 1910, i, 95).

Pentaerythritol is also obtained from aldol and formaldehyde in presence of calcium hydroxide, but the latter is not able to effect the condensation of acetaldehyde to aldol.   T. H. P.

Mechanism of Oxidative Changes. HEINRICH WIELAND (*Ber.*, 1913, **46**, 3327—3342).—The catalytic action of palladium or platinum is not due to the activation of molecular oxygen with intermediate formation of peroxide, but it is attributed to the activation of hydrogen. This theory is extended to biological oxidations, and it is shown that certain of these can take place in presence of palladium black and in the complete absence of oxygen, provided that the accumulated hydrogen is removed by the presence of other substances with an affinity for hydrogen such as *p*-benzoquinone or methylene-blue.

Dextrose can be dehydrogenated by shaking with palladium black at 40° in an atmosphere of nitrogen, carbon dioxide being formed from the beginning of the reaction as well as hydrogen. The change is accelerated on the addition of *p*-benzoquinone, which is converted into quinhydrone or of methylene-blue, which is decolorised. In presence of oxygen which forms water with the liberated hydrogen, the change is still more rapid. Gluconic acid is even more quickly dehydrogenated.

Lactic acid yields pyruvic acid under similar conditions. Phenol, *m*-cresol, guaiacol, pyrogallol and aniline can be dehydrogenated in the absence of oxygen. Tyrosine and uric acid are resistant, but in both these cases the action of the oxydase is known to be combined with that of a hydrolysing enzyme.

Alcohol in presence of methylene-blue or of *p*-benzoquinone is converted into acetic acid by an acetone preparation of acetic acid bacteria, all oxygen being excluded. Acetaldehyde behaves similarly, whereas methyl alcohol or formaldehyde are converted into formic acid. Dextrose is dehydrogenated by the acetic acid ferment in presence of methylene-blue, carbon dioxide being formed.

The reducing enzymes, for example, Schardinger's reductase, act in the same manner. Salicylaldehyde is converted into salicylic acid by the milk enzyme either in presence of oxygen or in presence of methylene-blue in the absence of oxygen.   E. F. A.

Biochemical Synthesis of a Sugar of the Hexobiose Group, Gentiobiose. ÉMILE BOURQUELOT, HENRI HÉRISSEY, and J. COIRRE (*Compt. rend.*, 1913, **157**, 732—734; *J. Pharm. Chim.*, 1913, [vii], **8**, 441—449).—The authors have prepared and isolated gentiobiose in a pure state by the action of emulsin, from almonds, on a concentrated solution of dextrose at 15—20° for one month. The excess of dextrose was removed by fermenting it with top yeast, after destroying the emulsin by heat and diluting the solution. The fermented liquid was neutralised with calcium carbonate, filtered and evaporated to dryness under reduced pressure. The dry residue was extracted with 95% alcohol, from which extracts two crops of crystals were obtained, the first containing mineral matter, and the second being pure gentiobiose as shown by its physical and chemical properties. W. G.

Peculiarity in the Solubility Curve of Sugar in Water. PH. ORTH (*Bull.* Assoc. chim. Sucr. Dist., 1913, **31**, 94—103).—A theoretical paper. It is shown that the equation $S = 28162/(157\cdot97 - t)$ gives the solubility of sucrose in water at a temperature t. The coefficient of supersaturation C_1 is obtained by the expression $C_1 = S(157\cdot97 - t_1)/28162$, in which S is the solubility at a temperature t and t_1, the lower temperature to which the solution is cooled without crystallisation. The constant $157\cdot97$ is shown to represent the temperature at which the solubility of sucrose in water becomes infinitely large, that is, the temperature at which sucrose and water are miscible in all proportions. A number of other empirical equations are given dealing with the freezing-point constant and the specific heat of aqueous solutions of sucrose, and also with the heat of solution.

J. F. S.

The Nitration of Cellulose, and the Decomposition of Nitrocellulose by Acids and Alkalis. G. MEISSNER (*Zeitsch. ges. Schiess. Sprengstoffwesen*, 1913, **8**, 252—254, 269—271).—An account of numerous experiments on the yields, stability, and variations in the products obtained by nitrating cellulose under different conditions, together with an account of the decomposition of these compounds by acids and alkalis. F. M. G. M.

Unstable Products in the Nitration of Cellulose. ERNST BERL and MAX DELPY (*Zeitsch. ges. Schiess. Sprengstoffwesen*, 1913, **8**, 129).—When water is removed from nitrocellulose by systematic treatment with alcohol, it gives rise to a brown powder, decomp. 162°, soluble in concentrated sulphuric acid; this when extracted with ether furnishes two *compounds*: (1) a yellowish-brown powder, decomposing at 174°, containing about 10% of nitrogen, and converted by concentrated alkalis into a compound soluble in water; and (2) a violet powder containing 9·45% of nitrogen and decomposing at 157°.

F. M. G. M.

Fatty Acid Esters of Hydrocellulose and their Hydrolysis. ALBRECHT STEIN (*Zeitsch. angew. Chem.*, 1913, **26**, 673—677).— Triacyl derivatives of hydrocellulose are prepared without difficulty by

acting on hydrocellulose with the anhydride of a fatty acid in the presence of concentrated sulphuric acid. The properties of the hydrocellulose esters of the homologues of acetic acid are similar to those of acetyl cellulose.

In order to obtain information as to the manner in which the catalyst acts in the esterification of hydrocellulose, the action of an acid anhydride on hydrocellulose in the presence of chloroacetic acid or trichloroacetic acid has been studied. It is found that the use of these catalysts leads to the production of an ester containing chlorine, in some cases to the extent of 2·8%.   W. H. G.

The Preparation of Triethylamine. JITENDRA NATH RAKSHIT (*J. Amer. Chem. Soc.*, 1913, **35**, 1781—1783).—If 75 c.c. of ethyl bromide and 50 c.c. of ammonia solution (D 0·88) are heated together in a closed 750 c.c. flask in the steam-oven for three hours, subsequent distillation with sodium hydroxide solution into dilute hydrochloric acid gives a mixture of ammonium chloride and ethylamine hydrochloride which are most easily separated by filtering the latter in a molten condition from the solid ammonium chloride.

The ethylamine from 62 grams of the hydrochloride is then mixed with 44 c.c. of ethyl bromide and again heated in a closed flask for three hours in the steam-oven. After cooling, the liquid is decanted from the separated crystalline solid and is then evaporated with dilute hydrochloric acid, when the residue (approximately 19 grams) consists of pure triethylamine hydrochloride.   D. F. T.

Resolution of α-Alanine into its Optical Antipodes by means of Active Acids. II. AMEDEO COLOMBANO and GIUSEPPE SANNA (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 292—298. Compare this vol., i, 1208).—In alcoholic solution, the ethyl ester of alanine and *d*-camphorsulphonic acid yield the *salt* of the *inactive* ester,

$$CO_2Et \cdot CHMe \cdot NH_2, C_{10}H_{15}O \cdot SO_3H, \tfrac{1}{2}H_2O,$$
m. p. 95—100°, $[α]_D +11\cdot49°$. When water is used as solvent, crystalline fractions are obtained of gradually increasing melting point and specific rotation, but separation of the *d*- and *l*-alanines in this way is not easy.

Such resolution is, however, readily effected by means of *d*-bromocamphorsulphonic acid, mixing of the ammonium salt of this acid with alanine ester hydrochloride in aqueous solution resulting in the separation of *ethyl* d-*alanine* d-*bromocamphorsulphonate*,

$$CO_2Et \cdot CHMe \cdot NH_2, C_{10}H_{14}OBr \cdot SO_3H, 1H_2O,$$
m. p. 145° or 192° (anhydrous), $[α]_D^{25} +67\cdot54°$ (hydrate), which corresponds with the dextro-ester and with *l*-alanine. Isolation of ethyl *l*-alanine *d*-bromocamphorsulphonate from the mother liquor is troublesome and gives only a small yield; possibly this ester could be more readily obtained by the use of *l*-bromocamphorsulphonic acid.
                                    T. H. P.

Tetra-aminoadipic Acid and αδ-Dihydroxy-βγ-diaminoadipic Acid. WILHELM TRAUBE and ARTHUR LAZAR (*Ber.*, 1913, **46**, 3438—3450. Compare A., 1903, i, 76).—An account of the replacement of the bromine atoms in the monolactam of αδ-dibromo-βγ-di-

aminobutane-$aa\delta\delta$-tetracarboxylic acid (1) and the dilactam of $a\delta$-dibromo-$\beta\gamma$-diaminoadipic acid (II) by the hydroxyl amino-, and dimethylamino-groups :

(I.) $CBr(CO_2H)_2 \cdot CH \underset{NH-\!-\!-CO}{\overset{CH(NH_2)}{<}} \!\!> CBr \cdot CO_2H$

(II.) $CO \underset{NH-\!-CH \cdot CHBr}{\overset{CHBr \cdot CH-\!-NH}{<}} \!\!> CO.$
When heated at 105° with alcoholic ammonia, the dilactam of dibromodiaminoadipic acid is converted into the *dilactam* of *$a\beta\gamma\delta$-tetra-amino-adipic acid*, $CO \underset{CH(NH_2) \cdot CH-\!-\!-NH}{\overset{NH-\!-\!-CH \cdot CH(NH_2)}{<}} \!\!> CO$, which crystallises in stellar aggregates of short, stout needles, and forms a sparingly soluble *sulphate*, B,H_2SO_4 (solubility in water at 100° = 0·177 : 100), a *nitrate* (leaflets), *platinichloride* (hexagonal pyramids or rhombohedra), *hydrochloride* (colourless, prismatic needles), and *picrate* (fern-like aggregates).

The hydrochloride reacts with potassium cyanate in hot aqueous solution, yielding the *dilactam* of *$\beta\gamma$-diamino-$a\delta$-dicarbamidoadipic acid*, $C_8H_{12}O_4N_6$, which crystallises with water (1 mol.) in colourless needles.

Attempts to prepare tetra-aminoadipic acid by acidifying solutions of the dilactam in aqueous alkalis were unsuccessful, the original dilactam being precipitated unchanged.

The *dilactam* of *a-bromo-$\beta\gamma\delta$-triamino-a(or δ)carboxyadipic [a-bromo-$\beta\gamma\delta$-triaminobutane-$a\gamma\gamma$(or $aa\gamma$)-tricarboxylic] acid*, $C_7H_8O_4N_3Br$, obtained in the form of its *ammonium* salt by the action of alcoholic ammonia at 80—90° on the monolactam of $a\delta$-dibromo-$\beta\gamma$-diamino-butane-$aa\delta\delta$-tetracarboxylic acid, crystallises with water ($1\frac{1}{2}$ mol.) in needles (decomp. 280°) and yields salts with both bases and acids ; the *silver* salt (slender, colourless needles), *barium* salt, and *hydrobromide* (prisms) are described. The position of the free carboxyl group has not yet been determined. When kept in contact with an excess of aqueous dimethylamine (45%) for four or five days at the ordinary temperature, the dilactam of $a\delta$-dibromo-$\beta\gamma$-diaminoadipic acid is converted into the *dilactam* of *$\beta\gamma$-diamino-$a\delta$-tetramethyl-diaminoadipic acid* (III), which is separated from the accompaning *3 : 4-diaminotetrahydrofuran-2 : 5-dicarboxylic acid* (IV) by taking advantage of the sparing solubility of the latter compound in water.

(III.) $CO \underset{CH(NMe_2)_2 \cdot CH-\!-\!-NH}{\overset{NH-\!-\!-CH \cdot CH(NMe_2)_2}{<}} \!\!> CO.$

(IV.) $\underset{NH_2 \cdot CH-\!-CH \cdot NH_2}{\overset{CO_2H \cdot CH \cdot O \cdot CH \cdot CO_2H}{}}$.
The furan compound crystallises in ill-defined tetragonal prisms which become yellow at 210°, and have m. p. 230° (decomp.). It forms with mineral acids very hygroscopic salts, of which the *nitrate* (decomp. 180°) is described. On treatment with fuming nitric acid, it yields *2-nitro-3 : 4-diaminofuran-5-carboxylic acid*, $C_5H_5O_5N_3$, crystallising in stellar aggregates of slender needles (decomp. above 300°). The dilactam, III, separates with $2H_2O$ in

well developed rhombic crystals, which darken at 243° and have m. p. 252° (decomp.). It forms a *hydrochloride*, $B,2HCl$, long, slender needles; a *picrate*, hexagonal leaflets; *platinichloride*, rectangular plates; *sulphate*, rhombic prisms, and an *oxalate*, prismatic needles.

The monolactam of $a\delta$-dibromo-$\beta\gamma$-diaminobutane-$aa\delta\delta$-tetracarboxylic acid reacts with silver nitrate in aqueous solution, yielding the *silver* salt, $C_8H_6O_7N_2Br_2Ag_2$, which is converted by boiling with water into the *monolactam* of $\beta\gamma$-*diamino*-$a\delta$-*dihydroxybutane* $aa\delta\delta$-*tetracarboxylic acid*, $OH \cdot C(CO_2H)_2 \cdot CH {<}{\begin{smallmatrix} CH(NH_2) \\ NH{-}CO \end{smallmatrix}}{>} C(OH) \cdot CO_2H$. The latter compound could not be obtained crystalline, and, therefore, was isolated in the form of its *silver* salt, $C_8H_9O_9N_2Ag$.

When heated either alone at 180° or in aqueous solution, it loses carbon dioxide and water, yielding the *dilactam* of $\beta\gamma$-*diamino*-$a\delta$-*dihydroxyadipic acid*, $CO {<}{\begin{smallmatrix} CH(OH) \cdot CH{-}{-}{-}NH \\ NH{-}{-}{-}CH \cdot CH(OH) \end{smallmatrix}}{>} CO$, which crystallises in tetragonal prisms capped with pyramids.

Attempts to prepare tetrahydroxyadipic acid from the dilactams of tetra-aminoadipic and $a\delta$-dihydroxy-$\beta\gamma$-diaminoadipic acids proved unsuccessful, the amino-groups in these compounds being stable towards the action of nitrous acid. F. B.

Preparation of Acetamide. E. F. HITCH and H. N. GILBERT (*J. Amer. Chem. Soc.*, 1913, **35**, 1780—1781).—Acetamide is conveniently prepared by heating a mixture of 42 grams of ammonium carbonate and 125 grams of acetic acid (compare Rosanoff, Gulick, and Larkin, A., 1911, i, 529) in a 250 c.c. round-bottomed flask in an air-bath. The flask is fitted with a Vigreux fractionating column carrying a thermometer and attached to a condenser. The mixture is boiled at such a rate that 20 to 30 drops distil per minute, and when the thermometer registers 223° the residue in the flask is almost pure acetamide.

The yield is 85—90% calculated on the ammonium carbonate, and the time required is four hours. D. F. T.

Synthesis of Amido-oxalylbiuret. JOHAN TH. BORNWATER (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **16**, 198—200).—In a previous paper (A., 1911, i, 617) the author has shown that finely-powdered carbamide reacts with an ethereal solution of oxalyl chloride, yielding parabanic acid and, apparently, oxalyldiureide,

$$C_2O_2(NH \cdot CO \cdot NH_2)_2,$$
which is quite different from Grimaux's compound (A., 1880, 105) obtained by fusion of a mixture of carbamide and parabanic acid. Subsequently, the subject has been re-investigated by Biltz and Topp (this vol., i, 600, 602), who are led to the conclusion that the two substances are probably identical, although certain differences remain unexplained. The author points out that Grimaux's compound has been incorrectly described as oxalyldiureide in the German literature, since Grimaux calls it, "amide d'un acide oxalylbiurétique." He has further effected the synthesis of the latter compound.

Carbethoxyethoxalylcarbamide, $CO_2Et \cdot NH \cdot CO \cdot NH \cdot CO \cdot CO_2Et$, needles, m. p. 152°, is obtained in 10% yield when ethyl oxamate and ethyl urethane are heated in dry benzene. When a solution of this substance in absolute alcohol is treated with dry, gaseous ammonia, amido-oxalylbiuret, $NH_2 \cdot CO \cdot CO \cdot NH \cdot CO \cdot NH \cdot CO \cdot NH_2$, is precipitated, which is identical with Grimaux's compound.

In effecting the biuret reaction, the author points out the desirability of first adding the highly diluted copper sulphate solution, and, subsequently, a solution containing at most 15% of potassium hydroxide. When the reagents are added in the reverse order and more concentrated solutions of potassium hydroxide are employed (compare Biltz and Topp, *loc. cit.*), there is a possibility that the substance is already undergoing partial decomposition before the copper sulphate is added.

The substance, $C_4H_5O_3N_3$, m. p. 272—273° (decomp.), obtained by the action of fuming hydriodic acid (D 1·96) on Grimaux's compound, is, possibly, uramil, the formation of which is explicable on the author's formulation of Grimaux's compound. H. W.

Simultaneous Reduction and Oxidation. I. Dichloropyruvic Acid, Nitrile and Ester from Trichlorolactic Acid, Nitrile and Ester. ARTHUR KÖTZ and K. OTTO (*J. pr. Chem.*, 1913, [ii], **88**, 531—552. Compare Wallach, this Journ., 1875, 351; A., 1878, 285, 288; Pinner, this Journ., 1877, ii, 584; A., 1884, 1298). —With the object of throwing further light on the mechanism of the transformation of chloral into dichloroacetic acid under the influence of aqueous potassium cyanide, the authors have undertaken a systematic examination of similar cases of simultaneous reduction and oxidation occurring in compounds of the type $CCl_3 \cdot CH(OH) \cdot R$, the present paper dealing particularly with the transformation of $\beta\beta\beta$-trichlorolactic acid, and its nitrile and ester into the corresponding derivatives of dichloropyruvic acid.

They consider that the first stage in the reaction between chloral and potassium cyanide consists in the formation of $\beta\beta\beta$-trichloro-lactonitrile (I), and that this loses hydrogen chloride, yielding the compounds (II) or (III), which are at once transformed into dichloro-pyruvonitrile (IV), the latter compound then undergoing hydrolysis to dichloroacetic and hydrocyanic acids:

(I) $CCl_3 \cdot CH(OH) \cdot CN \longrightarrow$ (II) $CCl_2{:}C(OH) \cdot CN$, or

(III) $\overset{\displaystyle\frown}{CCl_2 \cdot CH} \cdot CN \longrightarrow$ (IV) $CHCl_2 \cdot CO \cdot CN \longrightarrow CHCl_2 \cdot CO \cdot OH + HCN.$
The following evidence is given in support of the view that $\beta\beta\beta$-trichlorolactonitrile is intermediately formed in the reaction: (1) Although potassium cyanide is hydrolysed to potassium hydroxide and hydrogen cyanide, the action of potassium cyanide on chloral does not give rise to chloroform, and therefore the chloral cannot be present as such in the mixture. (2) $\beta\beta\beta$-Trichlorolactonitrile, on treatment with potassium hydroxide, gives rise to potassium dichloroacetate, no chloroform being produced in the reaction.

$\beta\beta\beta$-Trichlorolactonitrile thus differs from chloral in not undergoing hydrolysis with the formation of chloroform. This difference is referred by the authors to the reactivating influence of the cyanogen group on the hydrogen atom directly attached to the central carbon of the nitrile; on account of this mobility of the hydrogen atom, the molecule readily loses hydrogen chloride, whilst at the same time the ability to yield chloroform by hydrolysis disappears.

A similar difference is shown by $\beta\beta\beta$-trichloroethyl alcohol, ethyl $\beta\beta\beta$-trichlorolactate, and other compounds of the type

$$CCl_3 \cdot CH(OH) \cdot R.$$
On treatment with triethylamine, ethyl $\beta\beta\beta$-trichlorolactate and $\beta\beta\beta$-trichlorolactonitrile lose hydrogen chloride, yielding ethyl dichloropyruvate and dichloropyruvonitrile. The last-mentioned compound reacts with water and alcohol, yielding dichloroacetic acid and ethyl dichloroacetate.

The formation of dichloroacetamide, dichloroacetanilide, and ethyl dichloroacetate by the action of ammonia, aniline and alcohol on $\beta\beta\beta$-trichlorolactonitrile (Pinner and Wallach, *loc. cit.*) is considered by the authors to furnish additional support to their view that dichloropyruvonitrile is formed as an intermediate product in the action of potassium cyanide on chloral.

When heated with water or triethylamine, trichlorolactic acid decomposes, thus: $CCl_3 \cdot CH(OH) \cdot CO_2H \longrightarrow HCl + CHCl_2 \cdot CO \cdot CO_2H \longrightarrow CO_2 + CHCl_2 \cdot CHO.$

The readiness with which this decomposition takes place affords an explanation of the fact that the interaction of trichlorolactic acid and ammonia, hydroxylamine, phenylhydrazine, or carbamide gives rise to derivatives of glyoxal or dichloroacetaldehyde.

Dichloropyruvonitrile is obtained (1) by the interaction of molecular proportions of trichlorolactonitrile and triethylamine in ethereal solution at the ordinary temperature, and (2) by heating dichloroacetyl chloride with silver cyanide. It forms a colourless liquid, b. p. 111—113°/12 mm.

$\beta\beta$-Dichloro-a-benzyliminopropiobenzylamide,

$$CHCl_2 \cdot C(:N \cdot C_7H_7) \cdot CO \cdot NH \cdot C_7H_7,$$
prepared by heating ethyl trichlorolactate with benzylamine (3 mols.) in ethereal solution, crystallises with water (1 mol.) and has m. p. 101° (not sharp). It may also be obtained by heating ethyl dichloropyruvate with benzylamine (2 mols.) in ethereal solution. When prepared by the second method, it crystallises with $2H_2O$ in lustrous, white leaflets, m. p. 220—221°, or slender needles, m. p. 104° and 150°.

Ethyl dichloropyruvate, prepared by heating ethyl trichlorolactate and triethylamine in alcoholic solution, is a colourless liquid, b. p. 115°/12 mm. It rapidly takes up water on exposure to air, and then has the composition $C_5H_6O_3Cl_2, 2H_2O$.

Dichloropyruvic acid, $C_3H_2O_3Cl_2, H_2O$, obtained by hydrolysing the ester with hydrochloric acid, separates from a mixture of ether and light petroleum in white crystals, m. p. 119°, b. p. 215—220°, and after distillation has m. p. 110°. When boiled with water, it is converted into dichloroacetaldehyde.   F. B.

Nitrogen Carbides. HERMANN PAULY and ERNST WALTZINGER (*Ber.*, 1913, **46**, 3129—3140).—It has already been shown (A., 1910, i, 639) that tetraiodoglyoxaline decomposes on heating to form the compounds C_8N_3I and then C_8N_2, the reaction recalling the formation of paracyanogen from cyanuric iodide (Klason, 1886, 1001). The fact that the decomposition takes place at a temperature which, according to experience, is not inimicable to the glyoxaline ring, suggests that the compounds formed still have ring structure, since a partial loss of nitrogen might be expected to ensue if the ring were opened. In order to test this point, and also to learn whether the preliminary decomposition into a monoiodo-compound was general, tri-iodo-5- and 2-methylglyoxalines and tetraiodopyrrole (iodole) have also been heated. In these cases, however, the compounds melt and enclose some of the liberated iodine, so that the formation of intermediate compounds was masked, and, in addition, the presence of hydrogen was disturbing and led to the production of a little ammonium iodide,

All the compounds obtained, C_8N_2, C_8N_2Me and C_4NH, are amorphous, charcoal-like products, and have, in common with paracyanogen, the following properties : they yield cyanogen on heating to redness in an indifferent atmosphere ; they give up all their nitrogen as ammonia when heated with soda-lime ; they dissolve in molten alkalis, forming ammonia, cyanides and carbonates. Animal charcoal has some of these properties, but does not dissolve in molten alkali. It may consist in part of such nitrogen carbides.

Quantitative studies on the decomposition of tetraiodoglyoxaline were carried out in a glass tube which was slightly bent downwards, so that it dipped below the surface of a metal bath. One end of the tube was attached to a U-tube and a flask containing potassium iodide solution for the absorption of iodine. The iodine was swept out by a stream of carbon dioxide. Since the tetraiodoglyoxaline cannot be purified by recrystallisation, it was analysed before use. It was found that, however carefully prepared, it contained about 1% of a by-product which could be removed by volatilisation at 105° in vacuum. The carbides obtained, readily absorbed gases and moisture, so that all analytical processes were carried out with the greatest expedition.

The formation of the soot-like, sepia-coloured *iodo-nitrogen carbide*, $(C_8N_2I)_x$, takes place at 180°. The substance forms a brown solution in nitric acid, iodine being liberated. The *carbide*, $(C_8N_2)_x$ is best obtained by heating tetraiodoglyoxaline, first at 180° and then at 420°. When heated at 800—900° in a current of carbon dioxide, cyanogen and a little carbon monoxide were formed, but in an atmosphere of nitrogen, the formation of cyanogen was quantitative. J. C. W.

Iron Salts which Combine with Carbon Monoxide. II. The Action of Amines on Sodium Nitroprusside. WILHELM MANCHOT and PIERRE WORINGER (*Ber.*, 1913, **46**, 3514—3521).—It has been shown previously (A., 1912, i, 955) that the action of ammonia on sodium nitroprusside is expressed by the equation :

$$Na_2[Fe(CN)_5NO] + 3NH_3 + H_2O =$$
$$Na_2(NH_4)[Fe(CN)_5,NH_3] + NH_4 \cdot NO_2.$$
It has now been found possible to replace the NO-group by alkyl-amines instead of ammonia, and the compounds thus formed give similar reactions to the ammonia compound, and also possess the property of combining with carbon monoxide and oxygen. Methyl-amine, dimethylamine, trimethylamine, and ethylenediamine react very readily, but aromatic amines, such as aniline, toluidine, etc., have no action on sodium nitroprusside.

Trisodium ferropentacyanomethylamine, $Na_3[Fe(CN)_5, NH_2Me]$, was obtained in the form of yellow crystals from sodium nitroprusside and methylamine in aqueous methyl-alcoholic solution, dilution with the alcohol being necessary to moderate the reaction. The reaction mixture also contained sodium acetate, to prevent the formation of a disodium methylamine salt.

The *disodium ethylenediamineferropentacyanoethylenediamine*,
$$Na_2[Fe(CN)_5], C_2H_4(NH_2)_2,$$
was not obtained pure, although the product was well crystallised, and appeared homogeneous under the microscope. The addition of sodium acetate to the reaction mixture did not give a trisodium salt.

Although sodium nitroprusside does not react with pyridine, the salt *trisodium ferropentacyanopyridine*, $Na_3[Fe(CN)_5, C_5H_5N]$, can be obtained by the action of pyridine on an aqueous-methyl alcoholic solution of trisodium ammonium ferropentacyanoammine. It crystal-lises as a felted mass of long, yellow needles, and possesses properties similar to those of the alkylamine compounds.

Experiments to prepare the ferric compounds corresponding with the ferropentacyanocarbon monoxide salts have not hitherto been successful.   T. S. P.

Action of Organomagnesium Compounds on Ethyl Diazo-acetate. ERNST ZERNER (*Monatsh.*, 1913, 34, 1609—1630).—By means of the reaction between organomagnesium compounds and ethyl diazoacetate or diazomethane, the author hoped to be able to throw some light on the constitution of aliphatic diazo-compounds. No direct proof of the ring or open-chain structure could be obtained, but the results offer more support to the latter view than to the former. The author crities the Angeli-Thiele formula, $R:N:N$, however, and proposes instead the type $R:N\cdot N$, making the active nitrogen atom univalent.

Although Thiele has suggested that certain reactions of nitrous oxide agree with the constitution $O:N:N$, it was found that the gas has no action whatever on magnesium methyl iodide. When ethyl diazotate was added to magnesium methyl iodide at $0°$, however, a vigorous reaction occurred, and a crystalline solid and an oil were obtained. The former was most probably the *methylhydrazone* of *ethyl glyoxylate*, $CO_2Et\cdot CH:N\cdot NHMe$. It formed long, colourless needles, m. p. 91—92°, responded to Molisch's thymol reaction and Tollens's naphtharesorcinol test, and reduced ammoniacal silver and Fehling's solutions. It was hydrolysed by warm dilute sulphuric acid, and methylhydrazine sulphate and ethyl glyoxalate were obtained. An *acetyl* derivative, $C_7H_{12}O_3N_2$, was also prepared, in freely soluble white needles, m. p. 67—69°. The oily product also gave methyl-

hydrazine on hydrolysis. It was probably impure methylhydrazone of hydroxy*iso*butaldehyde, $OH \cdot CMe_2 \cdot CH:N \cdot NHMe$. The crystalline compound might also have been ethyl N-methylhydraziacetate,

$$CO_2Et \cdot CH \big\langle{}^{NH}_{NMe}\text{,}$$ but this would assume that the diazo-compound reacts differently from the fatty azoimides, which, under the influence of organomagnesium haloids, yield fatty diazoamino-compounds, as Dimroth has shown.

To elucidate this point the action of ethyl diazoacetate on magnesium phenyl bromide was investigated, since it was expected that either the known phenylhydrazone of ethyl glyoxylate or an isomeride would be obtained. However, the only crystalline product was one in which the ester group had also been attacked. It was most probably the *phenylhydrazone* of *hydroxydiphenylacetaldehyde*, $OH \cdot CPh_2 \cdot CH:N \cdot NHPh$. It crystallised in large, rectangular plates, m. p. 132°, and yielded a red, crystalline *product*, $C_{20}H_{16}N_2$, m. p. 69—70°, on boiling with dilute sulphuric acid, water being eliminated. The red compound gave intense, red solutions in concentrated mineral acids. On evaporating the solution in hydrochloric acid in a desiccator over lime, a snow-white, additive *product*, $C_{20}H_{17}N_2Cl$, was obtained. This was very sparingly soluble in water, but gave a turbidity with silver nitrate. It was freely soluble in organic media, and exhibited a fine blue fluorescence in alcohol. Here again the crystalline product might have been the hydrazi-compound,

$$OH \cdot CPh_2 \cdot CH \big\langle{}^{NPh}_{NH}\text{,}$$ but this did not give a condensation product with any chromophoric groups.

Magnesium ethyl iodide and ethyl diazoacetate were also brought together, and ethylhydrazine sulphate was obtained by hydrolysing the unpleasant smelling, brown syrup which resulted.

When diazomethane was distilled into magnesium benzyl chloride, an oily product which contained crystals of either the benzylhydrazone of formaldehyde, or benzylhydrazimethylene, was obtained. The *compound*, $C_8H_{10}N_2$, formed stable, white plates, m. p. 124°, whereas a crystalline product obtained by mixing 40% formaldehyde and benzylhydrazine was very unstable.　　　　　　　　J. C. W.

Organic Silicon Compounds which Liberate Hydrogen from Silicon Hexachloride and Magnesium Methyl Bromide or Iodide. GEOFFREY MARTIN (*Ber.*, 1913, **46**, 3289—3295. Compare this vol., i, 961).—By the action of magnesium methyl bromide on silicon hexachloride, a compound, $Si_6H_6O_{12}Me_2$, is obtained, which yields 102—118 c.c. of hydrogen per gram of substance when decomposed with potassium hydroxide. Under other experimental conditions, compounds $Si_6H_4O_{12}Me_4$, $Si_6HO_{11}Me_5$, and $Si_6H_2O_7Me_8$ are obtained; these yield less and less hydrogen on decomposition as the number of methyl groups increases.

Hexamethylsilicoethane, Si_2Me_6 (Bygden, A., 1912, i, 341), does not yield hydrogen on decomposition, although containing the linking Si—Si. Evidently the characteristic decomposition of silicon

compounds with alkali hydroxide is due to the association of oxygen complexes with the silicon atoms.   E. F. A.

The Isolation and Properties of Some Electropositive Groups and their Bearing on the Problem of the Metallic State. CHARLES A. KRAUS (*J. Amer. Chem. Soc.*, 1913, **35**, 1732—1741).—When solutions of mercury alkyl salts in liquid ammonia are electrolysed, the free mercury alkyl group is deposited at the cathode, except in the case of members of the series above C_4H_9Hg, when no deposition takes place. The electrolytic cell used contained small platinum wires as electrodes, the cathode being situated at the bottom of the cell. The free groups deposited as an attenuated, opaque mass, which, by means of pressure, could be brought into a fairly coherent form. They are good conductors of electricity and do not amalgamate with mercury to any extent.

The *mercury methyl group*, $HgCH_3$, was obtained pure from the compound MeHgCl by washing it free from salt with liquid ammonia. Decomposition takes place at ordinary temperatures, with the formation of mercury and mercury methyl, $HgMe_2$; there is appreciable decomposition at $-33°$. The ethyl derivative behaves similarly, but the propyl derivative is less stable. The ethyl mercury group, when compressed, exhibits metallic reflection of a copper colour, whereas the mercury methyl group is black.

Attempts to isolate groups by the electrolysis of liquid ammonia solutions of the following salts were not successful : Me_4SbI, Me_3SI, Ph_2II, $C_5H_{11}HgI$, $C_8H_{17}HgI$, PhHgI, and Me_3SnI.

The bearing of the above results on the metallic state is discussed, and the conclusion drawn that the electrons to which conduction is due in metals are the same electrons which are involved in the common chemical combination of metals with other elements.   T. S. P.

The Optical Activity of Petroleum and its Significance. FRANK W. BUSHONG (*Science*, 1913, **38**, 39—44).—Attention is drawn to the optical activity of the heavy oils. Since the naphthenic acids derived from the petroleum by treatment with alkali during refining are optically active, the activity of the original oil might be attributed to these acids. It does not necessarily follow, however, that the optically active constituents present in these naphthenic acids are identical with those originally present in the petroleum, and there seems good evidence that this is not the case, as both the author and others have found that the heavy oils retain most of their optical activity after treatment with alcoholic potash ; still, the optical activity may be due to some extent to these acids. It is probable that the oils contain active hydrocarbons (naphthenes), and it is generally held that the naphthenic acids are oxidation products of these.

[The author's views as to the cause of the activity of petroleum were somewhat misrepresented in an earlier abstract (this vol., i, 969).]   J. C. W.

Distillation of Coal under Reduced Pressure. AMÉ PICTET and MAURICE BOUVIER (*Ber.*, 1913, **46**, 3342—3353 ; *Compt. rend.*, 1913, **157**, 779—781).—In an earlier paper (Pictet and Ramseyer, A., 1911, i, 850) it has been shown that extraction of coal (Montrambert) with boiling benzene gives a mixture of hydroaromatic hydrocarbons, from which a hexahydrofluorene, $C_{13}H_{16}$, could be isolated ; it was also mentioned that distillation of the same coal under reduced pressure produced a similar mixture in which the same hydrocarbon could be detected. As the latter procedure was more rapid and gave better yields, it has now been applied more carefully.

The method was to heat 2—5 kilograms of the coal in a vertical iron retort of approximately 10 litres capacity ; the temperature was slowly raised to 450°, whilst the pressure was maintained at a few centimetres of mercury by means of water-pumps. The experiment generally occupied about five hours.

Of the products of the decomposition, the tar only was carefully investigated ; the gases were not collected, but were observed to resemble butadiene and isoprene in odour ; the water had an acid reaction and contained no ammonium salts ; the coke was found to yield still further quantities of combustible gas when heated more strongly. The tar, which amounted to approximately 4% of the coal, was lighter than water, had a brown colour with feeble green fluorescence, and resembled petroleum in odour ; it contained no phenols, but a considerable quantity of bases which appeared to be mainly of the secondary type. Careful fractionation under reduced pressure failed to disclose the presence of any solid substances, and oxidation yielded only aliphatic acids, indicating the absence of aromatic hydrocarbons. It is therefore probable that the tar is a mixture of hydroaromatic compounds of the naphthene class.

Decomposition of the crude tar by distillation at ordinary pressure through a red-hot iron tube packed with coke produced a considerable quantity of gas resembling coal gas in odour, and consisting mainly of hydrogen and paraffin hydrocarbons together with water containing much free ammonia and a dark-coloured tar resembling coal-tar in odour. This tar, unlike the original product, contained phenols, bases recalling the odour of pyridine, and aromatic hydrocarbons, amongst which benzene, naphthalene, and anthracene could be identified. It is tentatively suggested that in coal distillation the methane, ammonia, phenols, and aromatic hydrocarbons are not primary products, but are formed by the decomposition of intermediate products represented by the above " vacuum tar."

Treatment of certain fractions of the " vacuum tar" with sodium removes certain hydroxy-compounds (the presence of which had already been indicated by the results of analysis) which exhibit the usual behaviour of alcohols towards alkalis and acyl chlorides. The natural supposition that these alcohols form the origin of the phenolic substances during subsequent decomposition by further heat received no confirmation when they were passed in the vapourous condition through a red-hot tube, the only products being unsaturated hydrocarbons.

The hydrocarbon residues after extracting various fractions with

sodium immediately decolorise cold potassium permanganate solution, and consequently must contain unsaturated hydrocarbons. The latter were removed by the action of fuming sulphuric acid, and the residue again heated with sodium. By repeated fractional distillation the liquid was separated into various portions in the hope of identifying some of the constituents. Decahydronaphthalene was definitely proved to be absent, and a comparison of the compositions and densities of the various fractions with those of corresponding fractions from Caucasian petroleum clearly demonstrated their distinct character. A similar comparison with fractions from Canadian petroleum (which is also known to contain hydrocarbons of the general formula C_nH_{2n}) proved the identity of the fractions containing the hydrocarbons $C_{10}H_{20}$ and $C_{11}H_{22}$. The former of these is very sensitive to most reagents, and generally gives complex reaction products, but by the action of bromine vapour, dibromodurene (?), m. p. 202°, could be obtained; also by distillation over iron oxide at a dull red heat a distillate is obtained, which on nitration yields dinitrodurene (?), m. p. 202°. Although this evidence is not regarded as final, the authors consider themselves justified in identifying the hydrocarbon, $C_{10}H_{20}$, with hexahydrodurene (s-tetramethyl*cyclo*hexane), whilst to the hydrocarbon, $C_{11}H_{22}$, they ascribe the structure of a pentamethyl-*cyclo*hexane.   D. F. T.

Electrolytic Oxidation of Toluene. FRITZ FICHTER (*Zeitsch. Elektrochem.*, 1913, **19**, 781—784).—A suspension of toluene in 2N-sulphuric acid is placed in a large cylindrical lead vessel which serves as anode; a cathode consisting of a lead spiral is used. The suspension is vigorously stirred, and a current of 0·01 ampere per sq. cm. of anode is passed through until one-half of the toluene has disappeared. Stopping the process at this point, prevents the destruction of some of the products by further oxidation. The toluene layer on allowing it to settle contains after the oxidation toluquinone and a little benzaldehyde, whilst the aqueous layer contains quinol and phenol.

The process of the reaction proceeds as indicated :

$$CH_3 \cdot C_6H_5 \nearrow \begin{array}{l} HO \cdot C_6H_4 \cdot CH_3 \ (1:2) \longrightarrow \\ HO \cdot C_6H_4 \cdot CH_3 \ (1:4) \longrightarrow \\ C_6H_5 \cdot CHO \end{array}$$

$$(HO)_2C_6H_3 \cdot CH_3 \ (1:2:5) \longrightarrow CH_3 \cdot C_6H_3O_2$$
$$HO \cdot C_6H_3 \cdot CHO \ (1:4) \nearrow \begin{array}{l} C_6H_4(OH)_2 \ (1:4) \\ C_6H_5 \cdot OH \end{array}$$
It is thus obvious that the oxidation occurs mainly in the nucleus (compare also T. Kempf, A., 1901, i, 728; R. Kempf, A., 1911, i, 464).   J. F. S

Transformations of Unsaturated Haloid Compounds. II. Cinnamaldehyde and Phenyl Vinyl Ketone. FRITZ STRAUS and ABRAHAM BERKOW (*Annalen*, 1913, **401**, 121—159. Compare Straus, A., 1912, i, 989).—It has been shown (*loc. cit.*) that the changes R·CO·CH:CHR′ —→ R·CH:CH·CO·R′ —→ R·CO·CH:CHR′ can be effected by a series of substitutive reactions. The present paper deals with a simple case in which R′ is hydrogen. The conversion of cinnamaldehyde into phenyl vinyl ketone has been accomplished, but the reverse change of the ketone to the aldehyde has revaled unexpected and important peculiarities.

Cinnamaldehyde and phosphorus pentachloride readily yield the normal keto-chloride, cinnamylidene dichloride (*loc. cit.*), an ethereal solution of which reacts with a slight excess (over 1 mol.) of sodium methoxide to form α-*chloro-γ-methoxy-γ-phenyl-Δ*ª*-propene*,

$$CHCl:CH·CHPh·OMe,$$
b. p. 111°/18 mm., D_4^{15} 1·0959. The latter is converted in petroleum solution in the presence of calcium chloride into cinnamylidene dichloride by hydrogen chloride, yields cinnamaldehyde by hydrolysis, and is oxidised to α-methoxyphenylacetic acid by potassium perman·ganate in acetone. α-*Chloro-γ-ethoxy-γ-phenyl·Δ*ª*-propene*, $C_{11}H_{13}OCl$, b. p. 120·5°/12 mm., is prepared similarly. An ethereal solution of cinnamylidene dichloride and N-sodium hydroxide (1½ mols.) yields after a hundred and twenty hours a substance which loses water by distillation in a vacuum, and is converted into γ-*chloro-α-phenylallyl ether*, $(CHCl:CH·CHPh)_2O$, b. p. 127°/18 mm.

The *acetal* of phenyl vinyl ketone, $CH_2:CH·CPh(OMe)_2$, b. p. 85—86°/12 mm., D_4^{15} 0·9887, is obtained by boiling α-chloro-γ-methoxy-γ-phenyl-Δª-propene with 5% methyl-alcoholic sodium methoxide (2 mols.) for four days. The constitution of the acetal is proved by reduction by colloidal palladium and hydrogen at 2 atmospheres, whereby the *acetal*, b. p. 206—208° or 92—93°/18 mm., of phenyl ethyl ketone is obtained. The hydrolysis of the unsaturated acetal to phenyl vinyl ketone is difficult on account of the instability of the ketone, and has only been effected by means of 5% sulphuric acid at 60—70° in the absence of light.

Phosphorus pentachloride (1½ mols.) reacts with phenyl vinyl ketone in benzene to form αγ-*dichloro-α-phenyl-Δ*ª*-propene*, $CPhCl:CH·CH_2Cl$, b. p. 124—125°/16 mm., the constitution of which is proved by the action of ozone, followed by that of water, on the substance in carbon tetrachloride, whereby, amongst other products, benzoic and chloroacetic acids are obtained. The substance reacts with a slight excess (over 1 mol.) of methyl-alcoholic sodium methoxide to form quantitatively α-*chloro-γ-methoxy-α-phenyl-Δ*ª*-propene*, $CPhCl:CH·CH_2·OMe$, b. p. 131—132°/27 mm., D_4^{22} 1·146, which is reconverted into αγ-dichloro-α-phenyl-Δª-propene by hydrogen chloride in petroleum in the presence of calcium chloride, and yields benzoic acid by oxidation in acetone with potassium permanganate. By reduction in acetone with colloidal palladium and hydrogen at 2 atmospheres, α-chloro-γ-methoxy-α-phenyl Δª-propene is converted into *methyl γ-phenylpropyl ether*,

$$CH_2Ph·CH_2·CH_2·OMe,$$
b. p. 207—208° or 92—94°/12 mm., D_4^{15} 0·9990, which has also been prepared from γ-phenylpropyl chloride and an excess of boiling 5% sodium methoxide ; *methyl α-phenylpropyl ether*, OMe·CHPhEt, prepared from α-phenylpropyl chloride in a similar manner, has b. p. 183—185° or 76—77°/14 mm., D_4^{15} 0·9216, and a quite different odour.

By boiling for four and a-half to five days with 5% sodium methoxide, α-chloro-γ-methoxy-α-phenyl-Δ^a-propene is converted, unexpectedly, into *αγ-dimethoxy-α-phenyl-Δ^a-propene*,

$$OMe·CPh:CH·CH_2·OMe,$$

b. p. 100—102°/11 mm., D_4^{17} 1 0412, which yields benzoic acid by oxidation in acetone by potassium permanganate, and is reduced by hydrogen and colloidal palladium to *αγ-dimethoxy-α-phenylpropane*, OMe·CHPh·CH$_2$·CH$_2$·OMe, b. p. 215—217° (decomp.) or 94—95°/ 15 mm., D_4^{10} 0·9829. The last substance has also been prepared from γ-chloro-α-phenylpropyl alcohol (Fourneau, A., 1907, i, 762); the chlorohydrin in benzene in the presence of calcium bromide is converted by hydrogen bromide into *γ-chloro-α-bromo-α-phenylpropane*, CHPhBr·CH$_2$·CH$_2$Cl, b. p. 118—120°/20 mm., which is converted by sodium methoxide successively into *γ-chloro-α-methoxy-α-phenylpropane*, $C_{10}H_{13}OCl$, b. p. 110—112°/12 mm., and αγ-dimethoxy-α-phenylpropane.   C. S.

p-Nitrophenylethyl Chloride [β-Chloro-4-nitroethylbenzene]. JULIUS VON BRAUN and B. BARTSCH (*Ber.*, 1913, **46**, 3050—3055).— The product obtained by nitrating β-chloroethylbenzene can be separated into two portions, of which one is solid, the other liquid. The former, which may constitute 50% of the mixture, has been shown to be β-chloro-4-nitroethylbenzene (A., 1912, i, 498). The latter is now shown to have a similar constitution, since, on nitration, each substance yields *β-chloro-2-nitro-4-aminoethylbenzene*, which can be further reduced to *β-chloro-2 : 4-diaminoethylbenzene*, whilst, under the influence of sodium acetate and glacial acetic acid, each substance is transformed into a mixture of *4-nitro-β-acetoxyethylbenzene*, NO$_2$·C$_6$H$_4$·CH$_2$·CH$_2$·OAc and *4-nitro-α-acetoxyethylbenzene*,

$$NO_2·C_6H_4·CHMe·OAc,$$
from which, on saponification, the corresponding alcohols are obtained. The formation of the latter substance probably depends on the intermediate production of 4-nitrostyrene, NO$_2$·C$_6$H$_4$·CH:CH$_2$. A similar reaction is not observed to any extent with β-chloroethylbenzene or γ-chloronitropropylbenzene.

β-Chloro-2-nitro-4-aminoethylbenzene, m. p. 84°, is obtained by the action of nitric and sulphuric acids on the hydrochloride of β-chloro-4-aminoethylbenzene obtained from solid β-chloro-4-nitroethylbenzene (compare A., 1912, i, 498). The *hydrochloride*, m. p. 190°, and the *benzoyl* derivative, m. p. 130°, have been prepared. Identical products are obtained from liquid β-chloro-4-nitroethylbenzene. Reduction of β-chloro-2-nitro-4-aminoethylbenzene (whether obtained from solid or liquid β-chloro-4-nitroethylbenzene) by means of stannous chloride gives *β-chloro-2 : 4-diaminoethylbenzene hydrochloride*, m. p. 256°, after darkening at 250°. The colour reactions of this salt greatly

resemble those of tolylenediamine. The free base has not been isolated.

When solid β-chloro-4-nitroethylbenzene is heated with sodium acetate and glacial acetic acid and the product fractionated under diminished pressure, two substances are obtained, b. p. 189°/16 mm. and 161—163°/16 mm. respectively. The former consists of 4-nitro-β-acetoxyethylbenzene [4-nitrobenzylcarbinyl acetate], and is converted by saponification into 4-*nitro-β-hydroxyethylbenzene* [4-*nitrobenzyl-carbinol*], $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot CH_2 \cdot OH$, b. p. 177°/16 mm. (*benzoyl* derivative is oily; m-*nitrobenzoyl* derivative, m. p. 64—65°; *phenylurethane*, m. p. 127—128°), the constitution of which is proved by its conversion into β-chloro-4-nitroethylbenzene, 66% of which is obtained in the solid form. The fraction of lower b. p., consisting of α-acetoxy-4-nitroethylbenzene, yields the corresponding *alcohol*, b. p. 158°/16 mm. (m-*nitrobenzoyl* derivative, m. p. 152—153°; *phenylurethane*, m. p. 205—206°), which, on oxidation, gives p-nitrobenzoic acid. If the above operations are repeated with liquid β-chloro-4-nitroethylbenzene, the same products result and in the same yields.

β-Chloroethylbenzene, when treated with sodium acetate and acetic anhydride, gives an 85% yield of benzylcarbinyl acetate, b. p. 232°, which, on saponification, regenerates the alcohol. About 15% of α-*acetoxyethylbenzene*, b. p. 222°, is simultaneously produced, which loses some acetic acid on distillation and is saponified to phenylmethylcarbinol, b. p. 204°.

γ-*Acetoxy*-4-*nitropropylbenzene*, b. p. 210—212°/21 mm. (slight decomp.), is obtained as sole product of the action of acetic acid and sodium acetate on γ-chloro-4-nitropropylbenzene.   H. W.

Spectrochemical Notes. I. Hydrated Naphthalenes. II. Spectrochemical Behaviour of Acenaphthene Derivatives. III. Haworth's Dimethyl*cyclo*hexadiene. KARL VON AUWERS (*Ber.*, 1913, 46, 2988—2995).—Δ^1-Dihydronaphthalene and Δ^2-dihydronaphthalene (Straus and Lemmel, this vol., i, 256) have $D_4^{19\cdot2}$ 0·9982, $n_D^{19\cdot1}$ 1·58326, and $D_4^{19\cdot7}$ 0·9928, $n_D^{19\cdot7}$ 1·55489 respectively.

The 1 : 2 : 3 : 4-tetrahydronaphthalene obtained by von Braun and Deutsch (A., 1912, i, 435) is apparently not a homogeneous product, but the specimens obtained by Willstätter and King (this vol., i, 353) and by Straus and Lemmel (*loc. cit.*) agreed together in their properties, namely, $D_4^{17\cdot6}$ 0·9738, $n_D^{17\cdot6}$ 1·54529.

Decahydronaphthalene (Willstätter and King, *loc. cit.*) gave $D_4^{19\cdot1}$ 0·8951, $n_D^{18\cdot0}$ 1·48035.

A comparison of the refractive indices for various wave-lengths indicates that, of the above substances, Δ^1-dihydronaphthalene alone has high exaltation of specific refraction and dispersion; *cyclo*hexadiene is remarkable for showing a slight depression, a phenomenon which has also been observed with *cyclo*hexene. Tetrahydronaphthalene gives results in accord with those expected for a di-substituted benzene derivative, and decahydronaphthalene is approximately normal.

In connexion with the work of Crompton and Smyth (T., 1913, 103, 1302), who come to the decision that acenaphthene and its

mono-halogen derivatives are optically normal, attention is drawn to the fact that their calculations are made with the molecular refraction of naphthalene as a standard. As this substance exhibits a marked exaltation, it follows that the acenaphthene compounds are also optically exalted.

In reference to the two compounds described as dimethyl*cyclo*-hexadienes (Haworth, T., 1913, 103, 1242), one of which has already been prepared (Murawski, *Diss.*, Greifswald, 1911), the author, on optical and also chemical grounds (compare Auwers and Peters, A., 1910, i, 826), regards the substances as being at least mainly composed of the substances $\langle \rangle$:CH$_2$ and $\langle \rangle$:CH$_2$ respectively.

1 : 3-*Dimethyl*cyclo-Δ^1-*hexen*-3-*ol*, which Haworth failed to isolate as the intermediate product in the preparation of the latter of the above two substances, can be obtained from 1-methyl*cyclo*-Δ^1-hexen-3-one by the action of magnesium methyl iodide; it has b. p. 75°/15 mm., $D_4^{16\cdot4}$ 0·9336, $n_D^{17\cdot5}$ 1·47711.   D. F. T.

Organic Radicles. XVIII. Ditertiary Hydrazines. HEINRICH WIELAND and CARL MÜLLER (*Annalen*, 1913, 401, 233—243).—The dissociation of tetra-anisylhydrazine in solution into the free radicles ·N(C$_6$H$_4$·OMe)$_2$ (A., 1912, i, 907) is found to be in harmony with Piccard's colorimetric dilution law (A., 1911, ii, 561).

An interesting contribution to the chemistry of triphenylmethyl is recorded. When heated in boiling *m*-xylene, triphenylmethyl is converted into triphenylmethane and *p*-benzhydryltetraphenylmethane. In boiling *o*-xylene in an atmosphere of carbon dioxide, however, the products are triphenylmethane and a *triphenyl-o-xylylmethane*, CPh$_3$·C$_6$H$_3$Me$_2$, m. p. 165—168°, colourless leaflets. In boiling *p*-xylene, similar results are obtained, triphenylmethane and *triphenyl-p-xylyl-methane*, m. p. 158—159°, long prisms, being formed. These two hydrocarbons do not exhibit halochromy and, like tetraphenylmethane itself, develop intense yellow colorations with concentrated sulphuric acid and a trace of potassium dichromate.

Triphenylmethyl in benzene and triphenylmethyl peroxide in glacial acetic acid are reduced to triphenylmethane by hydrogen and palladium black. Triphenylmethyl and diphenylketen do not react in benzene at 60—70°.   C. S.

Constitution and Colour. III. FRIEDRICH KEHRMANN (*Ber.*, 1913, 46, 3036—3040. Compare A., 1908, i, 699, 993).—The author gives a further explanation of his views on this subject. In the formation of salts from phenazine, phenanthraquinone and similar substances, where the change is accompanied by a marked change in colour, the author is of opinion that the chromophore undergoes modification, for example, by an increase in the valency of one of the elements (nitrogen, oxygen, etc.), or by a change from the ortho- to the para-configuration or vice-versâ.

In reference to the views of Willstätter and Piccard (A., 1908, i, 475), the author draws attention to a constitutive characteristic common

to the coloured salts of the triphenylmethane class and to Wurster's salts; both classes have the auxochrome outside the quinonoid portion of the molecule, so that both may, in a wide sense, be regarded as of meriquinonoid type.　　　D. F. T.

Double Chlorides of Ferric and Ferrous Chloride with Some Aromatic Bases. RAPHAEL MONROE McKENZIE (*Amer. Chem. J.*, 1913, **50**, 308—335).—A number of double chlorides of ferrous and ferric iron with the hydrochlorides of aniline *o*-toluidine, *m*-toluidine, and *p*-toluidine have been prepared by adding the constituent substances together in hydrochloric acid solution, and evaporating over sulphuric acid and solid potassium hydroxide.

The following compounds are described: $FeCl_3,2NH_3PhCl$, crystallising in stout, green needles; $FeCl_3,2NH_3PhCl,H_2O$, crystallising in long, thin, very dark green needles; $FeCl_3,6NH_3PhCl$, crystallising in long, thin, orange-yellow, silky needles; $FeCl_3,6NH_3PhCl,2H_2O$, crystallising in orange needles; $FeCl_3,6NH_3(C_7H_7)Cl,3H_2O[1:2]$, forming brownish-yellow needle clusters; $FeCl_3,2NH_3(C_7H_7)Cl[1:3]$, forming shining yellow plates; $FeCl_3,3NH_3(C_7H_7)Cl[1:3]$: this substance is a viscid, fuming mass which is very deliquescent and could not be crystallised; $FeCl_3,3NH_3(C_7H_7)Cl[1:4]$: forming lustrous, red prisms or plates; $FeCl_2,2NH_3PhCl,2H_2O$, separates from hydrochloric acid in light yellow needles; $FeCl_3,3NH_3(C_7H_7)Cl,6H_2O[1:2]$, crystallising in long, fine, yellow needles, and $FeCl_2,6NH_3(C_7H_7)Cl,HCl,xH_2O[1:2]$: this salt was prepared in the absence of air.　　　J. F. S.

Quaternary Ammonium Salts from Trimethylamine and Arylsulphonyl Chlorides. DANIEL VORLÄNDER and OTTO NOLTE (*Ber.*, 1913, **46**, 3212—3228. Compare Kauffmann and Vorländer, A., 1910, i, 822).—When trimethylamine in aqueous solution is shaken with benzenesulphonyl chloride, a quaternary salt is formed, characterised by forming a sparingly soluble platinichloride which allows of the separation from trimethylammonium platinichloride (compare A., 1910, i, 822). *Benzenesulphonyltrimethylammonium chloride*, $SO_2Ph·NMe_3Cl$, obtained by saturating the platinichloride with hydrogen sulphide, crystallises in long, flat colourless prisms, m. p. 185° (decomp.), which are optically anisotropic. The *platinichloride*, $(PhSO_2·NMe_3)_2PtCl_6$, forms doubly refractive platelets or small, flat prisms, m. p. 215—220° (decomp.). The *aurichloride*, $SO_2Ph·NMe_3·AuCl_4$, yields yellow, doubly refractive needles, m. p. 194—200°. The *picrate* crystallises in splendid, yellow, anisotropic plates and stellate aggregates, m. p. 137°. The *dichromate* is characterised by doubly refractive, orange-yellow crystals, m. p. 202°. The *perchlorate* forms colourless needles, m. p. 145°. The colourless needles of the *stannichloride* have decomp. 245°. The *thallichloride* likewise forms colourless, double refractive needles.

Toluene-p-sulphonyltrimethylammonium platinichloride separates in optically anisotropic platelets and pointed needles. The *dichromate* forms doubly refractive, orange-red plates, decomp. 195°.

Cryptocrystalline α- and β-*naphthalenesulphonyltrimethylammonium platinichlorides* were obtained.

Similar salts were not obtained from triethyl- or tripropyl-amine or from dimethyl- or diethyl-aniline.

The existence of these neutral benzenesulphonylammonium salts stable towards water, which yet contain the very strongly acid benzene-sulphonyl radicle, proves that the salt-forming function of the ammonium does not depend on the positive and negative nature of the radicles.　　　　　　　　　　　　　　　　　E. F. A.

Catalysis on the Basis of Work with Imino-esters. The Problem of Saponification and Esterification. JULIUS STIEGLITZ (*J. Amer. Chem. Soc.*, 1913, **35**, 1774—1779).—A theoretical consideration of the mode of action of acids in accelerating the formation or hydrolysis of esters (compare A., 1908, ii, 29, 167, 472; this vol., ii, 396). Although purely mathematical considerations fail to decide with which oxygen compound (for example, acid or alcohol in esterification) the complex oxonium ion is produced, some decision can be drawn by analogy to the conversion of imino-esters by ammonia or amines into amidines which is also accelerated by acid. In this case the change may occur by interaction of the ammonium ion with the free imino-ester or of the imino-ester cation with free ammonia, according to the alternative schemes : $CPh(:NH)\cdot OMe + H\cdot NH_3^+ \longrightarrow$

$CPh\cdot C(NH_2)(OMe)\cdot NH_3^+ \longrightarrow CPh(:NH)\cdot NH_3^+ + MeOH$

or　$CPh(OMe):NH_2^+ + HNH_2 \longrightarrow CPh(NH_2)(OMe)NH_3^+ \longrightarrow$

$CPh\cdot C(:NH)NH_3^+ + MeOH.$ According to the latter scheme the salts of tertiary amines should be unable to form amidines from imino-esters, and according to Pinner this is actually the case.

The conclusion is therefore to be drawn that in the formation of amidines from imino-esters and amines in the presence of acids, action occurs between the amine (or ammonia) and the ion resulting from the additive compound of the imino-ester with the acid. Extending this analogy to the hydrolysis or formation of esters, it is in these cases most probable that the action is of a hydroxide, water, or alcohol on the oxonium ion of the ester or of the organic acid.　　　D. F. T.

Hydrates of Calcium Oxide and their Molecular Compounds. IV. Compounds of Hydrated Calcium Oxide with Phenols. FEDOR F. SELIVANOV (*J. Russ. Phys. Chem. Soc*, 1913, **45**, 1535—1556. Compare this vol., ii, 214, 406, 407).—The following compounds of calcium hydroxide with phenol have been prepared.

The *diphenolate*, $CaO,H_2O,2PhOH$, apparently analogous to the barium compound obtained by Laurent (*Ann. Chim. Phys.*, 1841, [iii], **3**, 203), is a colourless, hygroscopic compound, and is decomposed by carbon dioxide, although it remains unchanged in a sealed, exhausted tube. It is decomposed by water, with liberation of phenol and calcium hydroxide, a similar action being brought about by ether, benzene, alcohol, etc. On this ground the compound is regarded as possessing the constitution $Ca(OH)_2,2Ph\cdot OH$, which is confirmed by the mode of dissociation of the diphenolate in a vacuum ; the phenol is hence present as phenol of crystallisation, the water possessing a constitutional character. When heated

at 105—110°, the diphenolate is decomposed into phenol, water, and the *monophenoxide*, HO·Ca·OPh, in which the acid properties of the phenol are very faint, so that water effects decomposition into calcium hydroxide and phenol.

The diphenolate forms various hydrates, which may be expressed by the general formula $2Ca(OH)_2,4PhOH,(2n+1)H_2O$, where $n =$ 0, 1, 2, 3 or 4.

The diphenolate is capable of combining with phenol, giving the *tetraphenolate*, $Ca(OH)_2,4PhOH$, and the *hexaphenolate*,

$$Ca(OH)_2,6PhOH.$$

Calcium hydroxide and phenol are also able to form hygroscopic solid solutions, which separate in needles apparently of the rhombic system, and do not dissolve in water, but give with it an oily and an aqueous layer (compare Runge, *Ann. Phys. Chem.*, 1834, **31**, 69; **32**, 308) exhibiting an alkaline reaction. Similar solid solutions are formed by calcium hydroxide and thymol and by magnesium hydroxide and phenol.   T. H. P.

Introduction of Selenium into Organic Compounds. EMIL FROMM and KARL MARTIN (*Annalen*, 1913, **401**, 177—188).—Selenium, unlike sulphur, does not react with stilbene or ethyl cinnamate even by prolonged heating at high temperatures. Contrary to Bauer's statement (this vol., i, 263), 1-phenylbenzoselenazole is obtained in 15—20% yield by vigorously boiling benzanilide and selenium. It is not ruptured by fusion with potassium hydroxide, and forms a *tetrabromide*, $C_{13}H_9NBr_4Se$, m. p. 134°, brick-red powder, and a *tetraiodide*, $C_{13}H_9NI_4Se$, m. p. 84°, greenish-black, metallic crystals, with bromine and with iodine in cold and in boiling chloroform respectively. The four halogen atoms are very easily removed, so the substances probably have the constitution : $C_6H_4\!\!\begin{smallmatrix}>NX_2\\ >SeX_2\end{smallmatrix}\!\!>CPh$.

Equivalent quantities of potassium selenocyanate and *o*-nitrobenzyl chloride in boiling alcohol yield *o-nitrobenzyl selenocyanate*, $C_8H_6O_2N_2Se$, m. p. 77°, decomp. 215°, pale yellow crystals. *o*- and *p*-Chloronitrobenzenes do not react similarly, but 1-chloro-2 : 4-dinitrobenzene rapidly yields 2 : 4-*dinitrophenyl selenocyanate*, m. p. 163°, yellow crystals, which can be crystallised from concentrated nitric acid. 2 : 4-Dinitrophenyl selenocyanate and boiling aqueous alkalis yield a brownish-red solution containing the 2 : 4-dinitrophenylselenol, from which by atmospheric oxidation *di*-2 : 4-*dinitrophenyl diselenide*, $C_{12}H_6O_8N_4Se_2$, m. p. 264—265°, yellow crystals, is precipitated.

Dibenzyl diselenide, like dibenzyl disulphide (this vol., i, 357), reacts additively with bromine and iodine in chloroform to form a *tetrabromide*, $C_{14}H_{14}Br_4Se_2$, m. p. 137°, red powder, and *tetraiodide*, m. p. 98°, dark green, metallic crystals; the additive compounds react with silver oxide or acetate, but are thereby extensively changed, and, unlike the corresponding disulphides (*loc. cit.*), do not yield the diselenoxide.

Seleno-ethers are readily obtained by boiling dibenzyl diselenide with alcoholic sodium ethoxide (2 equiv.) and treating the resulting brownish-red solution of the selenol with an alkyl haloid. Thus

benzyl chloride yields Jackson's dibenzyl selenide, m. p. 45·5°, whilst methyl iodide, ethyl iodide, and ethylene dibromide yield respectively benzyl methyl·selenide, benzyl ethyl selenide, and *dibenzyl ethylene selenide*, $C_2H_4(Se·C_7H_7)_2$, m. p. 68—69°, pale yellow needles. Dibenzyl selenide reacts in chloroform with bromine or iodine to form the *dibromide*, $SeBr_2(C_7H_7)_2$, m. p. 84°, red powder, and *di-iodide*, m. p. 97°, violet crystals, from which, however, the selenoxide cannot be obtained by the action of alkalis, or silver oxide or acetate.

The so-called dibenzyl selenide nitrate obtained by Jackson in 1875 by the action of nitric acid on dibenzyl selenide proves to be *tribenzylselenonium nitrate*, $(C_7H_7)_3Se·NO_3$, decomp. 102—103°; the corresponding *chloride*, $C_{21}H_{21}ClSe$, has m. p. 92°.   C. S.

Nitroquinhydrones. M. M. RICHTER (*Ber.*, 1913, **46**, 3434—3438). —The author has previously pointed out (A., 1911, i, 136) that the introduction of negative groups into the quinone molecule diminishes the basic properties of the oxygen atom, and thus reduces the tendency to quinhydrone formation. In agreement with this view it is found that nitroquinol combines with *p*-benzoquinone to form an unstable quinhydrone, whilst in the case of 2 : 6-dinitroquinol the ability to give rise to quinhydrones has completely disappeared.

Nitroquinhydrone, $C_6H_4O_2,C_6H_3(OH)_2·NO_2$, prepared by evaporating an ethereal solution of *p*-benzoquinone and nitroquinol in the absence of moisture, crystallises in small needles or stout, obliquely cut prisms. It is almost black, and has m. p. 89—90°, with slight previous decomposition at 84°. On exposure to air, it loses *p*-benzoquinone, yielding nitroquinol.

By nitrating the diacetyl derivative of quinol, Hesse (A., 1880, 317) and Nietzki (A., 1883, 465) have obtained a dinitro-derivative, m. p. 96°, which they consider to be the diacetyl derivative of 2 : 6-dinitro-quinol. The author finds, however, that the substance is not a diacetate, but a monoacetyl derivative, one of the acetyl groups being removed during the nitration.

A similar elimination of an acetyl group occurs during the nitration of the diacetyl derivative of toluquinol.

On account of its yellow colour, the monoacetate is considered to be an aci-2 : 6-*dinitro-4-acetoxyphenol* of the annexed constitution. It has m. p. 95·6°, and on treatment with metallic nitrites in aqueous solution yields salts, which decompose explosively when heated. The *sodium* salt forms red needles, containing water (3 mols.), which is lost on exposure to sunlight, the anhydrous salt being orange in colour. The golden-yellow *barium* salt and red *potassium* salt (needles) are also described.

2 : 6-*Dinitro*-1 : 4-*diacetoxybenzene*, $C_6H_2(NO_2)_2(OAc)_2$, prepared by heating the preceding monoacetyl derivative or its sodium and potassium salts with acetic anhydride, crystallises in slender, colourless needles, m. p. 135°.

2 : 6 - *Dinitro* - 1 - *benzoyloxy-4-acetoxybenzene*, $OAc·C_6H_2(NO_2)_2·OBz$, obtained by the action of benzoyl chloride on the monoacetate in
benzene solution in the presence of pyridine, forms small, white needles, m. p. 128—129°.

2 : 6-Dinitroquinol and its monoacetyl derivative possess pronounced acid properties, and combine with aniline, toluidine, benzidine, diphenylformamidine, carbamide hydrazine and pyridine to form coloured additive compounds.

The additive *compound* of aniline with 2 : 6-dinitroquinol crystallises in dark red needles, m. p. 102—103° (decomp.).

The additive *compound* of aniline with *aci*-2 : 6-dinitro-4-acetoxyphenol forms orange needles, m. p. 120° (decomp.).　　　　F. B.

The Constitution of the Monomethyl and Monoethyl Ethers of Aminoresorcinol from the Monomethyl and Monoethyl Ether of Benzeneazo-4-resorcinol. FERDINAND HENRICH and H. BIRKNER (*Ber.*, 1913, **46**, 3380—3384).—The constitution of the ethyl ether obtained by the action of ethyl iodide on the potassium salt of benzeneazo-4-resorcinol has never been finally settled (Will and Pukall, A., 1887, 660). Of the two possible formulæ,

$$\text{NPh:N} \diagdown \begin{array}{c} \text{OH} \\ \diagup \end{array} \text{OEt}$$
and $\text{NPh:N} \diagdown \begin{array}{c} \text{OEt} \\ \diagup \end{array} \text{OH}$, the former is rendered more probable by the

work of Bechhold (A., 1889, 1155) on the corresponding methyl ether, but the evidence is far from satisfactory.

The reduction products obtained from the nitrosoresorcinol ethers of

the structure $\text{NO} \diagdown \begin{array}{c} \text{OH} \\ \diagup \end{array} \text{OR}$ and $\text{NO} \diagdown \begin{array}{c} \text{OR} \\ \diagup \end{array} \text{OH}$, where R repre-

sents the methyl or ethyl radicle (Henrich and Rhodius, A., 1902, i, 447), will by comparison with the reduction products of the above azo-compounds fix definitely the constitution of the latter. Experiment shows that it is the *o*-amino-ether which is identical with the corresponding ether above, so that the first of the two possible formulæ for the ethyl (and methyl) ether is the correct one, alkylation having occurred in the para-position.

Improved methods are described for the methylation (by methyl sulphate) and ethylation of the benzeneazoresorcinol.　　　D. F. T.

Action of Organomagnesium Derivatives on Trialkylacetophenones. (Mme.) PAULINE RAMART-LUCAS (*Ann. Chim. Phys.*, 1913, [viii], **30**, 349—432).—The reaction between magnesium methyl, ethyl, phenyl, or benzyl haloid and trimethylacetophenone proceeds normally and leads to the formation of the tertiary alcohol,

$$\text{CMe}_3 \cdot \text{CPhR} \cdot \text{OH}.$$
Such carbinols do not exhibit ordinary alcoholic functions, and are readily dehydrated, yielding an unsaturated hydrocarbon. The individual compounds have been described (A., 1910, i, 378 ; 1911, i, 636 ; 1912, i, 351, 449). Magnesium propyl or *iso*propyl iodide acts

as a reducing agent to trimethylacetophenone and converts it into the corresponding secondary alcohol.

a-Phenyl-a-anisyl-ββ-dimethylpropan-a-ol,

$$CMe_3 \cdot CPh(OH) \cdot C_6H_4 \cdot OMe,$$

m. p. 67—68°, b. p. 210—215°/15 mm., and *a-phenyl-a-phenetyl-ββ dimethylpropan-a-ol,* b. p. 215—220°/15 mm., have been prepared from trimethylacetophenone and magnesium anisyl or phenetyl bromide. The following alcohols have been obtained in a similar manner from *aa*-diethylpropiophenone or triethylacetophenone; the yields are generally smaller than those obtained with trimethylacetophenone.
β-Phenyl-γ-methyl-γ-ethylpentan-β-ol, $CMeEt_2 \cdot CPhMe \cdot OH$,   b.   p. 83—84°/3 mm., D_4^{25} 0·9781, n_a 1·51692, n_D 1·52061, $n_β$ 1·52986 ; *aa-diphenyl - β - methyl - β - ethylbutan - a - ol,* $CMeEt_2 \cdot CPh_2 \cdot OH$, b. p. 200—205°/13 mm., D_4^{25} 0·95005, n_a 1·56573, n_D 1·57206 ; by distillation at the ordinary pressure, the latter decomposes into benzophenone and γ-methylpentane.   *aβ-Diphenyl-γ-methyl-γ-ethylpentan-β-ol,*

$$CMeEt_2 \cdot CPh(OH) \cdot CH_2Ph,$$

b. p. 200—202°/15 mm., D_4^{25} 0·9791, n_a 1·55249, n_D 1·55696, $n_β$ 1·57944, yields deoxybenzoin and γ-methylpentane by distillation under atmospheric pressure.   *β-Phenyl-γγ-diethylpentan-β-ol,*

$$CEt_3 \cdot CPhMe \cdot OH,$$

b. p. 160°/18 mm., and *aa-diphenyl-ββ-diethylbutan-a-ol,*

$$CEt_3 \cdot CPh_2 \cdot OH,$$

m. p. 47—48°, b. p. 215—220°/17 mm., are described ; the latter decomposes quantitatively into benzophenone and γ-ethylpentane by distillation at the ordinary pressure.

The preceding tertiary alcohols have been dehydrated by heating them with formic, oxalic, or dilute sulphuric acid, or, best, with a mixture of acetic anhydride and acetyl chloride ; in some cases, the constitutions of the resulting hydrocarbons have been established by the examination of their products of oxidation. Alcohols which contain the group $OH \cdot CPh \cdot OH<$ yield hydrocarbons of the type $\cdot CPh \colon C<$, whilst alcohols which contain the group $>CMe \cdot CPh_2 \cdot OH$ apparently yield a mixture of hydrocarbons of the types $>C \overset{CH_2}{\diagup \diagdown} CPh_2$ and $>CPh \cdot CPh \colon CH_2$; hydrocarbons of the latter type are produced owing to an intramolecular transformation preceding dehydration. β-Phenyl-γγ-dimethyl-Δ^a-butene, $CMe_3 \cdot CPh \colon CH_2$, b. p. 88—92°/15 mm., D_4^{25} 0·8839, n_a 1·49708, n_D 1·50133, $n_β$ 1·51185, $n_γ$ 1·52106, yields acetophenone or trimethylacetophenone by oxidation by chromic and acetic acids or by acidified potassium permanganate respectively. *γ-Phenyl-δδ-dimethyl-$\Delta^β$-pentene,* $CMe_3 \cdot CPh \colon CHMe$, b. p. 91—93°/12 mm., D_4^{25} 0·9064, n_a 1·51100, n_D 1·51550, $n_β$ 1·52710, $n_γ$ 1·53776, yields trimethylacetophenone by oxidation. The dehydration of *aa*-diphenyl-γγ-dimethylpropan-a-ol yields a *substance,* b. p. 159—160°/11 mm., D_4^{25} 1·0031, n_D 1·57589, which is probably a mixture of 1 : 1-diphenyl-2 : 2-dimethyl-*cyclo*propane and 1 : 2-diphenyl-1 : 2-dimethyl*cyclo*propane or βγ-diphenyl-γ-methyl-Δ^a-butene, since it yields both acetophenone and benzophenone by oxidation (A., 1912, i, 449). *aβ-Diphenyl-γγ-dimethyl-Δ^a-butene,* $CMe_2 \cdot CPh \colon CHPh$, b. p. 164—165°/11 mm., yields benzoic
acid, trimethylacetophenone, and a *substance*, $C_{20}H_{20}O$, m. p. 131°, by oxidation. The dehydration of α-phenyl-α-anisyl-ββ-dimethylpropan-α-ol yields a liquid, b. p. 188—189°/15 mm., which is probably a mixture, since its products of oxidation contain *p*-anisic acid and *p*-methoxybenzophenone. Similar remarks apply to the liquid, b. p. 198—200°/15 mm., obtained by the dehydration of α-phenyl-α-phenetyl-ββ-dimethylpropan-α-ol. *αβ - Diphenyl - γ - methyl-γ-ethyl-Δ^α-pentene*, $CMeEt_2 \cdot CPh:CHPh$, b. p. 175—180°/12 mm., D_4^{25} 0·9791, $n_α$ 1·56110, n_D 1·56671, $n_β$ 1·58131, $n_γ$ 1·59467, yields benzoic acid, deoxybenzoin, and αα-diethylpropiophenone by oxidation. *β-Phenyl-γγ-diethyl-Δ^α-pentene*, $CEt_2 \cdot CPh:CH_2$, b. p. 130—132°/15 mm., yields acetophenone and triethylacetophenone by oxidation. αα-Diphenyl-ββ-diethylbutan-α-ol is the only alcohol of the whole series which is not dehydrated by heating with acetic anhydride and acetyl chloride ; the effect of this reagent, like that of boiling, is to decompose the alcohol into benzophenone and γ-ethylpentane.

Further attempts have been made to ascertain the constitution of the acid, $C_{17}H_{18}O_2$, m. p. 173° (*chloride*, $C_{16}H_{17} \cdot COCl$, m. p. 95—96°; *amide*, m. p. 149°), obtained ultimately from diphenyl-ψ-butylcarbinol (A., 1912, i, 623). From its method of formation the acid might be αβ-diphenyl-α-methylbutyric acid, ββ-diphenyl-αα-dimethylpropionic acid, or αα-diphenyl-β-methylbutyric acid ; it is certainly not the first acid (*loc. cit.*). The last acid has been synthesised by the action of sodamide, followed by that of *iso*propyl iodide, on diphenylacetonitrile in boiling benzene ; the resulting αα-*diphenyl-β-methylbutyronitrile*, $CPh_2Pr^β \cdot CN$, b. p. 193—195°/15 mm., is hydrolysed by acetic and hydrochloric acids at 180°, whereby are produced αα-*diphenyl-β-methyl-butyric acid*, $CPh_2Pr^β \cdot CO_2H$, m. p. 166°, its *anhydride*, $C_{34}H_{34}O_3$, m. p. 162—163°, and a *substance*, $C_{16}H_{16}O_2$, m. p. 109—110°. The acid, $C_{17}H_{18}O_2$, m. p. 173°, therefore, is not αα-diphenyl-β-methyl-butyric acid, neither is it ββ-diphenyl-αα-dimethylpropionic acid, m. p. 134—135°, which has been synthesised by Nef. C. S.

Tertiary Derivatives of *o*- and *p*-Aminobenzyl Alcohol. II. JULIUS VON BRAUN, O. KRUBER, and E. AUST (*Ber.*, 1913, **46**, 3056—3069).—It has been previously shown (A., 1912, i, 968) that the group $-CH_2 \cdot OH$ can be introduced into tertiary aromatic amines by the use of an excess of formaldehyde. The present communication deals (1) with the reactivity of the tertiary, basic groups ; (2) the possibility of replacing the hydrogen atoms of the benzene nucleus, and (3) the capacity for condensation of the hydroxyl group present in the side-chain.
I. Tertiary aminobenzyl alcohols cannot be de-alkylated by means of cyanogen bromide, since the hydroxy-group is also affected. If the latter is protected, however, dealkylation is readily effected. Thus, when 6-dimethylamino-3-methylbenzyl acetate is treated with cyanogen bromide at the ordinary temperature during several days, 6-*cyano-methylamino-3-methylbenzyl acetate*, $CN \cdot NMe \cdot C_6H_3Me \cdot CH_2 \cdot OAc$, b. p. 210°/10 mm., is obtained, whilst, in the same manner, the corresponding *cyano*-compound, b. p. 213—216°/11 mm., is prepared from

4-dimethylamino-3-methylbenzyl acetate. Secondary aminobenzyl alcohols cannot be prepared by saponification of these compounds when the –CH$_2$·OH is in the ortho- or para-position to the cyano-group. When 6-cyanomethylamino-3-methylbenzyl acetate is boiled with aqueous alcoholic sulphuric acid, a *base*, C$_{10}$H$_{12}$ON$_2$, b. p. 166—168°/8 mm., m. p. 59—60°, is obtained (*platinichloride*, m. p. 214°), which is probably a quinoxaline derivative of the annexed formula.
Under similar conditions, the cyano-group of 4-cyanomethylamino-3-methylbenzyl acetate is not replaced; concentrated hydrochloric acid at 120°, however, forms an amorphous *product*, which softens at 70°, and has m. p. 76—80°. It appears to be an anhydro-product of the secondary base (annexed formula), since it combines with dimethylaniline in hot, faintly acid solution to form *trimethyldiaminophenyltolylmethane*, m. p. 55°. That 4-*methylamino-3-methylbenzyl alcohol* is capable of existence in the free state (unlike methyl amino- and ethylamino-benzyl alcohols) is proved by its isolation from the products of the action of a large excess of formaldehyde on monomethyl-*o*-toluidine. It is a yellow oil, b. p. 130—132°/8 mm., which yields a *picrate*, m. p. 112°, and a platinichloride, reddish-yellow crystals, m. p. 173°.

II. 4-*Nitro-6-dimethylamino-3-methylbenzyl alcohol*, b. p. 191—192°/8 mm., m. p. 51° (*platinichloride*, m. p. 198°; *picrate*, m. p. 153°), is formed when a mixture of nitric and sulphuric acids is slowly added to a solution of 6-dimethylamino-3-methylbenzyl alcohol in concentrated sulphuric acid, the temperature being kept at 0° during two hours and the mixture subsequently being allowed to remain for three hours at the ordinary temperature. Should the temperature be allowed to rise, considerable quantities of a substance are formed which can be isolated in the form of its sparingly soluble *sulphate.* The free *base* (annexed formula) has m. p. 136°, and is not hydrolysed by prolonged warming with 2N-sulphuric acid. The *picrate* has m. p. 154°. 6-*Nitro-4 dimethylamino-3-methylbenzyl alcohol*, b. p. 204—208°/11 mm. (slight decomp.), m. p. 64—65° (*platinichloride*, reddish-yellow, crystalline powder), is similarly prepared from 4-dimethylamino-5-methylbenzyl alcohol.
4-Nitro-6-dimethylamino-3-methylbenzyl alcohol is readily reduced by stannous chloride and hydrochloric acid to 4-*amino-6-dimethylamino-3-methylbenzyl alcohol*, white crystals, m. p. 103—104°. The base is completely decomposed by distillation, yields a *picrate*, m. p. 179°, a viscous *acetyl* compound, and a *monobenzoyl* compound, m. p. 135°. It is slowly diazotised by nitrous acid. It combines with allylthiocarbimide, yielding the crystalline *compound*, NMe$_2$·C$_6$H$_2$Me(CH$_2$·OH)·NH·CS·NH·C$_3$H$_5$, m. p. 178°, and with salicylaldehyde, yielding the *salicylidene* compound, m. p. 70°,

Although the composition of the base seems, therefore, to be firmly

established, certain indications lead the authors to consider that there is some tendency for it to pass into the *anhydro*-compound (annexed formula) in the presence of aqueous mineral acids; thus the base, in itself colourless, dissolves in aqueous acid with a reddish-yellow coloration, whilst the colourless *hydrochloride* becomes yellow on exposure to moist air; further, the base, like the readily dehydrated p-aminobenzyl alcohol and its monoalkyl derivatives and unlike the tertiary amino-alcohols in which dehydration is impossible, readily condenses with aromatic compounds in faintly acid solution to form derivatives of diphenylmethane. So with dimethylaniline, it yields *4-amino-2 : 4′-tetramethyldiamino-3-methyldiphenylmethane*, m. p. 92° (*benzoyl* derivative, m. p. 134°), whilst the corresponding *compound* from aniline is oily and gives a *diacetyl* derivative, m. p. 207°.

III. The condensation of dimethylaminobenzyl alcohol and its homologues with dimethylaniline and its homologues, which does not occur to an appreciable extent with aqueous acid solution, can be effected at higher temperatures by the help of zinc chloride. The authors have already shown that a derivative of diphenylmethane is thus formed in the case of 4-dimethylaminobenzyl alcohol and dimethylaniline (A., 1912, i, 970), and now show by a series of examples that the reaction takes a similar course with their homologues containing methyl groups. Thus 4-dimethylaminobenzyl alcohol and dimethyl-m-toluidine yield *4 : 4′-tetramethyldiaminophenyl-o-tolylmethane*, $NMe_2 \cdot C_6H_4 \cdot CH_2 \cdot C_6H_3Me \cdot NMe_2$, b. p. 240—244°/8 mm. (*platinichloride*, m. p. 188—190° after darkening from 150°; *picrate*, m. p. about 70°), the constitution of which follows from its identity with the product obtained by the action of dimethyl-m-toluidine on 4-dimethylaminobenzyltoluidine in hydrochloric acid solution (compare Cohn and Fischer, A., 1900, i, 690).

Trimethyldiaminophenyl-m-tolylmethane (see above) is difficultly converted by exhaustive methylation into a pure di-quaternary iodide. When heated at 120° during three hours with methyl iodide and methyl alcohol, it yields a mono-*methiodide*, $C_{19}H_{27}N_2I$, m. p. 152°, which, when distilled in a vacuum, gives 4 : 4′-tetramethyldiaminophenyl-m-tolylmethane (obtained from 4-dimethylamino-3-methylbenzyl alcohol and dimethylaniline, A., 1912, i, 970), which is further identified by means of its picrate, m. p. 183°.

The statement of the D.R.-P. No. 107712, that aminobenzylaniline and its homologues only condense with amines which do not contain a substituent in the para-position is incorrect, at any rate as far as p-toluidine is concerned; when dimethylaminobenzyltoluidine is treated with p-toluidine in hydrochloric acid solution, 2′-*amino-4-dimethylaminophenyl-m-tolylmethane*, $NH_2 \cdot C_6H_3Me \cdot CH_2 \cdot C_6H_4 \cdot NMe_2$, b. p. 240—245°/10 mm., m. p. 87°, is obtained in poor yield. The *picrate* has m. p. 180—181°. When heated with methyl iodide and methyl alcohol, the base yields a di-quaternary iodide, m. p. 204° (previously obtained from 2-dimethylamino-5-methylbenzyl alcohol and dimethyl-

aniline), which, when heated in a vacuum, yields 4 : 6'-tetramethyl-diaminophenyl-*m*-tolylmethane, m. p. 84°.

4-Dimethylamino-3-methylbenzyl alcohol condenses with dimethyl-*o*-toluidine to form *s-tetramethyldiaminodi*-m-*tolylmethane*,

$$CH_2(C_6H_3Me \cdot NMe_2)_2.$$
yellow oil, b. p. 228—229°/11 mm.; *picrate*, m. p. 187°; *platinichloride*, needles, m. p. 224° after darkening at 222°; *methiodide*, m. p. 199° after softening at about 190°. The constitution of the base is proved by its identity with the product obtained by the methylation of *s*-dimethyldiaminodi-*m*-tolylmethane prepared by Gnehm and Blumer by the condensation of formaldehyde with methyl-*o*-toluidine.

The liquid nature of many of the basic derivatives of diphenyl-methane and the frequently indistinct melting point of their salts has led the authors to investigate the suitability of their nitro-derivatives in characterising them. They seem to be generally well adapted for this purpose. According to the quantity of nitric acid used, mono- or di-nitro-derivatives can be obtained which are crystalline, and can readily be reduced by stannous chloride to the corresponding mono- and di-amino-compounds. In this connexion, the following substances have been prepared : 2 : 2'-*dinitro*-4 : 4'-*tetramethyldiaminodi*-m-*tolyl-methane*, $CH_2[C_6H_2Me(NO_2) \cdot NMe_2]_2$, yellow leaflets, m. p. 125°; 4 : 4'-dinitro-2 : 2'-tetramethyldiaminodi-*m*-tolylmethane, m. p. 102°, which, on reduction, yields the corresponding *di-amino*-compound ; 2' : 4-*dinitro*-2 : 4'-*tetramethyldiaminophenyl*-m-*tolylm*-*thane*,

$$NMe_2 \cdot C_6H_2Me(NO_2) \cdot CH_2 \cdot C_6H_3(NO_2) \cdot NMe_2,$$
dark red crystals, m. p. 187°, which is reduced to the *diamino*-derivative, colourless crystals, m. p. 140°; 2'-*nitro*-2 : 4'-*tetramethyl-diaminophenyl*-m-*tolylmethane*, $NMe_2 \cdot C_6H_3Me \cdot CH_2 \cdot C_6H_3(NO_2) \cdot NMe_2$, red crystals, m. p. 94°; corresponding *amino*-compound, m. p. 97—98°.

According to Biehringer (A., 1897, i, 73), 2 : 2'-diamino-4 : 4'-tetra-methyldiaminodiphenylmethane loses ammonia when heated with hydrochloric acid with formation of an acridine ring. The authors find that a similar ring formation does not occur when the hydrogen atoms of the amino-group are replaced by methyl. When heated with hydrochloric acid at a temperature not exceeding 180°, the bases are unchanged ; under more drastic treatment, formaldehyde is eliminated, but the liberation of methyl-, dimethyl- or trimethyl-amine could not be detected.   H. W.

Tertiary Derivatives of *o*- and *p*-Aminobenzyl Alcohol. III. JULIUS VON BRAUN and OTTO KRUBER (*Ber.*, 1913, **46**, 3460—3470).—In previous papers (A., 1912, i, 968; preceding abstract), the authors have shown that tertiary aromatic amines of the dialkylaniline type readily condense with formaldehyde, either alone or in the presence of hydrochloric acid, yielding derivatives of 2 : 2'- and 4 : 4'-tetra-alkyl-diaminodiphenylmethane, $CH_2(C_6H_4 \cdot NMe_2)_2$, and of *o*- and *p*-dialkyl-aminobenzyl alcohols. The reaction has now been extended to the following amines in order to ascertain the effect of nuclear substituents on the course of the condensation : (1) dimethyl-*m*-toluidine, (2) diethyl-*m*-toluidine, (3) dimethyl-*m*-chloroaniline, (4) phenylbenzyl-methylamine, (5) dimethylcumidine, (6) dimethyl-*p*-chloroaniline,

(7) dimethyl-*p*-bromoaniline, (8) dimethyl-*p*-bromo-*m*-toluidine, and (9) dimethyl-*o*-chloroaniline.

The meta-substituted amines, (1) and (3), resemble the unsubstituted dimethylaniline in that they are almost quantitatively converted by the theoretical amount of formaldehyde ($\frac{1}{2}$ mol.) into the corresponding diphenylmethane derivatives, whilst, with excess of formaldehyde, only small yields of the dialkylaminobenzyl alcohols are obtained. The behaviour of the para-substituted amines (5)—(8) is similar to that of dimethyl-*p*-toluidine. They do not form diphenylmethane derivatives, but, with excess of the aldehyde, give rise to the dialkylaminobenzyl alcohols in good yield.

In the case of the amines 6, 7 and 8, containing a halogen atom in the para-position to the dimethylamino-group, the prolonged action of formaldehyde in the presence of hydrochloric acid causes partial oxidation of the alcohol to the corresponding acid.

It is also found that dimethyl-*o*-chloroaniline condenses with formaldehyde much more readily than dimethyl-*o*-toluidine, and the conclusion is, therefore, drawn that the inhibiting effect of ortho-substituents on the reactivity of the para-hydrogen atoms of the dialkylanilines is not always the same (compare Friedländer, A., 1899, i, 350), but may vary considerably with the nature of the substituent.

Dimethyl-*m*-toluidine condenses with formaldehyde ($\frac{1}{2}$ mol.), yielding 4 : 4'-tetramethyldiaminodi-*o*-tolylmethane, b. p. 253—256°/12 mm., m. p. 82° (*picrate*, m. p. 150°); with excess of formaldehyde it yields *4-dimethylamino-3-methylbenzyl alcohol* as a yellow, almost odourless oil, b. p. 138—142°/10 mm., which forms a *picrate*, felted needles, m. p. 145—146°, an oily *methiodide*, a *platinichloride*, needles, m. p. 178°, and *m-nitrobenzoyl* derivative, m. p. 64°.

4 : 4'-*Tetraethyldiaminodi-o-tolylmethane*, $CH_2(C_6H_3Me\cdot NEt_2)_2$, b. p. 260—266°/10 mm., m. p. 54—55°, and *4-diethylamino-3-methylbenzyl alcohol*, b. p. 160—170°/18 mm. (decomp.) are formed by condensing diethyl-*m*-toluidine with formaldehyde. The alcohol is very resistant towards reducing agents and forms a *picrate*, m. p. 100—103°; the *platinichloride* and *methiodide* are oils.

m-Chlorodimethylaniline condenses with formaldehyde ($\frac{1}{2}$ mol.) in the presence of hydrochloric acid, yielding 4 : 4'-*tetramethyldiaminodi-o-chlorodiphenylmethane*, b. p. 272—276°/9 mm., m. p. 96—97° [*picrate*, m. p. 130—133°; *platinichloride* (decomp. 230°)], which on oxidation with lead dioxide is converted into 4 : 4'-*tetramethyldiamino*-2 : 2'-*dichlorobenzhydrol*. This forms colourless crystals, m. p. 121°, yields blue solutions in glacial acetic acid, and condenses with dimethylaniline in acid solution to form 4 : 4' : 4''-*hexamethyltriamino*-2 : 2'-*dichlorotriphenylmethane*, $NMe_2\cdot C_6H_4\cdot OH(C_6H_3Cl\cdot NMe_2)_2$, which separates from alcohol in lustrous crystals, m. p. 193°, and is oxidised to a blue *dye* of extraordinary fastness to light.

2-Chloro-4-dimethylaminobenzyl alcohol, obtained in poor yield (2%) from *m*-chlorodimethylaniline and excess of formaldehyde, forms a yellow oil, b. p. 156—160°/9 mm.; the *picrate* has m. p. 150°, the *platinichloride*, m. p. 184°.

p-Benzylmethylaminobenzyl alcohol, $C_7H_7\cdot NMe\cdot C_6H_4\cdot CH_2\cdot OH$, prepared from benzylmethylaniline, distils with decomposition at 230°

under diminished pressure, and, therefore, could not be isolated in a pure condition.

Dimethylcumidine gives rise to 6-*dimethylamino*-3-*isopropylbenzyl alcohol*, a yellow oil, b. p. 140—144°/8 mm. (*picrate*, m. p. 118—119°; *methiodide*, m. p. 147°; *platinichloride*, reddish-yellow leaflets, m. p. 187°), which condenses with 1-phenylpiperidine in the presence of zinc chloride, yielding 4-*piperidino*-6'-*dimethylamino*-3'-*isopropyldiphenylmethane*, NMe₂·C₆H₃Prᵝ·CH₂·C₆H₄·NC₅H₁₀, as a viscid oil, b. p. 260—266°/9 mm. (*picrate*, m. p. 100—105°; *platinichloride*, m. p. 219—220°).

Dimethyl-*p*-chloroaniline very readily condenses with formaldehyde, yielding 5-*chloro*-2-*dimethylaminobenzoic acid* (*hydrochloride*, m. p. 172—173°; *platinichloride*, m. p. 190°) and 5-*chloro*-2-*dimethylaminobenzyl alcohol*, a yellow oil, b. p. 158—160°/10 mm. (*picrate*, m. p. 152°; *methiodide*, m. p. 137°), which condenses with *p*-chlorodimethylaniline and dimethylaniline, yielding 5 : 5'-*dichloro*-2 : 2'-*tetramethyldiaminodiphenylmethane*, CH₂(C₆H₃Cl·NMe₂)₂, b. p. 240—260°/14 mm., m. p. 151°, and 5-*chloro*-2 : 4'-*tetramethyldiaminodiphenylmethane*, b. p. 242—246°/12 mm., m. p. 144° (*picrate*, yellow leaflets, m. p. 165°; *methiodide*, m. p. 195°), respectively.

The behaviour of dimethyl-*p*-bromoaniline is similar, 5-*bromo*-2-*dimethylaminobenzoic acid* (not isolated) and 5-*bromo*-2-*dimethylaminobenzyl alcohol*, b. p. 160—170°/13 mm. (*picrate*, m. p. 153°) being produced.

By brominating dimethyl-*m*-toluidine, Wurster and Riedel⁻ (A., 1880, 109) obtained a bromo-compound of m. p. 98°, b. p. 276°. The authors find, however, that the bromination of pure dimethyl-*m*-toluidine in glacial acetic acid solution yields a bromo-derivative, m. p. 55°, b. p. 146—148°/17 mm., which decomposes completely on distillation under ordinary pressure. It forms a methiodide, m. p. 177°, identical with that described by Fischer and Windaus (A., 1900, i, 484), and accordingly must be a p-*bromodimethyl*-m-*toluidine*.

5-*Bromo*-2-*dimethylamino*-4-*methylbenzyl alcohol*, obtained together with the corresponding *acid* by the condensation of the preceding bromodimethyltoluidine with formaldehyde, has b. p. 168—172°/14 mm., forms a *picrate*, crystallising in leaflets, m. p. 150°, and on nitration in concentrated sulphuric acid solution yields a yellow, crystalline *nitro*-derivative, m. p. 83°, of the annexed constitution.

Me

3 - *Chloro* - 4 - *dimethylaminobenzyl alcohol*, b. p. 168—170°/11 mm. (*picrate*, m. p. 130°; *platinichloride*, m. p. 168°; *methiodide*, m. p. 119°; *nitro*-derivative, C₉H₁₁O₃N₂Cl, m. p. 80°), prepared from *o*-chlorodimethylaniline and excess of formaldehyde in the presence of hydrochloric acid, condenses with dimethylaniline and *o*-chlorodimethylaniline to form3-*chloro*-4 : 4'-*tetramethyldiaminodiphenylmethane*, NMe₂·C₆H₃Cl·CH₂·C₆H₄·NMe₂, a liquid, b. p. 248—250°/12 mm. (*picrate*, m. p. 166—167°; *dimethiodide*, m. p. 201°), and 3 : 3'-*dichloro*-4 : 4'-*tetramethyldiaminodiphenylmethane*, CH₂(C₆H₃Cl·NMe₂)₂, which forms a viscid oil, b. p.

258—260°/10 mm., yields a deep yellow *dinitro*-derivative, m. p. 144°, and is also obtained by the direct condensation of *o*-chlorodimethyl-aniline with the calculated amount of formaldehyde.　F. B.
Steric Hindrance with Tertiary Aromatic Amines. JULIUS VON BRAUN and OTTO KRUBER (*Ber.*, 1913, **46**, 3470—3479).—In preparing the methiodides of the tetramethyldiaminodiarylmethanes, tabulated below, the authors found that the bases 5, 7, and 8, containing a substituent in the ortho-position to one of the dimethylamino-groups, combined rapidly with two molecules of methyl iodide, whilst in the case of the amines 2, 4, and 9, in which substituents occur in the ortho-position to both the dimethylamino-groups, the addition of methyl iodide proceeded very slowly. It would thus appear that the occurrence of the reaction at the sterically unhindered dimethylamino-group induces the same reaction at the sterically hindered group.

(1) 4 : 4'-Tetramethyldiaminodiphenylmethane.
(2) 4 : 4'-Tetramethyldiaminodi-*m*-tolylmethane.
(3) 4 : 4'-Tetramethyldiaminodi-*o*-tolylmethane.
(4) 6 : 6'-Tetramethyldiaminodi-*m*-tolylmethane.
(5) 4 : 4'-Tetramethyldiaminophenyl-*m*-tolylmethane.
(6) 4 : 4'-Tetramethyldiaminophenyl-*o*-tolylmethane.
(7) 4 : 6'-Tetramethyldiaminophenyl-*m*-tolylmethane.
(8) 4 : 4'-Tetramethyldiamino-*o* : *m*-ditolylmethane.
(9) 6 : 4'-Tetramethyldiaminodi-*m*-tolylmethane.
(10) 4 : 6'-Tetramethyldiamino-*o* : *m*-ditolylmethane.

The addition of methyl iodide to tertiary aromatic amines is, however, not particularly subject to steric influences, and the authors have, therefore, examined the behaviour of the above amines towards cyanogen bromide and iodoacetonitrile.

With respect to the action of cyanogen bromide on tertiary aromatic amines, it has already been shown that whilst sterically unhindered amines react with extreme ease at the ordinary temperature yielding compounds of the type $R \cdot NMe_3Br$ and $R \cdot NMe \cdot CN$, amines containing an ortho-substituent enter into reaction with great difficulty. In the case of iodoacetonitrile, the presence of an ortho-substituent completely suppresses the reaction.

In agreement with the results obtained by the addition of methyl iodide, it was found that the di-*o*-substituted amines 2, 4, and 9 do not react with either cyanogen bromide or iodoacetonitrile, whilst the amines 5, 7, 8, and 10, containing a substituent in the ortho-position to only one of the dimethylamino-groups, enter into reaction as readily as the amines 1, 3, 6 in which steric influences are completely absent, the reactions proceeding according to the following scheme:

$$CH_2(C_6H_4 \cdot NMe_2)_2 \xrightarrow{CN \cdot Br} CH_2(C_6H_4 \cdot NMe_3Br)_2 \text{ and}$$
$$CH_2(C_6H_4 \cdot NMe \cdot CN)_2.$$

$$CH_2(C_6H_4 \cdot NMe_2)_2 \xrightarrow{CH_2I \cdot CN} NMe_3I \cdot C_6H_4 \cdot CH_2 \cdot C_6H_4 \cdot NMe \cdot CH_2 \cdot CN +$$
$$CH_2(C_6H_4 \cdot NMe \cdot CH_2 \cdot CN)_2 \text{ and } CH_2(C_6H_4 \cdot NMe_3I)_2$$

That the presence of meta-substituents has little effect on the inter-

action of tertiary amines and cyanogen bromide or iodoacetonitrile has been shown by the behaviour of *m*-chlorodimethylaniline and dimethyl-*m*-toluidine, both of which react with these compounds almost as readily as dimethylaniline and dimethyl-*p*-toluidine.

m-*Tolyltrimethylammonium bromide*, obtained together with m-*tolyl-methylcyanamide*, $C_6H_4Me\cdot NMe\cdot CN$, a yellow oil, b. p. 142—144°/8 mm., by the action of cyanogen bromide on dimethyl-*m*-toluidine, volatilises at about 200° without melting.

m-Chlorodimethylaniline and cyanogen bromide give rise to m-*chlorophenylmethylcyanamide*, $C_6H_4Cl\cdot NMe\cdot CN$. This has m. p. 72°, and is readily hydrolysed to *m*-chloromethylaniline, which is thus obtained more readily and in better yield than by the direct methylation of *m*-chloroaniline, Iodoacetonitrile reacts with dimethyl-*m*-toluidine, yielding m-*tolyltrimethylammonium iodide*, m. p. 177°, and *methylcyanomethyl*-m-*toluidine* [N-*methyl*-m-*toluidinoacetonitrile*],
$$C_6H_4Me\cdot NMe\cdot CH_2\cdot CN,$$
a yellow oil, b. p. 158°/8 mm. With *m*-chlorodimethylaniline it yields m-*chlorophenyltrimethylammonium iodide*, m. p. 187°, and *methylcyanomethyl*·m-*chloroaniline* [N-*methyl*-m-*chloroanilinoacetonitrile*],

$$C_6H_4Cl\cdot NMe\cdot CH_2\cdot CN,$$
b. p. 175—180°/9 mm.

4 : 4'-*Tetramethyldiamino*-o : m-*ditolylmethane*,

$$CH_2(C_6H_3Me\cdot NMe_2)_2,$$

prepared by condensing 4-dimethylamino-3-methylbenzyl alcohol with dimethyl-*m*-toluidine in the presence of zinc chloride, is a yellow oil, b. p. 244—246°/10 mm., and readily combines with methyl iodide to form a *dimethiodide*, m. p. 232—234°.

6 : 4'-*Tetramethyldiaminodi*-m-*tolylmethane*, obtained from 2-dimethylamino-5-methylbenzyl alcohol and dimethyl-*o*-toluidine in a similar manner, has b. p. 218—222°/11 mm., yields a *picrate*, m. p. 95°, and forms a *dimethiodide*, lustrous leaflets, m. p. 195°.

4 : 6'-*Tetramethyldiamino*-o : m-*ditolylmethane*, prepared from 2-dimethylamino-5-methylbenzyl alcohol and dimethyl-*m*-toluidine, has b. p. 230—235°/12 mm., and forms a *dimethiodide*, m. p. 209°.
Of the compounds produced by the action of cyanogen bromide and iodoacetonitrile on the 10 amines enumerated above, the following are described : the *dicyano*-compound,

$$CH_2(C_6H_3Me\cdot NMe\cdot CN)_2$$
(lustrous leaflets, m. p. 130°), derived from 6, together with the corresponding *dicyanomethyl* compound,

$$CH_2(C_6H_3Me\cdot NMe\cdot CH_2\cdot CN)_2,$$
needles, m. p. 134°, and the *cyanomethyl-methiodide*,

$$NMe_3I\cdot C_6H_3Me\cdot CH_2\cdot C_6H_3Me\cdot NMe\cdot CH_2\cdot CN,$$

lustrous leaflets, m. p. 143°; the *dimethiodide* from 6 has m. p. 243°. The *dicyano*-compound from 3 has m. p. 125°; the *dimethiodide*, m. p. 205°.

The *dicyano*-derivative from 7 forms long needles, m. p. 151°; the *dicyanomethyl* derivative, leaflets, m. p. 104°; the corresponding *cyanomethyl-methiodide*,

Me

NMe₃I⟨ ⟩·CH₂⟨ ⟩   or   CN·CH₂·NMe⟨ ⟩·CH₂⟨ ⟩ ,

NMe·CH₂·CN   NMe₂I
has m. p. 165°.

Of the derivatives formed by the action of iodoacetonitrile on the amines 5, 8 and 10, only the *dimethiodides* and the *dicyanomethyl* compound derived from 8 were isolated.

The action of cyanogen bromide on 5, 8 and 10 yields the corresponding *dicyano*-derivatives, which have m. p. 96—97°, 90—91°, and 120° (with previous softening at 115°) respectively.

The behaviour of 4 : 4'-tetramethyldiamino-3-chlorodiphenylmethane and 2 : 4'-tetramethyldiamino-5-chlorodiphenylmethane towards cyanogen bromide and iodoacetonitrile is similar to that of the analogously constituted methyl compounds 5 and 7. The first-named base yields a *dicyano*-derivative, m. p. 157°; the corresponding *dicyanomethyl* compound and *cyanomethyl-methiodide* have m. p. 105° and 141°.   F. B.

Oxonium Compounds. III. GEORGE L. STADNIKOV (*J. Russ. Phys. Chem. Soc.*,1913, **45**, 1391—1414. Compare A., 1912, i, 971).— The greater part of this paper has been already abstracted (this vol., i, 1183).

The author further shows experimentally that, in the action of 3 mols. of diphenylmethyl ethyl ether on magnesium propyl iodide under the conditions employed by Tschelincev and Pavlov (this vol., i, 461), part of the etherate passes into solution. During distillation, this etherate is subjected to a very high temperature (280°), and it is hence not surprising that it decomposes with formation of tetraphenylethane. Other results obtained by these authors are also criticised.

Gorski's results (this vol.. i, 462) are not new (see Oddo, A., 1911, i, 443).   T. H. P.

Triphenylthiocarbinol. DANIEL VORLÄNDER and ERNST MITTAG (*Ber.*, 1913, **46**, 3450—3460).—Although triphenylcarbinol contains three phenyl groups its acid properties are no greater than those of an aliphatic alcohol. It has, however, more pronounced basic properties than any other tertiary alcohol, and shows a marked tendency to lose its hydroxyl group.

This behaviour is in accordance with the rules laid down by Vorländer (A., 1902, i, 309), according to which the reactivating influence of unsaturated groups on adjacent atoms or groups attains a maximum in the 3 : 4-position. The unsaturated phenyl groups in triphenylcarbinol occupy the 3 : 4-position with respect to the oxygen atom, which, therefore, is very mobile and readily separates from the molecule in the form of hydroxyl: (O⁴=C³)·C²·O¹·H. In order to ascertain the effect of substituting sulphur in place of oxygen in the above system, the authors have examined the behaviour of triphenylcarbinyl-

4 *u* 2

mercaptan, and find that, in accordance with the above rule, it shows a marked tendency to rupture between the sulphur and central carbon atoms. Its acid properties are scarcely more pronounced than those of hydrogen sulphide or methyl mercaptan. It dissolves in alkali hydroxides, but the salts thus formed are readily hydrolysed by water. It comparison with other thio-alcohols it shows a marked tendency to lose the thiol group. On treatment with concentrated sulphuric acid or perchloric acid it evolves hydrogen sulphide and is transformed into triphenylcarbinol. A similar decomposition occurs when the thiocarbinol is heated with acetic acid or acetic anhydride. With hydrogen chloride in benzene solution it yields hydrogen sulphide and ω-chlorotriphenylmethane. When boiled with dilute aqueous alkali hydroxides it slowly forms the corresponding alkali sulphides.

The behaviour towards silver salts is very characteristic. It instantly reacts with silver nitrate in alcoholic solution, yielding silver sulphide and triphenylcarbinol; in this respect it resembles the hydrosulphides of the alkali-metals or metals of the alkaline earths. With silver perchlorate in benzene solution it forms silver sulphide and triphenylmethyl perchlorate.

The benzoyl and acetyl derivatives, and also the methyl ether, resemble the parent substance in being readily ruptured between the sulphur and central carbon atoms. Thus, the methyl ether on treatment with alcoholic silver nitrate yields the silver salt of methyl mercaptan, whilst with concentrated sulphuric acid or dilute hydrochloric acid, the mercaptan itself is produced; with alcoholic silver nitrate the benzoyl derivative yields silver thiobenzoate.

The readiness with which triphenylcarbinylmercaptan suffers rupture between the sulphur and central carbon atoms indicates that the union between these atoms is very similar to that between the chlorine and carbon atoms in ω-chlorotriphenylmethane. On the other hand, the union between the cyano-group and central carbon atom in triphenylacetonitrile is much more stable, for this compound does not react with silver nitrate, and is unattacked by sulphuric or perchloric acids.

Attempts to prepare triphenylcarbinyl mercaptan and triphenylacetonitrile by the action of hydrogen sulphide and hydrogen cyanide on triphenylcarbinol were unsuccessful.

By passing hydrogen sulphide into ω-chlorotriphenylmethane at 120—150°, triphenylmethane, sulphur, and hydrogen chloride were produced.

Reduction of the thiocarbinol with sodium and alcohol yields triphenylmethane and sodium sulphide, whilst the action of chlorine in carbon tetrachloride solution gives rise to ω-chlorotriphenylmethane.

The behaviour of triphenylmethyl disulphide, $(CPh_3)_2S_2$, has also been investigated. On treatment with perchloric acid it liberates hydrogen sulphide, but not so readily as the thiocarbinol. It is transformed by chlorine into ω-chlorotriphenylmethane.

Triphenylcarbinyl mercaptan [ω-*thioltriphenylmethane*], $CPh_3 \cdot SH$, prepared by saturating a solution of sodium ethoxide in ethyl alcohol with hydrogen sulphide and heating the resulting solution of sodium

hydrosulphide with ω-chlorotriphenylmethane, separates from alcohol in long, white, prismatic crystals, m. p. 107°. The *sodium* salt is obtained by shaking an ethereal solution of the thiocarbinol with concentrated aqueous potassium hydroxide. The *lead* and *mercuric* salts are also described.

The acetyl and benzoyl derivatives, prepared by the action of the acid chlorides on the carbinol in pyridine solution, have m. p. 139—141° and 185° respectively, and are decomposed by sulphuric acid with the evolution of hydrogen sulphide (compare Wheeler, - A., 1902, i, 28; Meyer and Fischer, 1911, i, 120).

Triphenylmethyl disulphide is obtained in colourless needles by the addition of sulphuryl, chloride to an ice-cold, alcoholic solution of the sodium salt of the thiocarbinol; it becomes yellow, and begins to decompose at 140°, m. p. about 155°.

Triphenylmethyl methyl sulphide, prepared by the action of methyl sulphate on a solution of the thiocarbinol in methyl-alcoholic sodium methoxide, or by heating the carbinol with methyl iodide and potassium hydroxide in methyl-alcoholic solution, has m. p. 105—106° (compare Meyer and Fischer, *loc. cit.*). F. B.

Action of Dimethylamine on the Iodohydrins of Styrene; Study of the Two Phenyldimethylaminoethanols. MARC TIFFENEAU and ERNEST FOURNEAU (*Bull. Soc. chim.*, 1913, [iv], 13, 971—981).—The authors have confirmed Krassusky's views that the formation of an amino-alcohol from a chloro- or iodo-hydrin takes place through the intermediate formation of an ethylene oxide (compare A., 1908, i, 139). The two isomeric styrene iodohydrins, $OH \cdot CHPh \cdot CH_2I$ and $CHPhI \cdot CH_2 \cdot OH$, both react with dimethylamine to give the same β-dimethylamino-α-phenylethanol, $OH \cdot CHPh \cdot CH_2 \cdot NMe_2$, which is also obtained by the interaction of styrene oxide and dimethylamine. It is a liquid, b. p. 132—133°/15 mm., D_4^0 1·021 (compare Tiffeneau, *Ann. Chim. Phys.*, 1907, [viii], 10, 342). It yields a *hydrochloride*, m. p. 147°; a *picrate*, m. p. 35—40°; a benzoyl hydrochloride, m. p. 210° (compare *loc. cit.*); a *morpholone hydrochloride*, m. p. 229°, from interaction in benzene solution with ethyl chloroacetate; a *methiodide*, m. p. 225°; a *methochloride*, m. p. 199—200°, by the action of silver chloride on the methiodide. This methochloride, which is the hydrochloride of secondary phenylcholine, gives an *aurichloride*, m. p. 154°, soluble in water, and a *picrate*, prismatic needles, m. p. 195°.

Styrene methyliodohydrin reacts similarly with dimethylamine, yielding β-*dimethylamino-α-methoxy-α-phenylethane*, $OMe \cdot CHPh \cdot CH_2 \cdot NMe_2$, b. p. 105—107°/15 mm., 229—230°/760 mm.; D_4^0 1·0013, which gives a *hydrochloride*, m. p. 228°; a *hydriodide*, m. p. 205°, and a *methiodide*, m. p. 180°. Styrene ethyliodohydrin similarly yields β-*dimethyl-amino-α-ethoxy-α-phenylethane*, b. p. 118—119°/19 mm., 229—230°/760 mm., D_4^0 0·9623, giving a *hydrochloride*, m. p. 134°, a *hydriodide*, m. p. 153°, and a *methiodide*, m. p. 157°.

In further proof that the styrene iodohydrin, $CHPhI \cdot CH_2 \cdot OH$, does not yield the corresponding dimethylaminoethanol,

$$NMe_2 \cdot CHPh \cdot CH_2 \cdot OH,$$

but the isomeric ethanol, the former has been prepared by other methods and characterised as follows :

Phenylacetyl chloride was brominated by direct addition of bromine to the acid chloride at 80°, the product being finally boiled with excess of alcohol, giving *ethyl α-bromophenylacetate*, b. p. 145°/15 mm. This substance reacts with dimethylamine in benzene solution to give *ethyl α-dimethylaminophenylacetate*, $NMe_2 \cdot CHPh \cdot CO_2Et$, b. p. 135°/13 mm., which is readily reduced by sodium in absolute alcohol to *α-dimethyl-amino-α-phenylethanol*, $NMe_2 \cdot CHPh \cdot CH_2 \cdot OH$, b. p. 135—138°/15 mm. and 248—250°/760 mm., solidifying at $-5°$. The following derivatives have been prepared : *hydrochloride*, m. p. 114° ; *picrate*, m. p. 115° ; *gold* salt, m. p. 110°, decomposed on boiling with water, reduced gold being deposited ; *benzoyl* derivative, m. p. 165° ; *morpholone hydrochloride*, m. p. 220°, sparingly soluble in alcohol ; *methiodide*, difficult to crystallise ; *methochloride* [primary *phenylcholine hydrochloride*], $NMe_3Cl \cdot CHPh \cdot CH_2 \cdot OH$, yielding a crystalline *gold* salt and a *picrate*, m. p. 165°. W. G.

Electrolysis in Non-Aqueous Solvents. *o*-Nitrobenzoic Acid Solutions of Potassium *o*-Nitrobenzoate. CARL SCHALL (*Zeitsch. Elektrochem.*, 1913, **19**, 830—833).—Berl (A., 1904, i, 282) showed that the electrolysis of fused organic salts led to results which differed from those obtained from the electrolysis of aqueous solutions of these salts. In the case of the sodium salt of *o*-nitrobenzoic acid melted with its free acid, the product was nitrobenzene, and not 2 : 2'-dinitrodiphenyl as was expected. The author has electrolysed a 15% solution of potassium *o*-nitrobenzoate in *o*-nitrobenzoic acid at 160—170°, using a small porous pot as anode vessel and a beaker as cathode vessel. The anode consisted of 6—7 cms. of platinum wire wound into a spiral, and the cathode was a platinum foil 3 cms. × 7 cms. The electrolysis was carried out by a current of 5 amperes and 50 volts. During the electrolysis an odour of aniline was noticed. On allowing the fusion to cool, the cathode material contained a small quantity of a liquid with an *iso*nitrile odour, and a black substance which dissolved in alkali and acid. The anode vessel contained a little *o*-nitrophenol, a little 2 : 2'-dinitrodiphenyl, and a brown powder of undetermined composition. The experiment of Lilienfeld (D.R.-P. 1902, 147943) was repeated ; by this 2 : 2'-dinitrodiphenyl should be obtained by the electrolysis of copper *o*-nitrobenzoate in aqueous solution. The author is unable to obtain any of this compound either under the specified or any other conditions. J. F. S.

Nitro-*o*-sulphobenzoic Acid and Some of its Derivatives. MARTIN BELL STUBBS (*Amer. Chem. J.*, 1913, **50**, 193—204. Compare Taverne, A., 1906, i, 273).—If *o*-sulphobenzoic acid is treated with a mixture of fuming nitric and concentrated sulphuric acids, the mixture heated until all the nitric acid has been eliminated, and water added to the cooled product, *5-nitro-2-sulphobenzoic anhydride*,

$$NO_2 \cdot C_6H_3 \underset{CO}{\overset{SO_2}{<}} O,$$
m. p. about 212° (uncorr.), separates in white crystals. *Potassium*

hydrogen 5-*nitro*-2-*sulphobenzoate* crystallises with $1H_2O$, the *lead* salt with $2H_2O$, the *barium* salt with $3H_2O$, and the *copper* salt with $2H_2O$; the *calcium* salt also contains water of crystallisation, whilst the *potassium* salt is anhydrous. On treating the *chloride*,

$$NO_2 \cdot C_6H_3(SO_2Cl) \cdot COCl,$$
a yellow oil, with dry ammonia, the *sulphinide*,

$$NO_2 \cdot C_6H_3 {<}^{SO_2}_{CO} {>} NH,$$
is produced; its *sodium* salt crystallises with $1H_2O$. When the *ethyl* ester of the *chloride*, $NO_2 \cdot C_6H_3(SO_2Cl) \cdot CO_2Et$, obtained as an oil by the action of alcohol on the chloride, is neutralised with barium carbonate, *barium ethyl* 5-*nitro*-2-*sulphobenzoate*,

$$[NO_2 \cdot C_6H_3(CO_2Et) \cdot SO_3]_2Ba, 3H_2O,$$
is produced, which forms colourless needles. E. G.

Characterisation of 3 : 5-Dibromotyrosine. CARL TH. MÖRNER (*Zeitsch. physiol. Chem.*, 1913, **88**, 124—137).—In view of its importance as a product of hydrolysis of a natural protein (gorgonin), 3 : 5-dibromotyrosine has been studied in detail.

Dibromo-*l*-tyrosine crystallises anhydrous in long, slender needles grouped in voluminous bundles or balls, or with $2H_2O$ in thin plates similar to benzoic acid. It has $[a]_D^{20} + 1 \cdot 3°$.

Dibromo-*dl*-tyrosine crystallises $+ H_2O$ in transparent, four-edged prisms or thick plates. It is nearly twice as soluble in water as the *l*-isomeride. Both forms have m. p. about 245° (much decomp.). They are stable to concentrated sulphuric and hydrochloric acids even on heating. The bromine atoms are removed quantitatively on heating with zinc dust. E. F. A

Ketens. XXIV. Mixed Diphenylacetic Anhydrides and their Decomposition. HERMANN STAUDINGER, E. ANTHES, and H. SCHNEIDER (*Ber.*, 1913, **46**, 3539—3551).—It has been previously shown (Staudinger and Ott, A., 1908, i, 602) that anhydrides of malonic acid decompose when heated, yielding carbon dioxide and ketens. The scope of this method of preparation is greatly limited by the difficulty of preparing such anhydrides, and the authors have therefore investigated the behaviour of mixed anhydrides of malonic and other acids (compare Staudinger and Bereza, A., 1909, i, 83) which can be readily prepared by the action of ketens on malonic acid.

The authors have prepared a series of mixed anhydrides by the action of diphenylketen on derivatives of malonic acid. These are stable, well-crystallised substances which appear to be unimolecular, and thus differ remarkably from the amorphous, polymerised dimethyl- and diethyl-malonic anhydrides (A., 1908, i, 939). An anhydride could not, however, be obtained from malonic acid itself, decomposition occurring in this case at a low temperature with formation of diphenyl-acetic anhydride and brown, resinous products.

The action of heat on the mixed anhydrides causes a primary dissociation into diphenylacetic anhydride and the corresponding malonic anhydride; the latter then loses carbon dioxide to yield the keten. Dimethylketen and diethylketen can be obtained in this

manner from dimethyl- and diethyl-malonic diphenylacetic anhydrides
respectively.   In the latter case, however, small quantities of diphenyl-
keten are also produced.   This is attributed to the partial decom-
position of diphenylacetic anhydride into diphenylketen and diphenyl-
acetic acid, the latter substance also uniting with a portion of the
diethylketen and thus reducing the yield of the latter.   A similar
secondary decomposition occurs quantitatively during the decom-
position of benzylidenemalonic diphenylacetic anhydride, so that the
product of the reaction is diphenylketen instead of the expected
benzylideneketen, whilst the desired ketens were also not obtained
from isopropylidenemalonic diphenylacetic anhydride and dichloro-
malonic diphenylacetic anhydride.   Ethylchloroketen, on the other
hand, was readily obtained from ethylchloromalonic diphenylacetic
anhydride.

The mixed anhydrides are prepared by the addition of diphenyl-
keten to very concentrated solution or suspension of the malonic acid
in absolute ether, reaction being allowed to proceed in an atmosphere
of carbon dioxide.   After a period which depends on the derivative of
malonic acid employed, the mixed anhydride separates in the
crystalline state.   The m. p.'s of the products depend somewhat on the
manner of heating.

Dimethylmalonic diphenylacetic anhydride, $CMe_2(CO \cdot O \cdot CO \cdot CHPh_2)_2$,
has m. p. 91° (decomp.).   When heated at the ordinary pressure, it
yields only small quantities of dimethylketen ; when decomposed in a
vacuum, however, the yield of the latter amounts to 50%.   The liquid,
polymeric compound (Staudinger and Klever, A., 1907, i, 424) of
dimethylketen appears to be formed in small quantity, whilst the
residue consists of almost pure diphenylacetic anhydride.

Diethylmalonic diphenylacetic anhydride, m. p. 94°, when heated in a
vacuum gives a 64% yield of diethylketen ; at a somewhat higher
temperature, diphenylketen is evolved, which is identified by conver-
sion into diphenylacetanilide.

Diphenylacetic anhydride is obtained by the action of diphenylketen
on an ethereal solution of ethylmalonic acid.   The products of the
decomposition of ethylmalonic anhydride have not yet been investigated.

Benzylidenemalonic diphenylacetic anhydride, m. p. 103°, is more
stable than the preceding compounds.   When heated to 180° in a
vacuum, it yields diphenylketen.   Cinnamic and diphenylacetic acids
are obtained by saponification of the residue from the distillation.

iso*Propylidenemalonic diphenylacetic anhydride*, m. p. 101°, decomposes
slowly at its melting point.   When distilled in a vacuum it yields
diphenylketen ; the residue consists of dark brown, pasty mass, which
is probably formed by the rapid polymerisation of the keten and
subsequent decomposition of the polymerisation product.

Dichloromalonic diphenylacetic anhydride, m. p. 74° (decomp.), is an
unstable substance, which slowly decomposes at the ordinary tempera-
ture.   When heated, it yields more than the calculated quantity of
carbon dioxide, and, at a higher temperature, evolves hydrogen chloride.
Dichloroketen has not been isolated.

Ethylchloromalonic acid, m. p. 101—102°, is obtained by boiling an
absolute ethereal solution of ethylmalonic acid with sulphuryl chloride

(compare Conrad and Reinbach, A., 1902, i, 529). It combines with diphenylketen, yielding *ethylchloromalonic diphenylacetic anhydride*, m. p. 95—96°, which, when heated in a vacuum, gives *ethylchloroketen*, CEtClC:O. The latter condenses at −80° to yellow oily drops which in a few minutes, become transformed into a white solid mass. Attempts to obtain the unpolymerised keten at −180° were unsuccessful. In ethereal solutions at −80°, it can only be preserved for a short time. The keten vapours dissolve in ether with a yellow colour, but, after a few seconds, the solution becomes colourless and, on removal of ether, the keten remains as a glassy, somewhat viscous mass, which is no longer completely soluble in the solvent. The keten polymeride is soluble in carbon disulphide, and melts indefinitely at 84—86°. When heated, it decomposes completely, evolving hydrogen chloride and probably chlorobutyryl chloride.

Ethylchloroketen unites with aniline to form chlorobutyranilide.

H. W.

### Conversion of Triphenylmethyl into Triphenylacetic Acid.
ALEXANDER I. GORSKI (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1454—1460). —In consequence of the varying behaviour of heated and non-heated ethereal solutions of magnesium triphenylmethyl chloride towards aromatic aldehydes, Schmidlin (A., 1906, i, 392; 1907, i, 26, 601; 1908, i, 239; this vol., i, 50) assumes the existence of two isomeric organo-magnesium compounds of ω-chlorotriphenylmethane : a normal, stable β-compound, which gives β-benzopinacolin with benzaldehyde, and an unstable quinonoid α-compound, which gives *p*-benzoyltriphenylmethane.

Tschitschibabin (A., 1907, i, 1022) is, however, of the opinion that only one such organo-magnesium compound exists.

Since the experimental results given by Schmidlin in support of his assumption were not obtained under the conditions in which the conversion of the α- into the β-compound actually occurs, the author has investigated the reaction further. By passing dry carbon dioxide into a heated mixture of a benzene solution of triphenylmethyl and the etherate of magnesium iodide, he has succeeded in obtaining good yields of triphenylacetic acid and triphenylmethane; decomposition of the products by means of water failed to give any appreciable amount of triphenylmethyl peroxide. This result is regarded as evidence in favour of Tschitschibabin's view that Schmidlin's α-compound is really a mixture of an ethereal solution of triphenylmethyl with the etherate of magnesium chloride.

T. H. P.

α-*p*-Nitrophenyl-β-hydroxythionaphthen. HERMANN APITZSCH (*Ber.*, 1913, **46**, 3091—3103. Compare A., 1909, i, 46).—*p-Nitrobenzylthiosalicylic acid* [2-*p*-nitrobenzylthiolbenzoic acid],

$$NO_2 \cdot C_6H_4 \cdot CH_2 \cdot S \cdot C_6H_4 \cdot CO_2H,$$
practically colourless, shining prisms, m. p. 215·5° (corr.) after softening at 200°, is prepared by the addition of an alcoholic solution of *p*-nitrobenzyl chloride to an aqueous alcoholic solution of sodium thiosalicylate [*o*-thiolbenzoate] and acidification of the mixture with hydrochloric acid. It dissolves in alkali to a pure yellow solution,

which becomes dark reddish-brown on warming, and from which a definite compound could not be isolated. Small quantities of p-*nitrobenzyl 2-p-nitrobenzylthiolbenzoate*,

$$NO_2 \cdot C_6H_4 \cdot CH_2 \cdot S \cdot C_6H_4 \cdot CO \cdot O \cdot CH_2 \cdot C_6H_4 \cdot NO_2,$$
pale yellow crystals, m. p. 194°, are obtained as by-product in the preparation of the acid. Methyl alcohol and hydrochloric acid transform the acid into its *methyl* ester, m. p. 111—112°, which is also obtained by the action of *p*-nitrobenzyl chloride on methyl thiosalicylate in methyl alcoholic solution in the presence of the calculated amount of 2N-potassium hydroxide. When boiled with a methyl alcoholic solution of sodium methoxide and subsequently carefully acidified with acetic acid, the methyl ester is converted into 2-*hydroxy*-1-p-*nitrophenylthionaphthen*, $C_6H_4 \overset{C(OH)}{\underset{S}{<}} C \cdot C_6H_4 \cdot NO_2$, which exists

in a yellow ketonic form, a red enolic form, and as an orange-red mixture. The forms readily pass into one another, so that definite directions for the productions of a definite modification cannot readily be given. The red form, however, which decomposes at 195° after previous softening, is obtained when this crude product is crystallised from aqueous alcohol. From ethyl acetate, chloroform, or glacial acetic acid solution, the yellow keto-form frequently separates in well defined, rhombohedric crystals, usually mixed with the red needles. The mixed form is obtained from solutions of the crude product in benzene, toluene, or xylene in the form of thin, orange-red needles, which are stable and do not become yellow on drying.

In the following experiments the red modification was used. When treated with an equivalent quantity of sodium methoxide in absolute alcoholic solution, the *sodium* salt, $C_{14}H_8O_3NSNa$, blue needles, is obtained. Benzyl chloride in the presence of alkali in aqueous alcoholic or absolute alcoholic solution yields two *benzyl* derivatives, greenish-yellow needles, m. p. 143·5° after softening at 142°, and almost colourless, irregularly formed needles, m. p. 144—145° (corr.), which can be separated by crystallisation from alcohol. A mixture of the two forms melts at 120°. Treatment with ethyl bromide leads to the formation of only one *ethyl* derivative, yellow needles, m. p. 109·5°.

2-*Hydroxy*-1-p-*aminophenylthionaphthen*,

$$C_6H_4 \overset{C(OH)}{\underset{S}{<}} C \cdot C_6H_4 \cdot NH_2,$$
is obtained by the reduction of an alkaline, aqueous alcoholic solution of the nitro-compound by sodium hyposulphite. The substance is purified with difficulty, since it is readily decomposed when warmed in indifferent solvents. It forms white needles, m. p. 130° (corr.), which are sensitive to the action of light and air. The *picrate*, brown needles, begins to decompose at 165°. The salts with mineral acids are generally sparingly soluble and decompose readily. The *oxalate* is converted by nitric acid into a diazonium salt, which couples with R-salt in alkaline solution.

o-Benzylthiolbenzoic acid, needles, m. p. 189°, is formed from benzyl chloride, thiosalicylic acid, and potassium carbonate in boiling aqueous alcoholic solution.

Methyl 2-o-nitrobenzylthiolbenzoate, m. p. 122·5° (corr.), and *methyl* 2-m-*nitrobenzylthiolbenzoate,* rhombohedric plates, m. p. 88—89° (corr.), are obtained from methyl thiosalicylate, 2N-potassium hydroxide, and the requisite nitrobenzyl chloride. They resemble the non-nitrated benzylthiosalicylic acid, in that they do not yield a condensation product when boiled with aqueous alcoholic alkali. H. W.

Vinylphthalimide. MARCEL BACHSTEZ (*Ber.,* 1913, **46,** 3087—3089).—Since phthalylglycyl chloride decomposes when heated into carbon monoxide and chloromethylphthalimide (Gabriel, A., 1908, i, 181), whilst α-phthaliminoisobutyryl chloride decomposes according to the scheme :

$$C_8H_4O_2:N\cdot CMe_2\cdot COCl \longrightarrow CO + HCl + C_8H_4O_2:N\cdot CMe:CH_2$$

(Gabriel, A., 1911, i, 982), the author has examined the action of heat on α-phthalylalanyl chloride (A., 1908, i, 182), and has thereby obtained small quantities of *vinylphthalimide,*

$$C_8H_4O_2:N\cdot CH:CH_2,$$

rhombic plates, m. p. 86°. Attempts to improve the yield by the addition of traces of zinc chloride or aluminium chloride were unsuccessful. The substance unites with bromine to form *phthaliminoαβ-dibromoethane,* needles, m. p. 123—124°, which rapidly decomposes when preserved in the presence of moisture.

A further attempt was made to prepare vinylphthalimide by the abstraction of hydrobromic acid from β-bromoethylphthalimide (compare Johnson and Jones, A., 1911, i, 455) by the action of sodium phenoxide in alcoholic solution. Phenoxyethylphthalimide, m. p. 129—130° (Schmidt, A., 1890, 372), was thereby obtained.

Small quantities of vinylphthalimide were obtained by the action of phosphoric oxide on β-hydroxyethylphthalimide (compare Gabriel, A., 1905, i, 265). H. W.

Toad Venom. HEINRICH WIELAND and FRIEDRICH JOS. WEIL (*Ber.,* 1913, **46,** 3315—3327).—Bufotalin, the poisonous principle of the toad first isolated in an amorphous condition by Faust (A., 1902, i, 446), has now been obtained in the crystalline state. It has the composition $C_{16}H_{24}O_4$, is faintly dextrorotatory and neutral in character. Alkali converts it into the unsaturated bufotalic acid, proving bufotalin to be a lactone. The other two oxygen atoms are present as alcoholic hydroxyl groups. Concentrated hydrogen chloride in the cold eliminates two molecules of water, forming a pale yellow, crystalline compound, $C_{16}H_{20}O_2$, bufotalien. It takes up two atoms of hydrogen in presence of palladium black.

Acetyl chloride in pyridine or warming with acetic anhydride converts bufotalin into a doubly acetylated ether, one hydroxyl group in each molecule being acetylated and the two molecules united through oxygen. Treatment of this diacetyl ether with concentrated hydrochloric acid forms a yellow, strongly unsaturated compound, $C_{18}H_{22}O_3$. The same compound is obtained on heating bufotalein with acetic anhydride, which effects direct acetylation on the carbon. Acetic anhydride is added directly to the C:C complex from which acetic acid is subsequently eliminated.

During the conversion of diacetylbufotalin ether into acetyl bufotalin, the bridge oxygen is first eliminated as water. The single molecules, $-C(OAc){:}CH-$, undergo rearrangement to a saturated diketone, $-CO{\cdot}CHAc-$, which loses water to form the doubly unsaturated monoketone, $-CH{:}CH{\cdot}CH{:}OAc-$. The analogy between bufotalin, $C_{15}H_{22}(OH)_3{\cdot}CO_2H$, and cholic acid, $C_{22}H_{36}(OH)_3{\cdot}CO_2H$, is emphasised. The unsaturated derivatives of both groups give Liebermann's characteristic cholestol reaction with acetic anhydride and sulphuric acid.

Bufotalin is not identical with bufagin, $C_{18}H_{24}O_4$, obtained from the tropical toad by Abel and Macht (A., 1912, ii, 1193).

Bufotalin has m. p. 148° (decomp.), $[\alpha]_D^{20} + 5{\cdot}4°$; it dissolves in concentrated sulphuric acid with an orange-red coloration which becomes deep red on standing and shows a green fluorescence.

Bufotalien forms pale yellow platelets, m. p. 219°. *Acetylbufotalien* separates in lustrous, yellow platelets grouped in rosettes, m. p. 184° (decomp.). *Diacetylbufotalin ether* forms colourless, lustrous platelets, m. p. 254° to a red liquid.   E. F. A.

Action of Chloroacetic Acid on Phenolcarboxylic Acids and Nitrophenols. RICHARD MEYER and CASIMIR DUCZMAL (*Ber.*, 1913, **46**, 3366—3379).—Although the reaction of chloroacetic acid with alcohols and phenols producing ethers according to the equation $R{\cdot}OH + CH_2Cl{\cdot}CO_2H = HCl + OR{\cdot}CH_2{\cdot}CO_2H$ is a fairly general one, it is usually understood that this reaction fails with salicylic acid. The authors find that the reaction can be effected with salicylic acid, although less readily than with most other substances, and, indeed, mere mention of this fact has already appeared (Bogisch, *Diss.*, Stuttgart, 1889), although it has not found its place in the usual literature. The behaviour of the isomeric hydroxybenzoic acids and of the nitrophenols towards chloroacetic acid is also investigated.

The most satisfactory procedure for the reaction with salicylic acid is to dissolve equimolecular quantities of this substance and chloroacetic acid in a concentrated solution of a termolecular quantity of sodium hydroxide. The sodium salt of *o*-carboxyphenoxyacetic acid separates, and the reaction can be completed by heating for some hours on a water-bath. Any salicylic acid in the liberated acid product can be removed by extraction with ether. The yield of *o*-carboxyphenoxyacetic acid, $CO_2H{\cdot}C_6H_4{\cdot}O{\cdot}CH_2{\cdot}CO_2H$, m. p. 190—192°, calculated on the salicylic acid consumed amounts to approximately 80%.

m-Hydroxybenzoic acid, dissolved in sodium hydroxide solution of 35% strength, when gradually treated with chloroacetic acid gave rise to *m*-carboxyphenoxyacetic acid, m. p. 206—207°.

When equimolecular quantities of ethyl chloroacetate and sodium *m*-hydroxybenzoate are heated together in a sealed tube at 170° for thirty hours, *ethyl* m-*hydroxybenzoyloxyacetate* is obtained as a viscous oil, which can be hydrolysed by sodium hydroxide solution at 3° to *m*-*hydroxybenzoyloryacetic acid*,

$$CO_2H{\cdot}CH_2{\cdot}O{\cdot}CO{\cdot}C_6H_4{\cdot}OH,$$
prisms, m. p. 138—140°. On warming with sodium hydroxide solution it is hydrolysed to *m*-hydroxybenzoic acid.

When treated in boiling sodium hydroxide solution (35%) with an equimolecular quantity of chloroacetic acid, *p*-hydroxybenzoic acid is converted into *p*-carboxyphenoxyacetic acid, m. p. 278°.

The action of ethyl chloroacetate on sodium *p*-hydroxybenzoate is similar to the meta-compound and requires similar conditions; the product is an oily *ethyl* ester, which on hydrolysis with cooled sodium hydroxide solution yields p-*hydroxybenzoyloxyacetic acid,*

$$CO_2H \cdot CH_2 \cdot O \cdot CO \cdot C_6H_4 \cdot OH,$$
silky needles, m. p. 174—175°.

o-Cresotic acid when treated in sodium hydroxide solution with chloroacetic acid produces 3-*carboxy*-o-*tolyloxyacetic acid*, needles, m. p. 203—204°. In a similar manner, *m*-cresotic acid gives rise to 4-*carboxy*-m-*tolyloxyacetic acid*, nodular aggregates, m. p. 164—165°, whilst the *p*-cresotic acid yields 3-*carboxy*-p-*tolyloxyacetic acid*, leaflets, m. p. 185°.

1 : 2- and 2 : 3-Hydroxynaphthoic acids were likewise applied to this synthetic reaction, sufficient sodium hydroxide being used to just neutralise the acid reagents. The former acid gave rise to 2-*carboxy*-1-*naphthoxyacetic acid*, silky needles, m. p. 206—207°, whilst the 2 : 3-isomeride produced 3-*carboxy*-2-*naphthoxyacetic acid*, leaflets, m. p. 224—225°.

Chloroacetic acid acts quite normally on the sodium salt of 2 : 4-dinitrophenol, but as the product is rather unstable, excess of alkali must be avoided ; the resulting 2 : 4-dinitrophenoxyacetic acid had m. p. 147—148°.

No success attended attempts to obtain a condensation product of chloroacetic acid with picric acid, even when the latter was applied as the silver salt ; as free picric acid and silver chloride were produced, it is probable that the primary product underwent immediate decomposition.

In all the above cases especial attention was given to the yields of the products, and although the interaction of *o*- and *p*-nitrophenols with chloroacetic acid had already been investigated, experiments were performed to determine the yields ; *m*-nitrophenol was found to behave similarly to the others, producing 3-*nitrophenoxyacetic acid*, needles, m. p. 154—155°.

None of the above substances gives a quantitative result ; it is found that the ortho-compounds give by far the poorest yields, and the difficulty of reaction observed with salicylic acid is evidently to be attributed to its ortho-configuration. With the meta- and para-compounds the yields are much better, the para-compounds being the more satisfactory. D. F. T.

The Condensation Product of Methyl 2 : 3-Hydroxynaph-thoate with Benzaldehyde. LEO ROSLAV (*Monatsh.*, 1913, **34**, 1503—1518. Compare Friedl, A., 1910, i, 741 ; also the three follow-ing abstracts).—As Friedl has already shown, the chlorine atom of methyl 1-*a*-chlorobenzyl-2-naphthol-3-carboxylate, the product obtained when hydrogen chloride is passed into a cold mixture of the above

substances, is highly reactive. Many reactions are now described in which this property is exemplified.

On condensation in presence of sodium in benzene, the compound yielded *methyl aβ-diphenylethane-aβ-bis-2-naphthol-3-carboxylate*,

$$C_2H_2Pb_2[C_{10}H_5(OH)\cdot CO_2Me]_2,$$
in microscopic prisms, m. p. 227°, which gave violet-red solutions in sulphuric acid. When boiled with *p*-cresol in benzene, it formed *methyl 1-a-p-tolyloxybenzyl-2-naphthol-3-carboxylate*,

$$C_6H_4Me\cdot O\cdot CHPh\cdot C_{10}H_5(OH)\cdot CO_2Me,$$
in microscopic leaflets, m. p. 192—193°, whilst thymol yielded *methyl 1-a-thymoxybenzyl-2-naphthol-3-carboxylate*, in yellow, microscopic, rhombic leaflets, m. p. 187—188°.

The chlorine atom in the benzyl group was also replaced by bases, and the following compounds were obtained : from *p*-aminoazobenzene, the *a-benzeneazoanilino*-derivative, slender, orange-yellow needles, m. p. 221°; from carbamide, the *a carbamido*-derivative, only one amino-group reacting, small, faintly yellow prisms, m. p. 194—195°; from benzylamine, the *a-benzylamino*-derivative, long, rectangular plates, m. p. 105—106°, *hydrochloride*, m. p. 172° (decomp.); from piperidine, the *a-piperidino*-derivative, greenish-yellow, m. p. 145—146°, unstable *hydrochloride*, m. p. 174—175°; from phenylhydrazine, the *a-phenylhydrazino*-derivative, lemon-yellow, hard rosettes, m. p. 188°; from ethyl sodiomalonate, the mixed *ester*,

$$CH(CO_2Et)_2\cdot CHPh\cdot C_{10}H_5(OH)\cdot CO_2Me,$$
long, yellow prisms, m. p. 130—131°.

It was expected that with pyridine the substance might react in its ketonic form and yield an *o*-quinone, but a *pyridinium chloride*, $C_5H_5NCl\cdot CHPh\cdot C_{10}H_5(OH)\cdot CO_2Me$, was precipitated as a yellow powder, decomp. 162—163°, when the base was added to a solution of the compound in benzene. The aqueous solution, especially with silver oxide, soon deposited methyl 1-a-hydroxy-benzyl-2-naphthol-3-carboxylate (Friedl, *loc. cit.*), and potassium hydroxide gave, in addition, the above ethane derivative. Quinoline behaved similarly, but no pure product could be isolated.

Colour reactions with ferric and stannic chlorides, sulphuric and perchloric acids are described.   J. C. W.

Condensation of *p*-Tolualdehyde with Methyl 2:3-Hydroxy-naphthoate. Marius Rebek (*Monatsh.*, 1913, 34, 1519—1546).— Methyl 2 : 3-hydroxynaphthoate, which, with the ethyl ester, has been crystallographically examined by von Lang, condenses just as readily with *p*-tolualdehyde under the influence of hydrogen chloride or bromide as it does with benzaldehyde. *Methyl 1-a-chloro-p-methylbenzyl-2-naphthol-3-carboxylate*, $C_6H_4Me\cdot CHCl\cdot C_{10}H_5(OH)\cdot CO_2Me$, forms pale yellow, microscopic tablets, m. p. 143—145°, which give various colour reactions with sulphuric and perchloric acids and stannic and ferric chlorides. The *a-bromo*-derivative forms yellow, glittering, flat leaflets, m. p. 157—159°. In the case of hydrogen bromide, a good yield of the condensation product was obtained when molecular quantities of the reacting substances were diluted with ether. From such a solution, hydrogen chloride gave no crystals for some days,

when, finally, a condensation product of the α-chloro-derivative with more ester, namely, *methyl* p-*xylylidenebis*-2-*naphthol*-3-*carboxylate* (p-*tolyl-di*-2-*hydroxy*-3-*carbomethoxynaphthylmethane*),

$$C_6H_4Me\cdot CH[C_{10}H_5(OH)\cdot CO_2Me]_2,$$

was obtained in well-defined prisms, m. p. 218—222°, which crystallised with ½ mol. of chloroform.

On adding water to a cold acetone solution of the α-bromo-derivative, *methyl* 1-α-*hydroxy*-p-*methylbenzyl*-2-*naphthol*-3-*carboxylate*,

$$C_6H_4Me\cdot CH(OH)\cdot C_{10}H_5(OH)\cdot CO_2Me,$$

crystallises in yellow, rhombic leaflets, m. p. 155—158°. This compound tends to condense to an ether, especially in presence of alcohol or hydrochloric acid, or on melting. When the α-chloro-derivative was boiled with moderately strong hydrochloric acid, the same compound, *methyl* αα′-*oxidobis*-1-p-*methylbenzyl*-2-*naphthol*-3-*carboxylate*,

$$O[CH(C_6H_4Me)\cdot C_{10}H_5(OH)\cdot CO_2Me]_2,$$

was obtained in yellow, micro-leaflets, m. p. 216·5—219°. The speed of the action with water was roughly determined at ordinary temperatures.

When warmed with acetic anhydride and sodium acetate, the yellow halogen compounds became colourless, and an amorphous, acetylated derivative, which could not be crystallised, was obtained. Methyl alcohol condensed with the compounds to form *methyl* 1-α-*methoxy*-p-*methylbenzyl*-2-*naphthol*-3-*carboxylate*,

$$C_6H_4Me\cdot CH(OMe)\cdot C_{10}H_5(OH)\cdot CO_2Me,$$

in microscopic prisms, m. p. 178—180·5°. The α-halogen atom in the xylyl group was also replaced by a number of alcohol- and basic radicles, and the following corresponding condensation products obtained : α-*ethoxy*-derivative, stout, microscopic prisms, m. p. 95·5—97·5°; α-*propoxy*-derivative, yellow, microscopic prisms, m. p. 105·5—108·5°; α-*phenoxy*-derivative, faintly yellow prisms, m. p. 175—176°; p-*tolyloxy*-derivative, rectangular plates or leaflets, m. p. 165·5—167°; α-*thymoxy*-derivative, stout, microscopic needles, m. p. 188—189°; α-*anilino*-derivative, pale yellow, m. p. 210—211·5°; α-*phenylhydrazino*-derivative, lemon-yellow needles, decomp. 140°; α-*piperidino*-derivative, silky needles, m. p. 172—173·5°; p-*benzeneazoanilino*-derivative, orange, short prisms, m. p. 210—210·5°, reddened by hydrochloric acid.

Methyl α-chloro-1-p-methylbenzyl-2-naphthol-3-carboxylate was hydrolysed by adding hydriodic acid to a warm solution in acetic anhydride. p-*Methylbenzyl*-2-*naphthol*-3-*carboxylic acid*,

$$C_6H_4Me\cdot CH_2\cdot C_{10}H_5(OH)\cdot CO_2H,$$

formed intensely yellow crystals, m. p. 249—250° (decomp.), and gave a white *silver* salt, decomp. 210°, from which the *methyl* ester, m. p. 137—138°, was prepared. The latter was also present in the product from the above hydrolysis.

Characteristic colour reactions are exhibited by all these compounds.

J. C. W.

Condensation of Anisaldehyde with Methyl 2 : 3-Hydroxynaphthoate. FRITZ WEISHUT (*Monatsh.*, 1913, 34, 1547—1565).— Studies analogous to the foregoing were carried out with anisaldehyde.

Methyl 1-*a-chloro*-p-*methoxybenzyl*-2-*naphthol*-3-*carboxylate*,

$$OMe \cdot C_6H_4 \cdot CHCl \cdot C_{10}H_5(OH) \cdot CO_2Me,$$

formed yellow prisms, m. p. 171—173°, decomp. 185°, and gave a series of remarkable colour reactions with strong acids, due to the presence of a carbonium valence. Silver sulphate rendered a warm benzene solution violet-red; the colour disappeared on cooling and returned on warming. The *bromo*-analogue had m. p. 162—164°. An attempt to prepare this compound by condensation in methyl alcohol solution gave as a by-product, *methyl anisylidenebis*-2-*naphthol*-3-*carboxylate*, $OMe \cdot C_6H_4 \cdot CH[C_{10}H_5(OH) \cdot CO_2Me]_2$, in pale yellow, microscopic crystals, m. p. 213—215°.

Cold water precipitated from an acetone solution of the halogen derivatives, *methyl* 1-*a-hydroxy*-p-*methoxybenzyl*-2-*naphthol*-3-*carboxylate*, which formed pale yellow leaflets, m. p. 129—130°. The speed of the reaction with water was measured in the case of the *a*-chlorobenzyl-, *a*-chloro- and *a*-bromo-anisyl compounds of this series, and the influence of the methoxy-group and the halogen atom were determined. The methoxy-group renders the lability of the halogen atom of the order of an ionic reaction, whilst the bromo-compounds are more reactive than the chloro-. Boiling water gave rise to *methyl* *aa'-oxidobis*-1-p-*methoxybenzyl*-2-*naphthol*-3-*carboxylate*,

$$O[CH(C_6H_4 \cdot OMe) \cdot C_{10}H_5(OH) \cdot CO_2Me]_2,$$
in yellow prisms, m. p. (without crystal solvent) 202—204°.

Methyl alcohol yielded *methyl* 1-*a*-p-*dimethoxybenzyl*-2-*naphthol*-3-*carboxylate*, $OMe \cdot C_6H_4 \cdot CH(OMe) \cdot C_{10}H_5(OH) \cdot CO_2Me$, in pale yellow, glittering tablets, m. p. 176—177°. Ammonia in benzene formed *methyl* *iminobis*-1-p-*methoxybenzyl*-2-*naphthol*-3-*carboxylate*,

$$NH[CH(C_6H_4 \cdot OMe) \cdot C_{10}H_5(OH) \cdot CO_2Me]_2,$$
as a yellow substance, m. p. 145—148°. With carbamide in boiling acetone, *methyl* *carbamido-s-bis*-1-p-*methoxybenzyl*-2-*naphthol*-3-*carboxylate*, $CO[NH \cdot CH(C_6H_4 \cdot OMe) \cdot C_{10}H_5(OH) \cdot CO_2Me]_2$, was obtained as a microcrystalline powder, m. p. 187—189°.

The following *a*-substituted condensation products were also prepared : *a-anilino*-, faint greenish-yellow, microcrystalline powder, m. p. 191—192°; *a*-p-*benzeneazoanilino*-, small, orange needles, m. p. 194—195°; *a-benzylamino*-, faintly yellow crystals, m. p. 107—108°; *a-piperidino*-, pale yellow powder, m. p. 166—167°. The basic substituents, in general, give rise to compounds which react in the enolic form, giving intense colours with ferric chloride, but not with strong acids.

The *a*-hydroxyl and *a*-anilino-groups were replaced by the methoxy-group, merely on boiling the substances concerned with methyl alcohol. Similarly, hydrogen chloride reconverted the ether or the methoxy-compound into the *a*-chloro-derivative.   J. C. W.

Condensation of Methyl 2:3-Hydroxynaphthoate with p- and m-Nitrobenzaldehydes. JOSEF SEIB (*Monatsh.*, 1913, **34**, 1567—1591).—The influence of the nitro-group on the lability of the halogen atom in compounds analogous to the foregoing has been studied. A rough determination of the speed of the decomposition by cold water showed that the compounds were not half as reactive as

the unsubstituted ones, that the *m*-nitro-derivatives were more active than the para-isomerides and that, as before, bromine in the α-position is more labile than chlorine.

Methyl 1-*a-chloro*-p-*nitrobenzyl*-2-*naphthol*-3-*carboxylate*,

$$NO_2 \cdot C_6H_4 \cdot CHCl \cdot C_{10}H_5(OH) \cdot CO_2Me,$$
formed pale yellow, glistening prisms, m. p. 227—228·5°. On boiling with water it yielded the α·*hydroxy*-derivative in lemon-yellow prisms, m. p. 188—190°, which gave the α-*acetoxy*-compound, short prisms, m. p. 185—187·5°, on boiling with acetic anhydride. The α-*methoxy*-compound, formed slender, very pale yellow prisms, m. p. 149—150°; the α-*ethoxy*-derivative, long, yellow, rectangular tablets, m. p. 116—117°; the α-*phenoxy*-derivative, white needles, m. p. (with $1\frac{1}{2}$ mols. C_6H_6) 181—181·5°; the α-p-*tolyloxy*-derivative, pale yellow needles, m. p. 180—180 5°; the α-*thymoxy*-derivative, yellow, microscopic prisms, m. p. 208—209°; the α-*anilino*-derivative, glistening, lemon-yellow tablets, with $\frac{3}{4}C_6H_6$, m. p. 197·5—198°, without crystal solvent, pure yellow, m. p. 199—201°, colourless *hydrochloride*, m. p. 168—171°; the α-p-*azo-benzeneanilino*-derivative, long, velvety, dark yellow needles, m. p. 154—156°; the α-*benzylamino*-derivative, long, slender, white needles, m. p. 152—153°; the α-*piperidino*-derivative, yellow, rhombic leaflets, m. p. 176·5—177°. In their colour reactions, as before, the compounds with bases exhibit enolic properties, whereas the ketonic form is more pronounced in the remaining compounds.

Pyridine did not cause the total displacement of chlorine, but yielded the α-*pyridinium chloride*,

$$NO_2 \cdot C_6H_4 \cdot CH(C_5NH_5Cl) \cdot C_{10}H_5(OH) \cdot CO_2Me,$$
in pale yellow, prismatic tablets, m. p. 110°, which were completely hydrolysed in aqueous solution, especially in presence of silver oxide, to pyridine and the α-hydroxy-compound.

Methyl 1-*a-bromo*-p-*nitrobenzyl*-2-*naphthol*-3-*carboxylate* was obtained in yellow crystals, m. p. 207—208°. Hydriodic acid, however, yielded no crystalline product.

Methyl 1-*a-chloro*-m-*nitrobenzyl*-2-*naphthol*-3-*carboxylate* had m. p. 187—189°, and the *bromo*-analogue formed thin, pale yellow leaflets, with $1C_6H_6$, m. p. 177—178°. *o*-Nitrobenzaldehyde, on the contrary, yielded no definite condensation product with methyl 2 : 3-hydroxy-naphthoate. J. C. W.

Hydroxy-and Dihydroxy-diphenylcarboxylic Acids. MATHÄUS MURDBOVČIĆ (*Monatsh.*, 1913, **34**, 1417—1441).—3 : 3'-Dihydroxy-diphenyl-4 : 4'-dicarboxylic acid, 3-hydroxydiphenyl-4 : 4'-dicarboxylic acid, and several of their derivatives have been prepared.

Dianisidine was diazotised and converted into the nitrile and this was saponified, with difficulty, by boiling for seventy to eighty hours with alcoholic potassium hydroxide. The crude 3 : 3'-*dimethoxydiphenyl-4 : 4'-dicarboxylic acid*, being only sparingly soluble, was converted into the methyl ester and recovered from this by hydrolysis, as a white, microcrystalline powder, m. p. 270—271·5°. The *potassium* salt, $C_{16}H_{21}O_6K_2,2H_2O$, forms long needles from dilute solutions in spirit, and the *silver* salt is a brown, crystalline powder. The *methyl* ester forms white leaflets, m. p. 170—171°. On heating either the ester or

the acid with hydriodic or hydrobromic acid, 3 : 3′-*dihydroxydiphenyl-4 : 4′-dicarboxylic acid* was obtained as a white, amorphous, sparingly soluble powder, m. p. 318° (decomp.). It gives a colourless solution in sulphuric acid, a deep violet coloration with alcoholic ferric chloride, and apparently forms anhydrides under the influence of thionyl chloride. The *methyl* ester forms slender, colourless needles, m. p. 213—215°, and is readily converted into *methyl 3 : 3′-diacetoxydiphenyl-4 : 4′-dicarboxylate*, which crystallises from alcohol in leaflets, m. p. 140—142°.

The methoxy-acid, in contrast to the hydroxy-acid, reacted smoothly with thionyl chloride, forming the *acid chloride*, $C_{16}H_{12}O_4Cl_2$, from a benzene solution of which, ammonia precipitated the *amide*. This forms large needles, $C_{16}H_{16}O_4N_2$,EtOH, from dilute alcohol, m. p. 254—260° (260—261° alcohol-free). On condensing the acid chloride with benzene in presence of aluminium chloride, 3 : 3′-*dihydroxy-4 : 4′-dibenzoyldiphenyl*, $C_{26}H_{18}O_4$, was obtained. The ketone was purified by solution in alkali, reprecipitation by carbon dioxide, heating with hydriodic acid, and crystallisation from alcohol. It forms yellow needles, m. p. 215·5—217·5°, gives a deep yellowish-green, fluorescent solution in sulphuric acid and a reddish-brown coloration with ferric chloride. It was converted by methyl sulphate into 3 : 3′-*dimethoxy-4 : 4′-dibenzoyldiphenyl*, which forms colourless, flat needles, m. p. 156—158°.

As starting material for the preparation of the monohydroxy-compounds, technical ethoxybenzidine was chosen. This was converted into a black, spongy nitrile, which was then hydrolysed as before. Owing to the ready solubility of the acid, however, the crude product could not easily be purified. It was therefore hydrolysed by heating in phenol solution with hydriodic acid, and the crude 3-*hydroxydiphenyl-4 : 4′-dicarboxylic acid* was esterified and recovered by hydrolysis. It forms a white, microcrystalline powder, m. p. 324—325°, crystallises with $1H_2O$ from diluted methyl alcohol, and gives a violet ferric chloride reaction. The *potassium* salt, $C_{14}H_8O_5K_2,H_2O$, and the light brown *silver* salt were prepared. The *methyl* ester forms long, white, glistening needles or leaflets, m. p. 168°, and does not condense with benzaldehyde. *Methyl 3-acetoxydiphenyl-4 : 4′-dicarboxylate* crystallises in very soluble, flat needles, m. p. 119°.

The isomeric mono-esters were prepared according to Wegscheider's directions for hydroxyterephthalic acid (A., 1900, i, 658). Partial hydrolysis of the dimethyl ester with potassium hydroxide yielded 4′-*methyl 4-hydrogen 3-hydroxydiphenyl-4 : 4′-dicarboxylate*, which could be separated from the dicarboxylic acid by benzene, in which the latter is insoluble. It has m. p. 240—241·5° (decomp.), gives a deep violet coloration with ferric chloride, and forms a *potassium* salt. 4-*Methyl 4′-hydrogen 3-hydroxydiphenyl-4 : 4′-dicarboxylate* was obtained in small yield by heating the acid potassium salt with methyl iodide in a sealed tube. It crystallises from benzene in needles, m. p. 215—216°, which give no coloration with ferric chloride.

Schmidt and Schall (A., 1906, i, 23) described 4-hydroxydiphenic acid as a yellow compound. The author also obtained a yellow product,

but on attempting to condense it with benzaldehyde it crystallised as a colourless compound, m. p. 246·5°, the impurity remaining dissolved.

J. C. W.

The Ethers and Esters of Hydroxyquinolphthalein. FRIEDRICH KEHRMANN and RICHARD BERG (*Ber.*, 1913, **46**, 3020—3028).— When hydroxyquinolphthalein in solution in sufficient aqueous sodium hydroxide to form the normal salt is warmed with one and two-third times its weight of methyl iodide, the solution on acidification with acetic acid deposits the *trimethyl ether* (formula I), which frequently
separates from a mixture of benzene and methyl alcohol in a feebly coloured, presumably lactonoid form; this on recrystallisation from methyl alcohol passes into the quinonoid form, orange-yellow, microscopic leaflets, m. p. 257°; the solution in alkali is yellow with a green fluorescence. The mother liquor from which the trimethyl ether has separated contains the sodium salt of the *dimethyl ether* (formula II), and this substance is deposited as the *hydrochloride* on the addition of concentrated hydrochloric acid; the free ether is liberated from its hydrochloride by the action of sodium acetate solution. This dimethyl ether, m. p. 270—271°, crystallises from methyl alcohol in reddish-brown prisms containing 1MeOH; it dissolves in sodium hydrogen carbonate solution, giving the *sodium* carboxylic salt as a yellowish-red solution with a green fluorescence; addition of sodium hydroxide solution causes the formation of the *disodium* salt, with an increase of the fluorescence; *silver* salt, insoluble reddish-brown precipitate.

On saturating a concentrated methyl-alcoholic solution of the trimethyl ether with hydrogen chloride and keeping for several weeks, needles of the *chloride* (formula III) are obtained. By treatment

with warm sodium acetate solution, this is converted into the free methyl *ester* of the trimethyl ether (formula IV), which crystallises from a mixture of benzene and methyl alcohol in orange-yellow, iridescent leaflets, m. p. 271—272°.

A similar esterification of the above-mentioned dimethyl ether gives rise to an analogous ester *chloride*, yellow needles, which on decomposition by sodium acetate solution passes into the free *ester* of the dimethyl ether, red crystals, m. p. 248°.

The action of methyl sulphate on a solution of the ester of the trimethyl ether in nitrobenzene solution gave rise to the methyl sulphate salt of the methyl ester of the tetramethyl ether. From this "mixed" sulphate the more ordinary salts were easily obtainable, and their solubility is found to be comparable with those of the corresponding potassium salts; formula V is the *chloride*.

The chloride, *bromide*, and *iodide* are very soluble, the *nitrate*, *chlorate*, *dichromate*, and *persulphate* are moderately soluble, whilst the *perchlorate* and *platinichloride* are sparingly soluble in water. If an aqueous solution of the nitrate is treated in the cold with an excess of
fairly concentrated sodium hydroxide solution, a precipitate is produced, which subsequently redissolves as the *sodium* salt of the tetramethyl ether carboxylic acid; on the addition of acetic acid and warming, the tetramethyl ether lactone (formula VI), colourless prisms, m. p. 202°, is obtained.   D. F. T.

Resorcinolbenzein and Fluorescein. FRIEDRICH KEHRMANN (*Ber.*, 1913, **46**, 3028—3036).—A reply to von Liebig (A., 1912, i, 376; this vol., i, 79, 865). In the case of derivatives of fluorescein with which von Liebig obtained results at variance with those of the author and his collaborators, the substances have been reinvestigated with entire confirmation of the earlier results.

It has already been stated by Fischer and Hepp (A., 1895, i, 291) that the quinonoid dimethyl ether of fluorescein crystallises in two forms, namely, orange-yellow needles and deep red prisms. The difference in the m. p.'s recorded by von Liebig and by Kehrmann and Dengler (A., 1909, i, 249) is due to this dimorphism. Indeed, if a quantity of the orange-yellow needles is heated rapidly to 180°, it melts momentarily and resolidifies to melt again at approximately 194°; under similar treatment the red prisms melt at 208°.

The substance, m. p. 255°, obtained by von Liebig by the action of ammonia solution on the ether-insoluble residue (correctly regarded as trimethylfluorescein chloride) from the reaction product of methyl sulphate and disodium fluorescein, is not a dimethyl ether of fluorescein, but contains almost 2% of nitrogen and probably represents a carbinylimide or a carboxylimide.   D. F. T.

Synthesis of Depsides, Moss Acids, and Tannins. EMIL FISCHER (*Ber.*, 1913, **46**, 3253—3289).—A lecture before the German

Natural Science Congress (compare A., 1908, i, 892; 1909, i, 161, 309; Fischer and Freudenberg, A., 1910, i, 265; 1911, i, 874; 1912, i, 471, 887; Fischer and Hoesch, A., 1912, i, 859, etc.). The following facts are new. Evernic acid is dissolved by an ethereal solution of diazomethane after a time, and converted into the crystalline neutral ester, which is identified as methyl trimethyl-lecanoric acid. The constitution of evernic acid is thus established. Pentasalicyloglucose and the corresponding derivative of caffeic acid have been prepared, also pentacinnamoyl derivatives of α- and β-glucose, galactose, and mannose. *Penta-acetyl mannose* has m. p. 114—116°, $[\alpha]_D^{20} - 24\cdot 8°$.

E. F. A.

Humic Acids. IV. Investigations of Tacke and Süchting EUGEN GULLY (*Bied. Zentr.*, 1913, **42**, 655—659; from *Mitt. K. Bayr. Moorkulturanst.*, 1912, Heft. 5).—A reply to Tacke and Süchting (A., 1912, i, 473), in which the non-existence of humic acids is maintained. Further experiments showed that peat has no action on calcium oxalate; and that bases absorbed by *Sphagna* can be extracted by water free from carbon dioxide. The various results obtained with peat, such as the liberation of iodine from its salts, the inversion of sucrose, and the production of hydrogen from peat and iron are not considered sufficient evidence that humic acids exist.

N. H. J. M.

The Autoxidation of Organic Compounds. I. Autoxidation of Aromatic Aldehydes. HERMANN STAUDINGER [with E. HENE and J. PRODROM (*Ber.*, 1913, **46**, 3530—3535).—It has been previously shown (A., 1911, i, 877) that diphenylketen reacts more readily with methoxy- or dimethylamino-substituted aromatic compounds than with the unsubstituted substances, and similar observations have been made during experiments on the action of oxalyl chloride on carbonyl compounds (A., 1909, i, 905). The authors have therefore been led to the determination of the rate of autoxidation of benzaldehyde and a number of its *p*-substituted derivatives.

Weighed quantities of benzaldehyde, *p*-methoxybenzaldehyde, *p*-hydroxybenzaldehyde, and *p*-dimethylaminobenzaldehyde were heated with an excess of oxygen in closed flasks at 131° and the amount of oxygen absorbed was estimated. In a second series of experiments, a regular stream of oxygen was bubbled through the aldehyde, the course of the reaction being followed by estimation of the acid formed. At 131°, however, dimethylaminobenzoic acid readily evolved carbon dioxide; a temperature of 80° was found suitable. The results show that *p*-dimethylaminobenzaldehyde is much less autoxidisable than anisaldehyde, which, however, is less affected than benzaldehyde. This is inexplicable on Engler and Weissberg's hypothesis that the primary product during autoxidation is formed by the addition of a molecule of oxygen to the unsaturated carbonyl group; it is, however, to be expected if Baeyer and Villiger's supposition is adopted that the addition of the oxygen molecule is accompanied by dissociation of the hydrogen atom, $\text{Ph·C}\!\!<^O_H + \text{O·O} \longrightarrow \text{Ph·C}\!\!<^O_{O·O·H}$ (A., 1900, i, 437).

If Staudinger's views as to the asymmetric nature of the intermediate compound are accepted, the hydrogen atom would be more firmly attached to the strongly unsaturated carbonyl group of p-dimethylaminobenzaldehyde than to the relatively saturated carbonyl group of benzaldehyde, and therefore less capable of addition to the oxygen molecule. From this point of view, o-methoxybenzaldehyde should be the least readily, and m-methoxybenzaldehyde the most readily, autoxidisable of the three methoxybenzaldehydes, and this is shown to be actually the case.

Anti-auxochrome groups weaken the unsaturated character of the carbonyl group, and should therefore increase the mobility of the hydrogen atom and the tendency of the substance to autoxidation. p-Nitrobenzaldehyde, which should thus be readily autoxidised, absorbs little oxygen, since it is speedily resinified. The problem was, however, investigated by the introduction of acyl groups into amino- and hydroxy-groups. Acetoxybenzaldehyde, in contrast with hydroxy- and methoxy-benzaldehyde, was found to be almost as readily autoxidised as benzaldehyde.   H. W.

The Autoxidation of Organic Compounds. II. Relationships between Autoxidation and Benzoin Formation. HERMANN STAUDINGER [with E. HENE] (*Ber.*, 1913, **46**, 3535—3538). —If the possibility of formation of intermediate products be disregarded, the formation of benzoin derivatives from aldehydes is comparable with the autoxidation of the latter substances; in the one case, addition of the aldehyde to the carbonyl group occurs, in the other to the oxygen molecule (compare preceding abstract). A benzoin will only be readily produced, therefore, from an aldehyde which contains a relatively unsaturated carbonyl group and a relatively mobile hydrogen atom; thus, dimethylaminobenzaldehyde does not yield a benzoin, since, although the carbonyl group is strongly unsaturated, the hydrogen atom lacks mobility. Favourable conditions for benzoin formation are found in benzaldehyde, anisaldehyde, and p-chlorobenzaldehyde (compare Hantzsch and Glover, A., 1907, i, 538). From this point of view, mixed benzoin derivatives should be obtainable from a pair of aldehydes if the one possesses a sufficiently mobile hydrogen atom, the other a sufficiently unsaturated carbonyl group; the condensation products of p-dimethylaminobenzaldehyde and p-chlorobenzaldehyde with benzaldehyde are described.

p-*Dimethylaminobenzoin*, $NMe_2 \cdot C_6H_4 \cdot CH(OH) \cdot COPh$, m. p. 163—164°, is obtained in 86% yield when a solution of benzaldehyde and p-dimethylaminobenzaldehyde in alcohol is boiled with an aqueous solution of potassium cyanide. The constitution of this substance is deduced from the fact that it condenses with dimethylaniline in the presence of phosphoryl chloride to yield *benzoyltetramethyldiaminodiphenylmethane*, $COPh \cdot CH(C_6H_4 \cdot NMe_2)_2$, pale yellow needles, m. p. 162—164°, which are readily oxidised to a blue dye. Oxidation with Fehling's solution converts p-dimethylaminobenzoin into p-*dimethylaminobenzil*, yellowish-green crystals, m. p. 115—116°.

Under similar conditions, p-dimethylaminobenzaldehyde condenses

with p-chlorobenzaldehyde to yield p-*chloro*-p'-*dimethylaminobenzoin*, m. p. 127—128°.

Benzaldehyde and anisaldehyde, as also chlorobenzaldehyde and anisaldehyde, appear to yield mixed benzoins. A uniform product could not be isolated. Probably a mixture of benzoins is formed in each case which cannot be separated.

Attempts to prepare benzoins from aromatic and aliphatic aldehydes were unsuccessful. H. W.

The Existence of Mandelaldehyde in Aqueous Solution. W. LLOYD EVANS and CHARLES RAYMOND PARKINSON (*J. Amer. Chem. Soc.*, 1913, 35, 1770—1774. Compare this vol., i, 173).—It is already known that, whereas lactaldehyde is incapable of existence in water at 100° (Nef, A., 1905, i, 3), it is sufficiently stable in water at the ordinary temperature to be studied experimentally (Wohl and Lange, A., 1908, i, 943). Nef has shown that mandelaldehyde also cannot exist in water at 100°, and the present investigation demonstrates that it cannot exist even in the presence of cold aqueous alcohol or of dilute sulphuric acid.

Dibromoacetophenone was converted successively into phenylglyoxal acetal, $CHBz(OEt)_2$, and mandelaldehyde acetal, $CH(OEt)_2 \cdot CHPh \cdot OH$. The last-named substance was found to undergo hydrolysis, yielding benzoylcarbinol, $CH_2Bz \cdot OH$, when suspended in $N/20$-sulphuric acid at 0°, when suspended in water at 0°, or even when exposed to the moisture of the atmosphere. D. F. T.
6-Aminopiperonal. AUGUSTE RILLIET and L. KREITMANN (*Compt. rend.*, 1913, 157, 782—784).—Various unsuccessful attempts have been made to prepare the above substance by reduction of 6-nitropiperonal (compare Haber, A., 1891, 704; Friedländer and Schreiber, A., 1895, i, 524). The authors have succeeded by first protecting the aldehyde group.

6-Nitropiperonal condenses readily with various amines to give the corresponding piperonylidene derivatives, of which the following have been prepared : 6-*nitropiperonylidene*-p-*toluidine*, yellow needles, m. p. 121·5°; 6-*nitropiperonylidene*-p-*anisidine*, golden-yellow plates, m. p. 125·5°, and 6-*nitropiperonylidene*-o-*toluidine*, yellow needles, m. p. 128°. All of these are readily reduced in boiling alcoholic solution by sodium sulphide to the corresponding *amino*-compounds, having respectively m. p.'s 134·5°, 162°, and 106°. The hydrolysis of the two latter compounds has not given the desired results, being only brought about with difficulty, but 6-aminopiperonylidene-p-toluidine is readily hydrolysed by prolonged boiling with dilute aqueous alkali, giving 6-*aminopiperonal*, brilliant yellow prisms, m. p. 107°, dissolving in acids to a bright red solution. From it the following derivatives have been prepared : the *mercurichloride*, white needles, decomposing at 135°; a *platinichloride*, a red, amorphous powder, decomposing suddenly on heating ; 6-*benzoylaminopiperonal*, pale yellow needles, m. p. 187·5°; 6-*acetylaminopiperonal*, long, white needles, m. p. 161°, yielding a *phenylhydrazone*, white needles, m. p. 205°, and 6-*aminopiperonalphenylhydrazone*, m. p. 222° (decomp.). W. G.

Chemical Action of Light. XXVII. Autoxidation. V. GIACOMO CIAMICIAN and PAUL SILBER (*Ber.*, 1913, **46**, 3077—3084; *Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 339—348).—The action of oxygen and light on acetone, *cyclo*hexanone, the three methyl*cyclo*-hexanones, and methylheptenone has been studied. Except in the cases of acetone and methylheptenone (A., 1910, i, 496), the products obtained are due to the combined effect of autoxidation and hydrolysis (compare A., 1908, i, 277).

Acetone yields formaldehyde and acetic acid, whilst *cyclo*hexanone gives hexoic and adipic acids.

1-Methyl*cyclo*hexan-2-one yields *n*-heptoic acid (œnanthoic acid), adipic acid, and acetylvaleric acid, together with traces of aldehyde, the main reaction proceeding in accordance with the scheme :

$$
\begin{array}{ccc}
\text{CH·CH}_3 & \text{CO·CH}_3 & \begin{array}{c}\text{H·CO}_2\text{H}\\ \text{CO}_2\text{H}\end{array}\\
\underset{\text{H}_2\text{C}}{\diagdown}\underset{\text{CO}}{\diagup} & \underset{\text{H}_2\text{C}}{\diagdown}\underset{\text{CO}_2\text{H}}{\diagup} & \underset{\text{H}_2\text{C}}{\diagdown}\underset{\text{CO}_2\text{N}}{\diagup}\\
\underset{\text{H}_2\text{C}}{}\quad\underset{\text{CH}_2}{} \rightarrow & \underset{\text{H}_2\text{C}}{}\quad\underset{\text{CH}_2}{} \rightarrow & \underset{\text{H}_2\text{C}}{}\quad\underset{\text{CH}_2}{}\ \cdot\\
\underset{\text{CH}_2}{\diagup\diagdown} & \underset{\text{CH}_2}{\diagup\diagdown} & \underset{\text{CH}_2}{\diagup\diagdown}
\end{array}
$$

δ-Acetylvaleric acid has m. p. 31—33°, whilst the semicarbazone melts at 147°. Wallach gives the m. p.'s about 50° and 144—146° respectively (A., 1904, i, 425).

1-Methyl*cyclo*hexan-3-one is less affected than the 1 : 2-derivative, and gives a heptoic acid, b. p. 215—216°, which must have the constitution CH$_2$Me·CH$_2$·CHMe·CH$_2$·CO$_2$H, a dibasic acid, m. p. 97°, identical with the corresponding compound from 1 : 4-methyl*cyclo*-hexanone, and hence having the formula

CO$_2$H·CH$_2$·CH$_2$·CHMe·CH$_2$·CO$_2$H,
and a lactone which could not be prepared in the pure state.

1-Methyl*cyclo*hexan-4-one gives γ-methylhexoic acid, the above-mentioned dicarboxylic acid and the lactone corresponding with the hydroxy-acid. The latter could not be obtained in a pure condition.

Methylheptenone yields carbon dioxide, acetone, formic acid, acetic acid, and lævulic acid, together with a ketoglycol consisting mainly of the compound OH·CMe$_2$·CH(OH)·CH$_2$·CH$_2$·CO·CH$_3$, possibly mixed with the hydroxydiketone, OH·CMe$_2$·CO·CH$_2$·CH$_2$·CO·CH$_3$. Crystalline derivatives could not be obtained, but the identity of the product follows from its conversion by boiling dilute sulphuric acid into β-methylheptane-γζ-dione, CHMe$_2$·CO·CH$_2$·CH$_2$·CO·CH$_3$, and identification of the semicarbazone and dioxime of the latter with the similar compounds obtained by the oxidation of methylheptenone with potassium permanganate (compare Harries, A., 1902, i, 345). The autoxidation of methylheptenone in light proceeds mainly, therefore, according to the scheme : CMe$_2$:CH·CH$_2$·CH$_2$·CO·CH$_3$ →

OH·CMe$_2$·CH(OH)·CH$_2$·CH$_2$·CO·CH$_3$ →

OH·CMe$_2$·CO·CH$_2$·CH$_2$·CO·CH$_3$ →

CH$_3$·CO·CH$_3$ + CO$_2$H·CH$_2$·CH$_2$·CO·CH$_3$,
the acetic and formic acids, as probably also the carbon dioxide, being formed by a partial further oxidation of the acetone.   H. W.

Alkylation of 3- and 4-Methyl*cyclo*hexan-3- and 4-ones by means of Sodamide. ALBIN HALLER (*Compt. rend.*, 1913, **157**, 737—743).—Methyl*cyclo*hexan-3- and 4-one not only undergo methylation and allylation under the influence of sodamide, but also ethylation. During the latter reaction condensation of the product on itself is much more pronounced than with the methyl and allyl derivatives. Further, a comparative study of the alkylation of the three methyl*cyclo*hexanones shows that this condensation is much more pronounced the more remote the methyl group is from the ketonic group, and attains its maximum with *cyclo*hexanone itself.

Starting with 1-methyl*cyclo*hexan-3-one, ethyl iodide yields, in ethereal solution in the presence of sodamide, 1-methyl-4-ethyl*cyclo*hexan-3-one (compare A., 1905, i, 214, and Wallach, this vol., i, 482) and 1-*methyl*-2 : 4-*diethylcyclohexan-3-one*, b. p. 216—219°/760 mm., D_4^{17} 0·9061, n_D^{17} 1·4577, together with about 22% of the condensation product. Subsequent successive ethylation of this diethyl derivative furnishes :

1-*Methyl*-2 : 2 : 4-*triethylcyclohexan-3-one*, b. p. 242—244°/770 mm., D_4^{23} 0·9077, n_D^{23} 1·4609.

1-*Methyl*-2 : 2 : 4 : 4-*tetraethylcyclohexan-3-one*, b. p. 266—270°/770 mm., D_4^{20} 0·9358, n_D^{20} 1·4697, having an odour resembling menthone.

1-Methyl*cyclo*hexan-4-ol, b. p. 173—173·5°/760 mm., D_4^{20} 0·9170, n_D 1·4573, obtained by the hydrogenation of *p*-cresol, on oxidation with chromic acid yields 1-methyl*cyclo*hexan-4-one, b. p. 170°/760 mm., D_4^{20} 0·9132, n_D^{20} 1·4458. This ketone on successive methylation under the prescribed conditions with methyl iodide yields :

1 : 3-Dimethyl*cyclo*hexan-4-one (compare Wallach, *loc. cit.*).

1 : 3 : 5-*Trimethylcyclohexan-2-one*, b. p. 184—185°/748 mm., D_4^{20} 0·8992, n_D^{20} 1·4458.

1 : 1 : 3 : 5-*Tetramethylcyclohexan-2-one*, b. p. 190—191°/753 mm., D_4^{20} 0·8903, n_D^{20} 1·4459.

1 : 1 : 3 : 3 : 5-*Pentamethylcyclohexan-2-one*, b. p. 196—198°, D_4^{20} 0·8828, n_D^{20} 1·4461.

Successive introduction of a methyl group produces a regular rise in the boiling point of 6° to 7°, and a steady diminution in the density, whilst the refractive index remains practically constant.

The pentamethyl ketone on hydrogenation with sodium in absolute alcohol yields 1 : 1 : 3 : 3 : 5-*pentamethyl*cyclohexan-2-ol, b. p. 203°/760 mm., D_4^{20} 0·8929, n_D^{20} 1·4581, a viscous liquid having an odour resembling that of eugenol.

Progressive ethylation of 1-methyl*cyclo*hexan-4-one similarly yields :

1-*Methyl*-3-*ethylcyclohexan-4-one*, b. p. 196—198°/761 mm., D_4^{20} 0·8996, n_D^{20} 1·4494, having an odour of menthone.

1-*Methyl*-3 : 5-*diethylcyclohexan-4-one*, b. p. 216—218°/765 mm., D_4^{20} 0·9023, n_D^{20} 1·4562, its odour being identical with that of menthone.

1-*Methyl*-3 : 3 : 5-*triethylcyclohexan-4-one*, b. p. 237—240°/758 mm., D_4^{20} 0·9047, n_D^{20} 1·4615.

1-*Methyl*-3 : 3 : 5 : 5-*tetraethylcyclohexan-4-one*, b. p. 258—262°/760 mm., D_4^{20} 0·9301, n_D^{20} 1·4675 : a viscous liquid with an odour of turpentine. W. G.

5-Acetylamino-2-hydroxyacetophenone and its Derivatives.
FRANZ KUNCKELL (*Ber. Deut. pharm. Ges.*, 1913, **23**, 472—490. Compare A., 1900, i, 663; 1911, i, 990; 1912, i, 268).—2-Hydroxy-5-acetyl-aminoacetophenone, $NHAc \cdot C_6H_3(OH) \cdot COMe$ (compare Kunckell and Hammerschmidt, this vol., i, 1204), is prepared by the gradual addition of aluminium chloride in bright sunlight to a solution of phenacetin in anhydrous carbon disulphide and acetyl bromide (Schmidt, *Diss.*, 1900) or acetyl chloride (Dirk*, *Diss.*, 1906). It forms monoclinic crystals, m. p. 165°. Concentrated hydrochloric acid converts it into 5-*amino-2-hydroxyacetophenone*, yellowish-green needles, m. p. 105°, the *hydrochloride*, white leaflets, m. p. 155° (decomp.), and *sulphate*, m. p. 150°, of which are also described. The *phenylhydrazone* of 2-hydroxy-5-acetylaminoacetophenone forms small, yellow needles, m. p. 107°, whilst the *oxime*, white needles, has m. p. 160°; the nitro-derivative, $C_{10}H_{10}O_5N_2$, yellow needles, m. p. 170°, is obtained by the gradual addition of concentrated nitric acid to a well-cooled solution of the substance in glacial acetic acid.

When treated with a solution of sodium ethoxide in absolute alcohol, 2-hydroxy-5-acetylaminoacetophenone yields the corresponding *sodium* derivative, lemon-yellow leaflets, m. p. 225° (decomp.), which, when heated with ethyl iodide and ethyl alcohol, is converted into 5-*acetyl-amino-2-ethoxyacetophenone*, white needles, m. p. 155° (*phenylhydrazone*, brown needles, m. p. 180°; *mononitro*-derivative, yellowish-red needles, m. p. 125°). Attempts to prepare the substance directly by the action of acetyl chloride and aluminium chloride on phenacetin were unsuccessful, the ethyl group being invariably eliminated. Boiling hydrochloric acid converts it into 5-*amino-2-ethoxyacetophenone hydrochloride*, m. p. 215°.
ω-*Chloro-2-hydroxy-5-acetylaminoacetophenone*,
$$CH_2Cl \cdot CO \cdot C_6H_3(OH) \cdot NHAc,$$
yellow needles, m. p. 190°, is prepared by the gradual addition of aluminium chloride in sunlight to a solution of phenacetin and chloro-acetyl chloride in carbon disulphide. The free *base*, yellowish-green needles, has m. p. 135°; *hydrochloride*, white leaflets, m. p. 210° (decomp.). The *oxime* of 2-hydroxy-5-acetylamino-ω-chloroacetophenone has m. p. 195°.

ω-*Chloromononitro-2-hydroxy-5-acetylaminoacetophenone*, yellow needles, m. p. 160°, is obtained by the gradual addition of concentrated nitric acid to a well cooled solution of ω-chloro-2-hydroxy-5-acetylamino-acetophenone in glacial acetic acid. The *oxime* has m. p. 230° (decomp.). The free *base* forms red needles, m. p. 145° (decomp); the *hydrochloride* of the latter decomposes, without melting, at 210°.

ω-*Chloro-2-hydroxy-5-benzoylaminoacetophenone*,
$$CH_2Cl \cdot CO \cdot C_6H_3(OH) \cdot NHBz,$$
m. p. 203°, is prepared by the action of benzyl chloride on an alcoholic solution of ω-chloro-5-amino-2-hydroxyacetophenone. The corresponding *benzoate* has m. p. 166—167°; the *oxime*, m. p. 197°. The *mononitro*-derivative, yellow needles, m. p. 190° (decomp.), is obtained by nitrating the benzoyl derivative in glacial acetic acid solution.

ω-Chloro-5-amino-2-hydroxyacetophenone couples with a diazotised

solution of aniline, yielding a *diazoamino*-compound,

$$CH_2Cl\cdot CO\cdot C_6H_3(OH)\cdot NH\cdot N_2Ph,$$
unstable, golden-yellow crystals, m. p. 127°. Attempts to diazotise the base led to the isolation of a *compound* (annexed formula), which explodes without melting at 140°. This substance is decomposed by boiling water, but a pure substance could not be isolated from the product.
The *phenylurethanes* of ω-chloro-2-hydroxy-5-acetyl-aminoacetophenone and of ω-chloro-5-amino-2-hydroxyacetophenone have m. p.'s 139° and 204° respectively.

The action of phenylhydrazine at a temperature not exceeding 120° on ω-chloro-2-hydroxy-5-acetylaminoacetophenone leads to the formation of the *substance*, $NHAc\cdot C_6H_3(OH)\cdot C(:N\cdot NHPh)\cdot CH:N\cdot NHPh$, needles, m. p. 223°. If the reaction is carried out at a higher temperature and with a relatively smaller quantity of phenylhydrazine, a *substance*, m. p. 247°, is obtained, which has not been completely investigated owing to lack of material. Phenylhydrazine reacts with ω-chloro-5-amino-2-hydroxyacetophenone in a similar manner, yielding the *hydrochloride* of the osazone,

$$HCl,NH_2\cdot C_6H_3(OH)\cdot C(:N\cdot NHPh)\cdot CH:N\cdot NHPh;$$
the pure *osazone*, m. p. 205°, is unstable. H. W.

ε-**Aminoketones.** KARL A. BÖTTCHER (*Ber.*, 1913, 46, 3158—3167).—The salts of several benzene-substituted ε-aminoketones have been prepared. Like the simple phenyl ε-aminoamyl ketone in contrast to methyl ε-aminoamyl ketone (Gabriel, A., 1909, i, 492), the new bases do not lose water to form heptacyclic imines, but unlike those simple amines, they yield no definite products under the influence of reducing agents, but are usually unaffected.

Benzoyl-leucine was converted into the chloride, and this condensed with toluene in presence of aluminium chloride. The new benzoyl derivative could not be purified, but was hydrolysed by means of fuming hydrochloric acid in a sealed tube and converted into *tolyl ε-aminoamyl ketone hydrochloride*, $C_{18}H_{20}ONCl$. This salt crystallises in rhombohedra, m. p. 163°, and forms a *platinichloride*, orange-yellow, crystalline powder, m. p. 211°, an *aurichloride*, sulphur-yellow rhombohedra, m. p. 114—116°, and a *picrate*, yellow, jagged crystals, m. p. 148°. The yield of the base was only 18%, but was raised to 41·5% by employing the phthalyl derivative in the condensation. For this purpose, benzoyl-leucine was hydrolysed with fuming hydrochloric acid, the resulting ε-aminohexoic acid was heated with phthalic anhydride, and then converted into ε-phthaliminohexoyl chloride by means of phosphorus pentachloride. On condensation with toluene, the *phthalimino*-derivative, $C_8H_4O_2:N\cdot[CH_2]_5\cdot CO\cdot C_7H_7$, was obtained in well-defined prisms, m. p. 134°. The phthalamino-acid was then prepared by boiling the imide with potassium hydroxide and precipitating with acid, and was finally hydrolysed in a sealed tube. Free *tolyl ε-aminoamyl ketone*, $NH_2\cdot[CH_2]_5\cdot CO\cdot C_7H_7$, was obtained as a colourless oil, b. p. 185—189°/15 mm., m. p. 39—40°, with a basic odour and

strongly alkaline reaction. The *benzenesulphonamide*,

$$C_7H_7 \cdot CO \cdot [CH_2]_5 \cdot NH \cdot SO_2Ph,$$
formed long, rectangular tablets, m. p. 135—136°. Like the sulphonyl derivative of heptylamine (Marckwald, A., 1900, i, 149) and like *ε - benzoylamylbenzenesulphonamide* [*benzenesulphonyl- ε - aminohexo - phenone*], $COPh \cdot [CH_2]_5 \cdot NH \cdot SO_2Ph$, which was prepared in rhombic tablets, m. p. 84—85°, from ε-benzoylamylamine [ε-aminohexophenone], it did not dissolve in alkalis, but was changed into oily drops on boiling with 33% potassium hydroxide.

ε-Phthaliminohexoyl chloride was also condensed with anisole. The *phthalimino*-derivative, $C_8H_4O_2 \cdot N \cdot [CH_2]_5 \cdot CO \cdot C_7H_7O$, was obtained in leaflets, m. p. 104°, and converted into the *hydrochloride* of ε-*p-methoxy-benzoylamylamine* (ε-*anisoylamylamine*) [p-*anisyl* ε-*aminoamyl ketone*], $OMe \cdot C_6H_4 \cdot CO \cdot [CH_2]_5 \cdot NH_2,HCl$, which crystallised in thin leaflets, m. p. 166°, and formed a *platinichloride*, sparingly soluble, pale orange, hexagonal leaflets, m. p. 212°; an *aurichloride*, long, orange-yellow rhombohedra, m. p. 118°, and a *picrate*, yellow leaflets, m. p. 135°. The oily base yielded a *phenylthiocarbamide*,
$$C_{13}H_{17}O_2 \cdot NH \cdot CS \cdot NHPh,$$
small tablets, m. p. 123°, and a *benzenesulphonamide*, prisms, m. p. 142°.

The following derivatives of ε-*o*-xyloylamylamine [*o*-xylyl ε-amino-amyl ketone] were also prepared : the *phthalimino*-derivative,

$$C_8H_4O_2 \cdot N \cdot C_{14}H_{19}O,$$
in long needles, m. p. 92°; the *hydrochloride*,

$$C_6H_3Me_2 \cdot CO \cdot [CH_2]_5 \cdot NH_2,HCl,$$

long leaflets, m. p. 122°; *platinichloride*, pale orange leaflets, m. p. 214°; *aurichloride*, thin, lemon-yellow leaflets, m. p. 129°; *picrate*, jagged leaflets, m. p. 142°. The corresponding derivatives of *m*-xylyl ε-aminoamyl ketone are as follows : *phthalimino*-compound, lanceolate crystals, m. p. 71°; *hydrochloride*, hygroscopic needles, m. p. 88—90°; *platinichloride*, very slender, pale orange needles, m. p. 208°; *auri-chloride*, yellow, rectangular, thick tablets, m. p. 99°; *picrate*, small, rectangular, yellow tablets, m. p. 136°. The following derivatives of *p*-xylyl ε-aminoamyl ketone were also prepared : *phthalimide*, needles, m. p. 82°; *hydrochloride*, hexahedra, m. p. 86—87°; *platinichloride*, orange-yellow needles, m. p. 206°; *aurichloride*, thin, yellow leaflets, m. p. 125°; *picrate*, branched needles, m. p. 122°.

Derivatives of ε-3 : 4-dimethoxybenzoylamylamine [veratryl ε-amino-amyl ketone] are also described : *phthalimide*, tufted needles, m. p. 147°; *hydrochloride*, $(OMe)_2C_6H_3 \cdot CO \cdot [CH_2]_5 \cdot NH_2,HCl$, small, slender needles, m. p. 106°; *platinichloride*, orange-yellow, slender, branched needles, m. p. 205°; *aurichloride*, ochreous needles, m. p. 165°. The following derivatives of 2 : 4-dimethoxyphenyl ε-aminoamyl ketone were also prepared : *phthalimide*, long needles, m. p. 117°; *hydro-chloride*, tufted leaflets, m. p. 151—152°; *picrate*, tufted prisms, m. p. 167°; *platinichloride*, orange-yellow, flat needles, m. p. 220°; *auri-chlorides*, $C_8H_9O_2 \cdot CO \cdot [CH_2]_5 \cdot NH_2,HCl,2AuCl_3$, from an aqueous solution, yellow leaflets, m. p. 96°, or

$$C_8H_9O_2 \cdot CO \cdot [CH_2]_5 \cdot NH_2,HCl,AuCl_3,H_2O,$$
from warm 50% acetic acid, orange-yellow prisms, m. p. 96°. Finally,

the following derivatives of 2 : 5-dimethoxyphenyl ε-aminoamyl ketone are described : *phthalimide*, lanceolate crystals, m. p. 108—109°, which was largely resinified on hydrolysis ; *hydrochloride*, yellowish-green, long needles, m. p. 109° ; *picrate*, yellow rhombohedra, m. p. 151° ; the platini- and auri-chlorides are unstable.   J. C. W.

Action of Heat on Ketoximes. ARTHUR KÖTZ and O. WUNSTORF (*J. pr. Chem.*, 1913, [ii], **88**, 519—530. Compare Angeli and Alessandri, this vol., i, 983).—When heated in the absence of air, ketoximes, which do not distil or sublime without change, undergo decomposition in one of two ways : (1) into ketones, nitrogen, and ammonia: $3CR_2:N\cdot OH \longrightarrow 3COR_2 + N_2 + NH_3$; (2) into nitriles and aldehydes or alcohols :

$$OH\cdot N:CPh\cdot CH_2Ph \longrightarrow CNPh + CH_2Ph\cdot OH$$
$$OH\cdot N:CPh\cdot CHPh\cdot OH \longrightarrow CNPh + C_6H_5\cdot CHO + H_2O.$$
Acetoxime and *cyclo*hexanoneoxime distil without change under ordinary pressure ; at 210—216°, acetoxime decomposes into ammonia, methane, and a mixture of bases, not identified.

When heated in an atmosphere of carbon dioxide, benzophenone-oxime yields benzophenone, nitrogen, and ammonia. Under diminished pressure, acetophenoneoxime may be distilled unchanged, but at ordinary pressures is resolved into acetophenone and ammonia.

Deoxybenzoin decomposes explosively at 270°, yielding benzonitrile, lophine, and benzyl alcohol. At 240°, α-benzoinoxime yields lophine, benzaldehyde, and benzonitrile, whilst oximinocamphor gives rise to camphoric anhydride and αε-dimethyl-Δᵃ-heptenonitrile (Tiemann, A., 1901, i, 18).

4-Oximino-1-methyl*cyclo*hexan-3-one (Takens, *Diss.*, Göttingen, 1910), m. p. 158—159° or 171°, accordingly as it is slowly or rapidly heated, undergoes complete decomposition when heated in an atmosphere of carbon dioxide above its m. p.   F. B.

Polychromic Salts of Oximino-ketones. ISRAEL LIFSCHITZ (*Ber.*, 1913, **46**, 3233—3250).—Additional information as to the constitution of chromoisomerides is given by the study of the electrical conductivity of polychromic salt solutions. Oximinodimethyldihydro-resorcinol, $OMe_2{<}{}^{CH_2\cdot CO}_{CH_2\cdot CO}{>}C:N\cdot OH$, has been studied as a more simple oximinoketone than violuric acid which contains nitrogen in the ring. The name dimethylviolanic acid is suggested for it. In addition to red and blue, it forms deep green alkali salts indicating that neither the third CO group nor the ring nitrogen in violuric acid are the cause of polychromism. The ring structure is, however, of importance, since oximinoacetylacetone, $(CH_3\cdot CO)_2C:N\cdot OH$, only forms orange to red salts and polychromic forms of the same salt do not exist. Moreover, these coloured salts are unstable. Ring structure alone does not cause polychromism, as neither fluorenoneoxime, benzo-phenoneoxime, benziloxime, nor oximinodibenzoylmethane exhibit the phenomenon.

When the cornflower-blue plates of sodium dimethylviolanate are

dissolved in methyl alcohol, the solution, likewise cornflower-blue, changes more or less quickly to bluish-green and then to a deep green, when the crystalline green chromoisomeride may be obtained from the solution. At the intermediate stage, it is possible to prepare crystal-line, bluish-green or greenish-blue mixed salts. All these solutions contain unimolecular partly dissociated salt, as proved by ebullioscopic measurements.

The green solution is characterised by a new second absorption band in the visible part of the spectrum, and belongs to a new series of chromoisomeric oximino-salts.

The change is rapid only in dilute solutions which are sufficiently dissociated, as it is retarded by additions which check the dissociation. The conductivity of the green isomeride is 2—3% less than that of the blue form.

The two forms differ chemically, the green form being very readily decomposed. In the case of oximinoacetylacetone the cæsium salt decomposes immediately, the rubidium salt can be kept for a time, and the potassium salt is relatively stable. The rate of decomposition, like the depth of colour, increases with the atomic weight of the metal.

Conductivity measurements indicate that dimethylviolanic acid contains yellow oxime ions, and has the structure

$$CMe_2 \!\! <^{CH_2 \cdot CO}_{CH_2 \cdot CO} \!\! > C{:}N \cdot OH,$$
whereas the blue sodium salt is derived from a blue acid having a higher dissociation constant, and probably the nitrosoenol structure,

$$CMe_2 \!\! <^{CH_2 \cdot C(OH)}_{CH_2 {-}{-}CO} \!\! > C \cdot NO.$$ This result is in agreement with the optical behaviour.

The behaviour of the blue potassium salt and the red lithium salt of diphenylvioluric acid in methyl alcohol and in acetone indicates that the red lithium salt in acetone contains an internal alkali complex salt, whereas in the violet-red solution in methyl alcohol this complex has decomposed. Probably the yellowish-red and violet salts are not mixed salts, but their isomerism is not due to differences in partial valency. The copper-red magnesium dimethylviolanate forms a violet-red solution in water, and a red solution of very low conductivity in organic solvents.

The green sodium dimethylviolanate is considered to have the structure $CMe_2 \!\! <^{CH_2 {-}{-}CO}_{CH_2 \cdot C(ONa)} \!\! > C \cdot NO.$

Dimethylviolanic acid is prepared as described by Haas (T., 1906, 89, 189). The *methyl* ester forms a yellow, crystalline crust, m. p. 92°. The *magnesium* salt forms lustrous, bright copper-red platelets; the *copper* salt separates in brown platelets with a bronze lustre; the *silver* salt, $2H_2O$, forms a dark green, microcrystalline powder.

Phenylviolanic acid, $CHPh \!\! <^{CH_2 \cdot CO}_{CH_2 \cdot CO} \!\! > C{:}N \cdot OH$, is a pale yellowish-green, crystalline powder, m. p. 175°. When warmed with water a chocolate-brown, lustrous powder is obtained.

The alkali salts of oximinoacetylacetone are described.   E. F. A.

3-Methyl-1 : 2-diketohydrindene, an Analogue of Isatin.
JULIUS VON BRAUN and G. KIRSCHBAUM (*Ber.*, 1913, **46**, 3041—3050).
—*3-Methyl-*1 : 2 *diketohydrindene* is readily obtained by the action of
cold formaldehyde and hydrochloric acid on oximino-3-methyl-
hydrindone (compare Perkin, Roberts, and Robinson, T., 1912, **101**,
232). It strongly resembles isatin, having a deep reddish-yellow
colour, giving the same indophenine reaction, and dissolving in alkali
with a very intense bluish-violet
colour, which is much more stable
than the corresponding coloration
from isatin. Of the two possible
formulæ (I. and II.) for the sodium
salt, the authors are led to prefer (II),
since the great change in colour from
red to bluish-violet is better explained (especially in view of the fact that
the salts of 2-methyldiketohydrindene which must have a structure
similar to that of formula I, are red), whilst, also, the free diketone
gives no coloration with ferric chloride, and does not combine with
bromine, that is, it has no tendency towards enolisation of the usual
type. With benzoyl chloride, the sodium salt of 1 : 2-diketo-3-methyl-

hydrindene yields 1 : 2-*diketo-3-benzoyl-3-methylhydrin-
dene*, which is readily explained by 1 : 4-addition. In
this light, the authors are led to propose the annexed
formula for the bluish-violet salts of isatin prepared by
Heller (A., 1907, i, 442), and find confirmation, there-
fore, in the fact, that all derivatives of isatin, in which,
the carbonyl group adjacent to the NH group is substituted and
which themselves are red or brown, yield blue solutions with alkali,
whilst derivatives in which the β-carbonyl group is substituted yield
yellow or brown solutions with alkali.
3-*Methyl-a-hydrindone*, b. p. 118—119°/11 mm., is obtained as a pale
yellow oil which could not be caused to solidfy by the action of
aluminium chloride on a solution of β-phenylbutyryl chloride in
light petroleum. The oily *phenylhydrazone, semicarbazone*, m. p.
230—231°, *oxime*, m. p. 141·5°, *benzylidene* derivative, m. p. 88—89°,
and *salicylidene* derivative, yellow needles, m. p. 172°, were analysed.
The regulated action of amyl nitrite and hydrochloric acid on an
alcoholic solution of 3-methyl-a-hydrindone leads to the formation of
the somewhat unstable oximinomethylhydrindone,

$$C_6H_4 \left< \begin{matrix} CHMe \\ CO \end{matrix} \right> C:N\cdot OH,$$
almost colourless crystals, m. p. 130°, which readily yields a *benzoyl*
derivative, m. p. 125°. Cold concentrated hydrochloric acid and
formaldehyde convert the oximino-derivative into 1 : 2-diketo-3-methyl-
hydrindene, which is obtained as a viscous red oil which could not be
distilled without decomposition and did not solidify. It yields

a *disemicarbazone*, m. p. 267° (decomp.),
and condenses with o-phenylenediamine in
warm methyl-alcoholic solution to a
quinoxaline derivative (annexed formula),
m. p. 202°. It dissolves instantly in
aqueous alkali with the formation of an intensely bluish-violet solution, which, in comparison with the similar solutions obtained from isatin or 1 : 2-diketohydrindene, is remarkably stable ; after four hours the colour commences to disappear, whilst after five hours the solution is dirty brown. Addition of acid then precipitates an *acid* which softens at 133°, and has m. p. 143° (decomp.). This substance could not be obtained pure, but probably has the composition

$$C_6H_4 \cdot Et \cdot CO \cdot CO_2H.$$
The rupture of the ring occurs more easily after benzoylation. When benzoyl chloride is added to an alkaline solution of the ketone, the *benzoyl* derivative, $C_{17}H_{12}O_3, H_2O$, m. p. 195° (decomp.), is precipitated, and the alkaline filtrate yields on acidification benzoic acid and a *diketo-acid*, $C_{17}H_{14}O_4$, m. p. 203°, which gives a *diphenylhydrazone*, $C_{29}H_{26}O_2N_4$, m. p. 238°, reaction occurring according to the scheme :

$$C_6H_4{<}^{CMe}_{C(ONa)}{>}CO \longrightarrow C_6H_4{<}^{CMeBz}_{CO}{>}CO \longrightarrow C_6H_4{<}^{CHMeBz}_{CO \cdot CO_2H}.$$
Methylhydrindone differs remarkably from hydrindone in its behaviour towards Grignard's reagents. Whereas the latter reacts vigorously with methyl magnesium iodide, yielding 1-*hydroxy*-1-*methylhydrindene*, $C_6H_4{<}^{CH_2}_{CMe(OH)}{>}CH_2$, b. p. 118°/14 mm., D_4^{20} 1·068, which can be distilled under ordinary pressure without notable elimination of water, the tertiary alcohol primarily formed from 3-methylhydrindone by a similar process loses the elements of water almost completely at 90°, and forms 1 : 3-*dimethylindene*,

$$C_6H_4{<}^{CHMe}_{CMe}{>}CH,$$
b. p. 212—214°/ordinary pressure, 86—88°/11 mm., D_4^{20} 0·9553, n_D^{20} 1·53444, which, unlike methylindene, is practically stable to air. It forms a *picrate*, yellow needles, m. p. 94—95°.   H. W.

1 : 2-Diketo-3-methylhydrindene. A Correction. Julius von Braun (*Ber.*, 1913, **46**, 3250. Compare preceding abstract).—The author has inadvertently overlooked the fact that the views advanced by him on the constitution of salts of isatin have been previously advocated by Ruhemann, T., 1909, **95**, 984).   H. W.

Diacetyldi-imino-α-naphthol and its Transformations. IV. Oswald Miller (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1480—1488. Compare this vol., i, 877).—Neither Meerson (A., 1888, 713) nor Kehrmann (A., 1895, i, 151) succeeded in obtaining diacetyldi-imino-α-naphthol by the action of acetic anhydride and sodium acetate on di-imino-α-naphthol hydrochloride. The latter, as the author has already pointed out (A., 1911, i, 308), crystallises with $2H_2O$, which partly decomposes the diacetyl compound at the moment of its formation ; the inaccuracy of Meerson's view that acetic anhydride plays a part in this decomposition, is evident from the fact that diacetyldi-imino-α-naphthol may be crystallised from this solvent, as from any other free from hydroxyl ions, without undergoing any decomposition.

Diacetyldi-imino-α-naphthol, $C_{14}H_{12}O_3N_2$, obtained by the action of

acetic anhydride and sodium acetate on anhydrous di-imino-α-naphthol hydrochloride, forms yellow prisms, m. p. 187°, and dissolves in fuming nitric acid or acetic acid with production in almost theoretical yields of acetylamino-1 : 4-naphthaquinone. The latter (1 mol.) combines with diacetyldi-iminonaphthol (1 mol.) to give the compound, $C_{14}H_{12}O_3N_2,C_{12}H_9O_8N$, m. p. 178° (decomp.), described by Meerson (*loc. cit.*). Decomposition of diacetyldi-iminonaphthol by heating in aqueous alcoholic solution results in the formation of four parts of 2-acetylamino-1 : 4-naphthaquinone and 1 part of 4-acetylamino-1 : 2-naphthaquinone.

The action of a glacial acetic acid solution of aniline on a solution of diacetyldi-iminonaphthol in 95% alcohol yields a mixture of the ordinary dianilide with a new anilide, 2-*acetylamino*-4-*phenylimino*-1 : 4-*naphthaquinone*, $C_{18}H_{14}O_2N_2$, which crystallises in yellowish-red needles, or in red plates with marked metallic lustre, m. p. 185°; by boiling acetic acid it is decomposed quantitatively into aniline and acetylamino-1 : 4-naphthaquinone. Its *platinichloride*,

$$(C_{18}H_{14}O_2N_2,HCl)_2,PtCl_4,$$
which forms yellowish-brown plates, is accompanied by that of 2-amino-4-phenylimino-1 : 4-naphthaquinone, m. p. 121° (compare Miller and Smirnov, A., 1911, i, 121). Thus, this new anilide, like the derivatives of naphthaquinones already investigated, shows a marked tendency to react in two directions.

The above method of obtaining the new anilide leads also to the formation of three compounds of this anilide with the dianilide : (1) $2C_{18}H_{14}O_2N_2,C_{22}H_{16}ON_2$, which forms reddish-yellow plates, m. p. 170—171°; (2) $1\cdot66C_{18}H_{14}O_2N_2,C_{22}H_{16}ON_2$, which forms red plates, m. p. 147—148°; (3) red needles and plates, m. p. 160°. The melting points of these compounds rise on melting and re-solidification.

<div align="right">T. H. P.</div>

The Three Isomeric Di-α-naphthoylbenzenes. CHRISTIAN SEER and OTTO DISCHENDORFER (*Monatsh.*, 1913, **34**, 1493—1502).—The *p*- and *m*-di-α-naphthoylbenzenes have been prepared by condensing terephthalyl chloride and *iso*phthalyl chloride respectively, with naphthalene in cold carbon disulphide solution, by means of aluminium chloride. Since phthalyl chloride reacts in the unsymmetrical form, and α-naphthoyl-*o*-benzoyl chloride will not react in the cold, such a condensation could not be carried out for the ortho-isomeride. The latter was obtained, however, from α-naphthoyl-*o*-benzoic acid by Guyot and Vallette's method (A., 1911, i, 652).

The yield of crude, light brown p-*di-α-naphthoylbenzene*,

$$C_6H_4(CO\cdot C_{10}H_7)_2,$$
was very high, but the compound was obtained crystalline with great difficulty, by distilling the crude product, dissolving the oily distillate, b. p. 315—330°/11—20 mm., in boiling glacial acetic acid, and filtering from resinous matter as soon as crystals appeared. It forms, colourless, glistening leaflets, m. p. 233—234°, and gives a blood-red solution in sulphuric acid. m-*Di-α-naphthoylbenzene* was also obtained in good yield in colourless, glistening leaflets from dilute pyridine, m. p. 191°.

α-Naphthoyl-*o*-benzoic acid was reduced by zinc and 80% acetic acid,

when the *lactone* of *phenyl-α-naphthylcarbinol-o-carboxylic acid*,

$$C_{10}H_7 \cdot CH \underset{C_6H_4}{\overset{O}{<}} CO,$$
crystallised on cooling. It was purified by extraction with boiling dilute hydrochloric acid, and formed faintly yellow spikelets from alcohol, m. p. 135—136°. The lactone was treated with magnesium α-naphthyl bromide, and the white, flocculent magnesium compound was decomposed with dilute hydrochloric acid, when 2 : 5-*di-α-naphthyl*-3 : 4-*benzofuran*, $C_6H_4 \underset{C(C_{10}H_7)}{\overset{C(C_{10}H_7)}{<}} O$, was obtained in bright yellow, glistening needles, m. p. 166°, which give deep yellow solutions with brilliant green fluorescence. On oxidation with sodium dichromate and acetic acid, a quantitative yield of o-*di-α-naphthoylbenzene* was obtained. This isomeride is freely soluble, forms colourless needles, m. p. 130—131°, and condenses with hydrazine hydrate to 1 : 4-*di-α-naphthylphthalazine*, $C_6H_4 \underset{C(C_{10}H_7):N}{\overset{C(C_{10}H_7):N}{<}}$, which crystallises in rhombic plates, m. p. 176°.

Attempts to prepare condensation products by heating these isomeric diketones with aluminium chloride were without success.

J C W.

Preparation of Bromoaminoanthraquinones. BADISCHE ANILIN- & SODA FABRIK (D.R.-P. 263395, 265727. Compare this vol., i, 1071).—The preparation of 3-bromo-2-aminoanthraquinone from 1-bromo-2-aminoanthraquinone-3-sulphonic acid by elimination of the sulphonic group (with sulphuric acid) and migration of the bromine atom has been previously described; and it is now found that this reaction is a general one when a bromine atom, amino- and sulphonyl group are all present in the same benzene nucleus.

3 : 7-Dibromo-2 : 6-diaminoanthraquinone is prepared by heating sodium 1 : 5-dibromo-2 : 6-diamino-3 : 7-disulphonate with 20 parts of sulphuric acid (60° Bé.) at 180—190°; it does not react with aniline.

3 : 6-*Dibromo-2 : 7-diaminoanthraquinone* is obtained in a similar manner from 1 : 8-dibromo-2 : 7-diaminoanthraquinone-3 : 6-disulphonic acid, and does not react with aniline or p-toluidine.

4-*Bromo*-1-*aminoanthraquinone*-2-*sulphonic acid* is obtained by sulphonating, and subsequently brominating (in aqueous solution), 1-aminoanthraquinone; when it is boiled with concentrated sulphuric acid it gives rise to 2-bromo-1-aminoanthraquinone (*loc. cit.*).

The second patent states that if the heating in the reactions described previously is carried out for a few moments only in the presence of mercury (or its salts) that the sulphonic group is eliminated, but the migration of the bromine atom does not occur; thus, when sodium 1-bromo-2-aminoanthraquinone-3-sulphonate (10 parts) is heated with 100 parts of sulphuric acid (66° Bé.) and mercury sulphate (0·5 part) at 180° during three minutes, it gives rise to 1-bromo-2-aminoanthraquinone, which readily furnishes 2-*amino*-1-p-*toluidinoanthraquinone* with p-toluidine, whilst 4-bromo-1-aminoanthraquinone-2-sulphonic acid gives rise to 4-bromo-1-aminoanthraquinone.

F. M. G. M.

Bromohydroxynaphthaquinones. V. OSWALD MILLER (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1467—1479).—The author finds that the dibromide, m. p. 149·5—151·5°, described by Diehl and Merz (*Ber.*, 1881, **14**, 1912) does not exist, and establishes the identity of the bromohydroxynaphthaquinones prepared from : (1) the dibromide, m. p. 218° (compare Miller, A., 1885, 667); (2) 2-hydroxy-α-naphthaquinone (compare Diehl and Merz, A., 1878, 888); (3) α-naphthaquinoneanilide (compare Balzer, A., 1882,204), and (4) bromo-β-naphthaquinone (compare Zincke, A., 1887, 53). In the last of these methods, which is aerobic, only one-third of the oxygen absorbed reacts according to the equation $C_{10}H_{15}O_2Br + O = C_{10}H_5O_3Br$, the remaining two-thirds acting on a second molecule of the bromonaphthaquinone to form secondary products.

3-*Bromo-2-hydroxy-1 : 4-naphthaquinone*, $C_6H_4 <^{CO \cdot C(OH)}_{CO \cdot CBr}$, crystallises in monoclinic prisms or hemihedral forms, m. p. 198·5° (corr. 202°). The canary-yellow colour of the powdered compounds persists on heating to 170°, at which temperature a number of orange-yellow spots make their appearance. These spots gradually increase in magnitude as the temperature is raised, until at 190° the whole mass exhibits the orange-yellow colour, the powder becoming converted at the same time into small prisms. On cooling, these prisms become somewhat paler and undergo disintegration. The golden-yellow liquid obtained on fusion solidifies only at about 170°, but subsequently melts as before at 198·5°. The identity of the products yielded by the different methods of preparation was ascertained by investigation of (1) the solubility in 95% alcohol; (2) the potassium salt, which is anhydrous; (3) the barium salt ($+4H_2O$), and (4) the aniline salt, m. p. 166·5° (decomp.). The homogeneity of the compound was established by heating it at various temperatures for ten hours, the non-volatilised residues in all cases melting at 198·5°.

The yields of phthalic acid obtained by oxidising various naphthaquinone derivatives by means of potassium permanganate in sulphuric acid solution are: α-naphthaquinone, 95·2%; 2-hydroxy-α-naphthaquinone, 93·4%; bromohydroxynaphthaquinone from Miller's dibromide, m. p. 218°, 96·4%; bromohydroxynaphthaquinone from 2-hydroxy-α-naphthaquinone, 97·3%. These results are regarded as a confirmation of the ordinary structural formula for naphthalene.

T. H. P.

Purpurogallin. I. MAXIMILIAN NIERENSTEIN and C. W. SPIERS (*Ber.*, 1913, **46**, 3151—3157).—The authors have oxidised pyrogallol by several processes, and have shown that the purpurogallin obtained is identical in all cases. This substance has the formula $C_{11}H_8O_5$, contains four free hydroxyl groups (estimated by Zerevitinov's method, A., 1908, i, 593, in a modified apparatus) and a carbonyl group, and yields naphthalene on distillation with zinc dust. The oxidation was effected by the following means: with sodium nitrite and acetic acid (Perkin and Steven, T., 1903, **83**, 197), which is the best method, and yields 10—16% of the substance; with silver nitrate or acid permanganate (Girard, 1869); with chromic acid or *p*-benzoquinone

(Wichelhaus, A., 1872, 172, who called the compound, in the latter case, pyrogalloquinone, and obtained quinol as a by-product) ; by passing a current of air through a solution of pyrogallol and gum arabic (Struve, A., 1872, 703) ; with horse-radish peroxydase ; with potassium ferricyanide (Hooker, A., 1888, 292), and by electrolysis (Perkin and Perkin, T., 1904, **85**, 243).

Purpurogallin was obtained in deep-red needles from glacial acetic acid. It always melted at 274—275° in a sulphuric acid bath, but in a paraffin bath, or in very long capillary tubes, it sublimed without melting.

Tetra-acetylpurpurogallin was easily prepared in orange-yellow needles, m. p. 179—180° (Herzig, A., 1910, i, 677, described a colourless product). The molecular-weight determinations with certain solvents gave abnormal results, which could be explained in the case of acetic acid by partial hydrolysis to *monoacetylpurpurogallin*, which formed brownish-red needles, m. p. 169—170°; these could be separated mechanically. The tetra-acetyl derivative was completely hydrolysed by 50% acetic acid, and readily formed a *phenylhydrazone*, $C_{11}H_4O_4(COMe)_4{:}N{\cdot}NHPh$, in brick-red needles, m. p. 254—258°.

The authors are studying the formation of hydroxy-*o*-benzoquinone, which Wichelhaus, Perkin and Steven, and Perkin (T., 1913, **104**, 661) have assumed to represent an intermediate stage in the oxidation of pyrogallol.   J. C. W.

Preparation of Nitrogenous Condensation Products of the Anthraquinone Series. FARBWERKE VORM. MEISTER, LUCIUS & BRÜNING (D.R.-P. 265725).—When aminoanthraquinones are heated at 200—220° with naphthols in the presence of zinc chloride they furnish condensation products which are formed from 1 molecule of the aminoanthraquinone and 2 molecules of the naphthol, with elimination of 3 molecules of water. The following *compounds* are described : (1) from 1-aminoanthraquinone with β-naphthol, a red, crystalline powder ; (2) from 2-aminoanthraquinone with β-naphthol, a yellowish red, crystalline powder ; (3) from 1-aminoanthraquinone with α-naphthol, a dark violet powder, and (4) from 4-chloro-1-aminoanthraquinone with β-naphthol, a red, crystalline powder.   F. M. G. M.

Retene. III. Condensation of Retenequinone with Ketonic Compounds. ALFRED HEIDUSCHKA and CH. KHUDADAD (*Arch. Pharm.*, 1913, **251**, 401—437. Compare A., 1912, i, 107).—Retenequinone, which resembles benzil and phenanthraquinone in its behaviour towards organomagnesium haloids (Heiduschka and Grimm, *loc. cit.*), has been examined as to its behaviour during condensation with various types of ketones, to ascertain whether its analogy to benzil and phenanthraquinone is also evident in such reactions. In the presence of aqueous or, better, alcoholic potassium hydroxide, retenequinone (1 mol.) condenses with only 1 mol. of an aliphatic ketone, $CH_2R{\cdot}COMe$ (where R may be hydrogen and no negative group, other than the carbonyl, is present) to form, unlike benzil and phenanthraquinone, only one product. Four formulæ are possible for the substance, but the two containing $>C{:}CR{\cdot}$ are excluded because the condensation product is rapidly attacked by Baeyer's reagent, whereby the presence

of the group $>$C:CH· is indicated. The condensation product, therefore, may have the constitution : $C_{16}H_{16}<\genfrac{}{}{0pt}{}{C:CH\cdot CO\cdot CH_2R}{CO}$ or

$$C_{16}C_{16}<\genfrac{}{}{0pt}{}{C=\!=\!=CH}{C(OH)\cdot CHR}>CO\ ;$$
the first, however, is excluded because the substance, except where R is hydrogen, does not condense with benzaldehyde in alkaline solution, thereby showing that a methyl or methylene group adjacent to a carbonyl group is not present.

Anhydroacetoneretenequinone, $C_{16}H_{16}<\genfrac{}{}{0pt}{}{C=\!=\!=CH}{C(OH)\cdot CH_2}>CO$, m. p. 206·5°,

colourless needles, does not react with phenylhydrazine or with phenylcarbimide in the cold, condenses with benzaldehyde in the presence of alcoholic potassium hydroxide to form a *substance*, $C_{23}H_{24}O_2$, m. p. 203—204° (decomp.), pale yellow needles, and is reduced by zinc dust and acetic acid to a *substance*, $C_{21}H_{20}O$, m. p. 201°, colourless needles. *Methylanhydroacetoneretenequinone*,

$$C_{16}H_{16}<\genfrac{}{}{0pt}{}{C=\!=\!=CH}{C(OH)\cdot CHMe}>CO,$$
m. p. 205°, colourless needles, obtained together with a small quantity of an isomeride from methyl ethyl ketone, forms a *dibromide*, $C_{22}H_{22}O_2Br_2$, m. p. about 195° (decomp.), and is reduced to a *substance*,

probably $C_{16}H_{16}<\genfrac{}{}{0pt}{}{C-\!-CH_2}{C\cdot CHMe}>CO$, m. p. 153—155°, by zinc dust and

acetic acid, or by boiling hydriodic acid, D 1·96, and to a *substance*, $C_{22}H_{24}O$, m. p. 192—193° (decomp.), by zinc and alcoholic hydrochloric acid. Retenequinone and methyl propyl ketone yield *ethylanhydroacetoneretenequinone*, $C_{23}H_{24}O_2$, m. p. 186—187°, colourless needles. Retenequinone condenses with methyl hexyl ketone and with methyl hexenyl ketone to form corresponding *substances*, $C_{26}H_{30}O_2$, m. p. 181—182°, and $C_{26}H_{28}O_2$, m. p. 213—214°, both colourless needles, and with mesityl oxide (only in the presence of alcoholic potassium hydroxide) to form iso*propylideneanhydroacetoneretenequinone*, $C_{24}H_{24}O_2$, m. p. 219°.

Retenequinone and benzyl methyl ketone in the presence of aqueous potassium hydroxide yield two *substances*, one, probably

$$C_{16}H_{16}<\genfrac{}{}{0pt}{}{C:CPh\cdot COMe}{C:CPh\cdot COMe}'$$
m. p. 200—202° (decomp.), faintly red crystals, the other, $C_{45}H_{40}O_2$, m. p. 214—215°, deep red crystals ; the residue from the mother liquor, by boiling with glacial acetic acid, yields a *substance*, $C_{29}H_{26}O_3$, m. p. 210—212°, colourless needles, which is *phenylanhydroacetoneretenequinone acetate*, since it is also obtained by heating phenylacetoneretenequinone with glacial acetic acid. *Phenylacetoneretenequinone*,

probably $C_{16}H_{16}<\genfrac{}{}{0pt}{}{C(OH)\cdot CHPh\cdot COMe}{CO}$, m. p. 190—192° (decomp.),

yellow crystals, is obtained from retenequinone and benzyl methyl ketone in the presence of alcoholic potassium hydroxide.

Retenequinone and ethyl acetonedicarboxylate in the presence of

alcoholic potassium hydroxide condense to form a *substance*, $C_{27}H_{28}O_6$, m. p. 185—187° (decomp.), yellow needles or leaflets, which receives the constitution $C_{16}H_{16}$<$\begin{smallmatrix} C ==== C(CO_2Et) \\ | \\ C(OH)\cdot CH(CO_2Et) \end{smallmatrix}$>$CO$.

Retenequinone and ethyl benzoylacetate, by treatment with acetic anhydride and a little concentrated sulphuric acid at 45—50° yield a *substance*, $C_{40}H_{36}O_6$, m. p. 235°, faintly yellow needles, which is probably $C_{16}H_{16}$<$\begin{smallmatrix} C:CBz\cdot CO_2Et \\ | \\ C:CBz\cdot CO_2Et \end{smallmatrix}$>.   C. S.

Action of Zinc on a Mixture of Fenchone and Allyl Iodide. MICHAEL ZAJCEV (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1578—1580).—The action of zinc on a mixture of fenchone and allyl iodide in presence of ether yields *allylfenchyl*, $C_{13}H_{22}O$, b. p. 107—109°, D_0^0 0·9747, D_{20}^{20} 0·96144, D_4^{20} 0·9597, $[\alpha]_D$ +12·44°, n_D 1·49143. Attempts to prepare the corresponding *chloride*, $C_{13}H_{21}Cl$, by saturating allylfenchyl with dry hydrogen chloride in the cold, yielded an impure product, b. p. 122—124°. The investigation is being continued.   T. H. P.

Synthesis of 3-Ethylpulegol. MICHAEL ZAJCEV (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1571—1577).—The preparation of 3-methylpulegol by the action of magnesium and methyl bromide on pulegone was unsuccessfully attempted by Grignard (A., 1901, i, 679) and by Rupe and Emmerich (A., 1908, i, 556), and this compound has only recently been prepared (compare Rupe, Schobel and Abegg, A., 1912, i, 573). The corresponding ethyl compound is, however, readily obtainable.

3 - *Ethylpulegol*, $CHMe$<$\begin{smallmatrix} CH_2\cdot CEt(OH) \\ CH_2 —— CH_2 \end{smallmatrix}$>$C:CMe_2$, has b. p. 105—110°/9 mm., D_0^0 0·9379, D_{20}^{20} 0·9239, D_4^{20} 0·9223, $[\alpha]_D^{20}$ +43·22°, and exhibits normal cryoscopic behaviour in benzene. When oxidised by means of permanganate, it yields (1) the *trihydric alcohol*,

$$CHMe<\begin{smallmatrix} CH_2\cdot CEt(OH) \\ CH_2 —— CH_2 \end{smallmatrix}>C(OH)\cdot CMe_2\cdot OH,$$
which is a viscous, cinnamon-coloured liquid; (2) β-methyladipic acid; (3) formic acid, and other products.   T. H. P.

Chemistry of Caoutchouc. VII. Theory of Vulcanisation. V. DAVID SPENCE and J. YOUNG (*Kolloid. Zeitsch.*, 1913, **13**, 265—271. Compare A., 1912, i, 706).—Further experiments have shown that there is no lower limiting temperature, as previously suggested, below which vulcanisation does not take place. By extending the period of observation it has been found that vulcanisation occurs at 50°, and from experiments made at intervals of 5° between 50° and 75°, the velocity of the vulcanisation process increases on the average in the ratio of 2·84:1 for a rise of temperature of 10°. The value of the temperature-coefficient lends support to the view that the vulcanisation process is a chemical change.

From comparative experiments on the speed of the vulcanisation

...

of caoutchouc, gutta-percha, and balata at 135°, it appears that the rate of the change is practically the same in all three cases. In each case, also, the vulcanisation reaches a limit when the quantity of sulphur, non-extractable with acetone, amounts to 32%. This proportion of sulphur corresponds with the formula $(C_{10}H_{16}S_2)_n$, and it is supposed that this compound is formed from each of the three substances.

The difference between caoutchouc, gutta-percha, and balata is considered to have its origin in differences in the colloidal condition of the hydrocarbon, the close similarity in the behaviour on vulcanisation being entirely opposed to the view that the differences are chemical in nature. H. M. D.

Formation of the Anthocyan Pigments of Plants. VI. FREDERICK KEEBLE, E. FRANKLAND ARMSTRONG, and W. NEILSON JONES (*Proc. Roy. Soc.*, 1913, B, 87, 113—131. Compare A., 1912, ii, 673 ; this vol., i, 325, 803).—The pale yellow sap colour of the petals of the wallflower is a mixture of hydroxyflavone glucosides (compare A. G. Perkin, T., 1896, 1566 ; Perkin and Pilgrim, T., 1898, 267). The mixture is hydrolysed by heating with acids and more slowly by emulsin. The hydrolysed pigment if reduced and subsequently oxidised yields a red pigment. A red pigment is obtained from most flowers containing similar soluble yellow pigments, suggesting that red mutations should be of possible occurrence in such species.

Oxidation by oxydase of the hydrolysed products of glucosides in presence of amino-acids yields pigments. Arbutin, for example, yields a red pigment probably produced by the interaction of quinhydrone with ammonia. It is suggested that many of the pigments and odorous substances formed during the ripening of fruits arise as results of reactions of this type.

A competition for oxydase ensues when a mixture of phenols is treated with a plant oxydase.

Quinol monomethyl ether gives no colour reaction with oxydase, but when a little benzidine solution is added, a deep and persistent carmine colour is obtained. The benzidine acts catalytically, playing the part of an organic peroxide, and bringing about the oxidation of a substance which resists the action of oxydase and hydrogen peroxide. It is suggested that the higher members of a flower colour series owe their origin to the presence of specific substances which, acting as receivers of oxygen, reduce the pigments characteristic of the lower members of the colour series, accept oxygen therefrom, and become oxidised to pigments of specific colour. E. F. A.

Anthocyanins. I. Pigment of Cornflowers. RICHARD WILLSTÄTTER and ARTHUR E. EVEREST (*Annalen*, 1913, 401, 189—232).—Since Morot in 1849, and Frémy and Cloëz in 1854, isolated in an impure state the blue pigment of the cornflower, very little work has been recorded, probably on account of the instability of the anthocyanin. An important observation by Molisch (*Bot. Zeit.*, 1905, 63, 145), that in the flowers and red leaves of many plants the anthocyanin occurs, not merely in solution in the cell juice, but also in the crystal-

line or amorphous state, revived interest in the subject, and observations, many of which are erroneous, have been recorded by Grafe, by Glan, by Griffiths (A., 1904, i, 179), and by Combes (A., 1911, ii, 1125).

Anthocyanins are the blue, violet, and red pigments which are extracted from flowers, fruits, and many leaves by water or aqueous alcohol, and are insoluble in ether; they are roughly classified by their colour reactions in acid and in alkaline solution and with lead acetate. For the sake of completeness, it may be recalled that red and blue flowers also contain yellow pigments, anthoxanthins, which are soluble in water or dilute alcohol, and are quite different from the chemically indifferent carotins. The blue pigment of the cornflower is unstable and very difficult to isolate, and has not yet been obtained crystalline. The various shades of colour in different parts of the flower are due to various derivatives of one substance. Thus the blue pigment is the potassium salt of an acid (cyanin), the violet pigment is the free acid, and the red pigments are oxonium salts of cyanin and plant-acids. In addition, a colourless substance can be isolated from the flowers, which is an isomeride of cyanin and is acid and forms colourless alkali salts.

All anthocyanins are present in flowers as glucosides and not, as previously stated by Grafe, partly in combination with dextrose and partly not. They all exhibit a characteristic reaction, the anthocyanidin reaction; an anthocyanin dissolved in N- or $2N$-sulphuric acid is quite unaffected by shaking with amyl alcohol, but after hydrolysis on the water-bath, the coloured fission product (anthocyanidin) is quantitatively extracted by the alcohol, forming a reddish-violet solution, which is changed to bluish-violet by washing, or more rapidly by sodium acetate. (In this connexion, Erdmann's test for new, or comparatively new, red wine is discussed.)

In order to isolate the colouring matter, dried cornflower meal, mixed with six parts of sand to facilitate filtration, is rapidly extracted with water or 20% alcohol, preferably in the presence of sodium nitrate or chloride to retard the change of the anthocyanin to the colourless modification. The deep blue solution is treated with alcohol and the potassium cyanin, after repeated fractional precipitation with water and alcohol, is obtained mixed with at least twice the weight of carbohydrates, albumins, and pentosans. In its further purification, the blue pigment is treated with alcohol and hydrochloric acid, whereby the pentosans (one of which is probably xylan) are precipitated, and the pigment is converted in *cyanin chloride*, $C_{28}H_{33}O_{17}Cl,3H_2O$, m. p. 203—204° (corr.) (anhydrous), dark blue, rhombic leaflets with golden reflex. The chloride is extremely hygroscopic, and forms stable red solutions in acids; its aqueous solution rapidly becomes colourless, but recovers its red colour by the addition of an acid. A solution of the chloride becomes violet in the presence of calcium carbonate, and changes from red through violet to cornflower blue by treatment with sodium carbonate.

By hydrolysis with boiling 20% hydrochloric acid for three to three and a half-minutes, cyanin chloride yields dextrose (2 mols.) and *cyanidin chloride*, $C_{16}H_{13}O_7Cl$, long, brownish-red, metallic needles,

which decomposes by slow heating, but has m. p. 220° (decomp.) when placed directly in a bath at this temperature. Like cyanin chloride, cyanidin chloride is converted by aqueous sodium carbonate, firstly, into a violet solution of the acid, cyanidin, and then into a blue solution of sodium cyanidin. Moreover, cyanidin chloride in dilute alcohol at 85° is slowly converted into an *isomeride*, colourless crystals, which is reconverted into red cyanidin salts by boiling dilute mineral acids; by prolonged keeping of its aqueous alcoholic or ethereal solution, the colourless isomeride changes to another *substance*, colourless needles, from which the red cyanidin salts cannot be regenerated.

Little can be stated at present with regard to the constitutions of cyanin and cyanidin. The fact, that the two substances form very stable salts with hydrochloric acid, indicates that cyanin and cyanidin are related to benzopyronium (Decker and Fellenberg, A., 1909, i, 116) rather than to the flavones. C. S.

Hydrogenation of a Secondary Alcohol derived from Furfuraldehyde in the Presence of Nickel. ROGER DOURIS (*Compt. rend.*, 1913, **157**, 722—724).—During the catalytic hydrogenation of certain secondary α-ethylenic alcohols, dehydration occurs, followed by hydrogenation of the ethylenic hydrocarbon produced. The author is extending this study to heterocyclic alcohols derived from furfuraldehyde. Furfuraldehyde itself gives α-methylfuran, α-methyltetrahydrofuran, methyl propyl ketone, and pentan-β-ol (compare Padoa and Ponti, A., 1907, i, 146). Furylethylcarbinol on hydrogenation in the presence of reduced nickel at 175° yields propyltetrahydrofuran, dipropyl ketone, *ethyltetrahydrofurylcarbinol*, $C_4H_7O\cdot CHEt\cdot OH$, a colourless, syrupy liquid, b. p. 87—90°/15 mm., D_4^0 1·0051, D_4^{20} 0·9869, and a small quantity of a liquid, b. p. 110—120°/15 mm., which contains a glycol.

Whilst furylethylcarbinol, unlike its propyl and *iso*amyl homologues, will not yield an acetic ester, yet its tetrahydro-derivative readily yields an *ester*, a colourless liquid, b. p. 90—91°/12 mm., D_4^0 1·0334, D_4^{16} 1·0149. W. G.

Action of Fermenting Yeast on Furfuraldehyde. Formation of Furyltrimethylene Glycol. II. CARL J. LINTNER and H. J. VON LIEBIG (*Zeitsch. physiol. Chem.*, 1913, **88**, 109—121. Compare A., 1911, ii, 816).—Furfuraldehyde in presence of yeast which is actively fermenting sucrose is converted into *furyltrimethylene glycol* [$\alpha\gamma$-dihydroxy-α-furylpropane], $C_4H_3O\cdot CH(OH)\cdot CH_2\cdot CH_2\cdot OH$. This crystallises in very tiny needles, m. p. 50·5°, $[\alpha]_D$ – 10·5°; with concentrated sulphuric acid it gives a gentian-blue coloration.

The *diacetate* forms a pale yellow oil with an aromatic odour, b. p. 246—248°/720 mm.; the *dibenzoyl* derivative is likewise a pale yellow oil. Both compounds have a normal molecular weight and give a blue coloration with sulphuric acid.

The *di-p-nitrobenzoate* forms an almost colourless, crystalline powder, m. p. 150—151°. The *diphenylurethane*, which is a colourless, light powder, has m. p. 195°.

It is assumed that the acetaldehyde formed as the first product of the fermentation of dextrose undergoes an aldol condensation with furfuraldehyde and that this aldol is immediately reduced to the glycol by the yeast.   E. F. A.

Thioflavones [2-Phenyl-1 : 4-benzothiopyrones]. SIEGFRIED RUHEMANN (*Ber.*, 1913, 46, 3384—3395).—The sodium salts of the thiophenols, like the ordinary phenols (this vol., i, 891), can undergo condensation with ethyl phenylpropiolate with formation of the ethyl esters of the corresponding β-arylthiolcinnamic acids. The free acids on heating lose carbon dioxide with formation of arylthiolstyrenes, and by successive treatment with phosphorus pentachloride and aluminium chloride they are almost quantitatively converted into thioflavones (2-phenyl-1 : 4-benzothiopyrones). The last-named substances are more resistant than the flavones towards alkali, but by prolonged boiling with concentrated potassium hydroxide solution two concurrent decompositions are effected, one yielding (with thioflavone itself) benzoic acid and o-thiolacetophenone, and the other acetophenone and o-thiolbenzoic acid.

The corresponding 1 : 4-benzothiopyrone, $C_6H_4{<}^{CO \cdot CH}_{S-CH}$, could not be produced in a similar manner on account of the impossibility of hydrolysing ethyl phenylthiofumarate (obtainable from the sodium compound of the thiophenol and ethyl chlorofumarate) without complete decomposition.

Ethyl β-o-tolylthiolcinnamate, $C_6H_4Me \cdot S \cdot CPh{:}CH \cdot CO_2Et$, a viscous, yellow oil, b. p. 230°/12 mm., which slowly crystallises, is obtainable by the gradual addition of ethyl phenylpropiolate to a hot solution of sodium in excess of o-tolyl mercaptan diluted with toluene ; *β-o-tolylthiolcinnamic acid*, produced by hydrolysis with alcoholic potassium hydroxide, forms colourless needles, m. p. 160—161° (decomp.), and on heating passes into o-*tolylthiolstyrene*, $C_6H_4Me \cdot S \cdot CPh{:}CH_2$, a yellow oil, b. p. 183—184°/12 mm., with loss of carbon dioxide. When powdered aluminium chloride is gradually introduced into a mixture of phosphorus pentachloride and β-o-tolylthiolcinnamic acid in benzene, intramolecular condensation to 2-*phenyl-8-methyl-1* : 4-*benzothiopyrone* (8-*methylthioflavone*), $C_6H_3Me{<}^{CO \cdot CH}_{S-CPh}$, pale yellow needles, m. p. 124—125°, is effected.

p-Tolyl mercaptan, obtained by reduction of *p*-toluenesulphonyl chloride, condenses in a similar manner to the ortho-isomeride, with ethyl phenylpropiolate, producing the *ethyl* ester, yellowish prisms, m. p. 77—78°, b. p. 240—242°/12 mm., of β-*p*-tolylthiolcinnamic acid, colourless needles, m. p. 167° (decomp.). By successive treatment with phosphorus pentachloride and aluminium chloride the acid is converted into 2-*phenyl-6-methyl-1* : 4-*benzothiopyrone* (6-*methylthioflavone*), colourless needles, m. p. 153—154°.

Thiol-*p*-xylene, b. p. 211—212°, obtained from the corresponding sulphinic acid, which was prepared by the diazo-reaction, condensed with ethyl phenylpropiolate, giving the viscous, yellow *ethyl* ester,

b. p. 242°/12 mm., of *β-p-xylylthiolcinnamic acid*, colourless prisms, m. p. 186—187° (decomp.). Treatment with phosphoric and aluminium chlorides converts this into 2-*phenyl*-5 : 8-*dimethyl*-1 : 4-*benzothiopyrone* (5 : 8-*dimethylthioflavone*), $C_6H_2Me_2 \begin{subarray}{l} \text{CO·CH} \\ \diagdown\text{S——CPh} \end{subarray}$, colourless needles, m. p. 133—134°.

Thiol-*m*-xylene, b. p. 212—214°, in a similar manner, condenses with ethyl phenylpropiolate, giving the *ethyl* ester, yellow prisms, m. p. 91—92°, b. p. 242—244°/12 mm., of *β-m-xylylthiolcinnamic acid*, yellow prisms, m. p. 184° (decomp.). This acid, when heated, loses carbon dioxide with formation of 3 : 4-*dimethylphenylthiolstyrene*, a yellow oil, b. p. 197—198°/14 mm., and under the usual treatment with phosphoric and aluminium chlorides gives rise to 2-*phenyl*-6 : 8-*dimethyl*-1 : 4-*benzothiopyrone* (6 : 8-*dimethylthioflavone*), yellow needles, m. p. 152—153°.

o-Anisyl mercaptan, in the form of its sodium compound, reacts with ethyl phenylpropiolate in the general manner, giving the *ethyl* ester, colourless needles, m. p. 67—68°, b. p. 246—248°/12 mm., of *β-o-anisylthiolcinnamic acid*, colourless needles, m. p. 148° (decomp.). The acid is readily converted into 8-*methoxy*-2-*phenyl*-1 : 4-*benzothiopyrone* (8-*methoxythioflavone*), $OMe·C_6H_3 \begin{subarray}{l} \text{CO·CH} \\ \diagdown\text{S——CPh} \end{subarray}$, colourless needles, m. p. 129—130°. This compound, like the oxygen analogue (*loc. cit.*), can be demethylated by hydriodic acid, producing 8-*hydroxy*-2-*phenyl*-1 : 4-*benzothiopyrone*, yellow prisms, m. p. 292° (decomp.).

The sodium compound of *p*-anisylmercaptan with ethyl phenylpropiolate produces the *ethyl* ester, b. p. 255—256°/14 mm., of *β-p-anisylthiolcinnamic acid*, colourless prisms, m. p. 217—218° (decomp.). This was transformed in the usual manner into 6-*methoxy*-2-*phenyl*-1 : 4-*benzothiopyrone* (6-*methoxythioflavone*), colourless needles, m. p. 155—156°.

The behaviour of the benzothiopyrone compounds with alkali, towards which they are very stable, was especially investigated with 2-phenyl-1 : 4-benzothiopyrone (that is, thioflavone itself). It is completely changed by boiling with concentrated alcoholic sodium hydroxide for five to six hours; acetophenone, *o*-thiolacetophenone, as an oil oxidisable to dithiodiacetophenone $(C_6H_4Ac)_2S_2$, needles, m. p. 167—168° (compare Farbwerke Meister, Lucius, & Brüning, A., 1908, i, 987), benzoic acid, *o*-thiolbenzoic acid, and dithiodisalicylic acid could be recognised among the reaction products. D. F. T.

Aconitine Alkaloids. Pyraconitine. HEINRICH SCHULZE and A. LIEBNER (*Arch. Pharm.*, 1913, **251**, 453—467. Compare Schulze and Bierling, this vol., i, 287).—Pyraconitine, $C_{32}H_{43(or 41)}O_9N$ (Dunstan and Carr give $C_{31}H_{41}O_{10}N$; T., 1894, **65**, 176), prepared by heating aconitine at 192°, has m. p. 171°, $[\alpha]_D^{20}$ − 112·2°, in 95% alcohol ($c = 8·6918$), and crystallises from ether in colourless needles containing $1\frac{1}{2}Et_2O$, and from alcohol in crystals containing $2\frac{1}{2}EtOH$. Dunstan and Read's pyrojapaconitin (T., 1900, **77**, 60), obtained by heating japaconitine at 192°, is identical with pyraconitine. The following

salts, prepared in all cases from both pyraconitine and "pyrojap-aconitine," are described : hydrochloride, m. p. 167° (decomp.); auri-chloride, m. p. 157—158° (decomp.) ; hydrobromide, m. p. 240—242° (decomp.) (hydrated) or 243—244° (decomp.)(anhydrous), $[a]_D^{20} - 105\cdot87°$ in water ($c = 4\cdot5339$); hydriodide, m. p. 157—158° (decomp.) (hydrated), and perchlorate, m. p. about 190°. The preceding constants differ from those recorded by Dunstan and Carr (*loc. cit.*).   C. S.

*iso*apoCaffeine. HEINRICH BILTZ [with PAUL KREBS and KARL STRUFE] (*Ber.*, 1913, **46**, 3407—3410).—The substance *iso*apocaffeine, which is obtained together with *apo*caffeine in the oxidation of caffeine and 1 : 3 : 7-trimethyluric acid (Biltz and Krebs, A., 1910, i, 523), is 3 : 7-dimethylcaffolide ; this has been demonstrated by a course of degradation detailed in this paper. The formation of *iso*apocaffeine from caffeine or trimethyluric acid must evidently be a fairly complex process which is partly synthetic ; it is suggested that in addition to the direct oxidation to *apo*caffeine, some dimethylalloxan and methyl-carbamide are produced, the latter substances then condensing to *iso*apocaffeine and *apo*caffeine. In support of this view it is mentioned that only when the oxidation is so moderated as to proceed slowly is any *iso*apocaffeine formed.

When an aqueous solution of *iso*apocaffeine is evaporated to a syrup, isocaffuric acid, $\begin{smallmatrix} NMe\cdot CO \\ CO-NH \end{smallmatrix} >C(OH)\cdot CO\cdot NHMe$, is obtained, which gradually crystallises in prisms, m. p. 191° (decomp.).

When heated on a water-bath with hydriodic acid (D 1·96), *iso*apo-caffeine undergoes reduction to 3-*methylhydantoin-5-carboxymethyl-amide*, $\begin{smallmatrix} NMe\cdot CO \\ CO-NH \end{smallmatrix} >CH\cdot CO\cdot NHMe$, prisms, m. p. 240°. This substance is hydrolysed by barium hydroxide solution with formation of methyl-amine and 3-*methylhydantoin-5-carboxylic acid*, $\begin{smallmatrix} NMe\cdot CO \\ CO-NH \end{smallmatrix} >CH\cdot CO_2H$, tablets, m. p. 130° (decomp.); the latter, on gradually heating to 190°, eliminates carbon dioxide with production of 3-methylhydantoin, $\begin{smallmatrix} NMe\cdot CO \\ CO \end{smallmatrix} >CH_2$.

*iso*apoCaffeine consequently has the structure $\begin{smallmatrix} NMe\cdot CO \\ CO-NH \end{smallmatrix} >C< \begin{smallmatrix} O-CO \\ CO\cdot NMe \end{smallmatrix}$.
    D. F. T.

Some New Salts of Quinine, Euquinine, Aristoquinine, Saloquinine, and Quinaphenine. DECIO ANGELONI (*Boll. chim. farm.*, 1913, **52**, 675—685).—A basic *salicylate* of *quinaphenine*, $C_{20}H_{23}O_2N_2\cdot CO\cdot NH\cdot C_6H_4\cdot OEt,OH\cdot C_6H_4\cdot CO_2H$, has m. p. 125—126°, and is obtained by adding an ethereal solution of the acid to an ethereal solution of an equimolecular quantity of the base. When 2 mols. of acid are taken and the base is poured into the acid, a *salt*, m. p. 112°, is obtained, which is, however, a mixture of the normal and basic salts.

When an ethereal solution of euquinine (1 mol.) is added to an ethereal solution of novaspirin ($\frac{1}{2}$ mol.), the normal *salt*, m. p. 95°, is obtained. By working in alcoholic solution, the basic *salt* may be prepared; it has m. p. 178°.

· Novaspirin and aristoquinine yield the normal *salt*, m. p. 89—90°, in which the aristoquinine behaves as a tetracidic base. Novaspirin and saloquinine in ethereal solution yield the normal *salt*, m. p. 116°. Novaspirin and quinaphenine also yield the normal *salt*, m. p. 118—120°.

Diaspirin and quinine in ethereal solution yield the basic *salt*, which crystallises in needles, m. p. 125°. By taking an excess of acid, the normal *salt* may also be prepared. Diaspirin and quinaphenine in ethereal solution yield the normal *salt*, m. p. 116°.

Diplosal and quinine in ethereal solution yield the basic *salt*, m. p. 105°, which crystallises in needles. Diplosal and quinaphenine in ethereal solution also form the basic *salt*, m. p. 86°.

The compositions of the salts obtained were established by nitrogen estimations. Information is also given as to the solubilities of the bases and acids employed in ether. R. V. S.

The Apparent Colloidal Character and the Molecular Weight of Colchicine. SIMON ZEISEL and K. VON STOCKERT (*Monatsh.*, 1913, 34, 1327—1338).—In aqueous solution, colchicine has many of the physical and physiological properties of a colloid. Diffusion experiments with a 20% solution show, however, that it is a crystalloid. The amyloid of the diffusion thimble has a great adsorptive power for the alkaloid, and until this is satisfied, the diffusion does not reach a normal value. Cryoscopic and ebullioscopic determinations of the molecular weight of colchicine, colchiceine, and trimethylcolchicinic acid in various solvents have also been made. In acetic acid or boiling ethylene dibromide, the results for colchicine agreed with the formula $C_{22}H_{25}O_6N$. In cold ethylene dibromide and especially in water, which is most unusual, bi- or even ter-molecular values were obtained. Colchiceine gave high values in freezing ethylene dibromide, and trimethylcolchicinic acid in boiling acetic acid.

J. C. W.

Bromine Derivatives of Colchicine. SIMON ZEISEL and K. VON STOCKERT (*Monatsh.*, 1913, 34, 1339—1347).—When an excess of hydrobromic acid is added to a dilute solution of colchicine, sulphur-yellow *dibromocolchicine*, $C_{22}H_{23}O_6NBr_2$, is precipitated, m. p. 146—150° (open tube), 125° (sealed capillary). One molecular proportion of the acid precipitates the *monobromide*, which crystallises in various forms from methyl alcohol, but with constant properties,

$$C_{22}H_{24}O_6NBr,MeOH,$$
m. p. 151·5° (corr., open tube), 133—135° (sealed tube). It is somewhat soluble in water, and the addition of excess of hydrobromic acid to the aqueous mother liquors causes the precipitation of the above dibromide. In methyl alcohol solution, colchicine gives with excess of bromine in the cold, a *tribromide*, $C_{18}H_{10}(OMe)_4O_2NBr_3$, m. p. 131° (open), 118—122° (sealed). The behaviour of these derivatives

towards alkali hydroxides, in open vessels or in sealed tubes, shows that two bromine atoms are firmly combined, whilst the third is fairly labile. *Tribromocolchiceine*, $C_{21}H_{20}O_6NBr_3,H_2O$, and *tribromotrimethyl-colchicinic acid*, $C_{19}H_{18}O_5NBr_3$, were also prepared.   J. C. W.

Synthesis of Hygrine. I. KURT HESS (*Ber.*, 1913, 46, 3113—3125).—Hygrine should have either the constitution I or II.

(I) $CH_2 <^{CH_2 \cdot NMe \cdot}_{CH_2 \cdot CH \cdot COEt}$ (II) $CH_2 <^{CH_2 \cdot NMe}_{CH_2 \cdot CH \cdot CH_2 \cdot COMe}$
Willstätter (A., 1900, i, 405) suggested that the second formula was probable, assuming, therefore, that hygrine and tropinone are somewhat similarly constituted, but the fact that the oxidation product, hygric acid (Liebermann and Cybulski, A., 1895, i, 310 ; Willstätter, *loc. cit.*, and A., 1903, i, 362), is not an acetic acid derivative akin to tropic acid supports formula I. The author has attempted to synthesise the above isomerides, and has so far succeeded in preparing the corresponding hydroxy-compounds :

(III) $CH_2 <^{CH_2 \cdot NMe}_{CH_2 \cdot CH \cdot CHEt \cdot OH}$ (IV) $CH_2 <^{CH_2 \cdot NMe}_{CH_2 \cdot CH \cdot CH_2 \cdot CHMe \cdot OH}$
The former compound was obtained by treating magnesium pyrryl bromide with propionyl chloride, reducing the 2-propionylpyrrole so obtained by sodium and alcohol, and methylating the product. The other compound was prepared by the addition of propylene oxide to magnesium pyrryl bromide, reduction of the *iso*propyl alcohol derivative by means of hydrogen in presence of spongy platinum, and methylation of the pyrrolidyl-2-*iso*propyl alcohol.

α-2-Pyrrylpropan-β-ol, $C_4H_4N \cdot CH_2 \cdot CHMe \cdot OH$, is a colourless, odourless, viscous oil, b. p. 94—96°/0·25 mm., which changes into a thick, red syrup in the air, and is soluble in water. No picrate nor oxidation product could be isolated, but it yielded 2-propylpyrrole (Dennstedt and Zimmermann, A., 1893, i, 226) on reduction with red phosphorus and hydriodic acid. It was accompanied by an isomeride, probably, $CH <^{CH \cdot NH}_{CH:C \cdot CHMe \cdot CH_2 \cdot OH}$, which had b. p. 99—107°/ 0·25 mm.

For the methylation, it was found necessary to prepare the potassium compound and then to add methyl iodide. *α-1-Methyl-pyrrylpropan-β-ol*, $C_8H_{13}ON$, is a pleasant smelling oil, b. p. 116—117°/18 mm. The reduction of pyrrylpropan-β-ol with hydrogen in presence of platinum was successful when the necessity of excluding all traces of oxygen was realised. For this purpose an apparatus is described which consists essentially of a cylinder and bulb connected by a tap, the cylinder being also fitted with an inlet tube and a ground-on cap. The suspension of platinum in glacial acetic acid was saturated with hydrogen in the bulb, the solution of the alcohol was then washed with hydrogen in the cylinder, and finally the two liquids were shaken together under a slightly increased pressure. The platinum was not added all at once, but fresh portions were occasionally saturated with hydrogen in the cylinder and then allowed to flow into the bulb. The process required a few days. In

this way the formation of pyrrole dyes by catalytic oxidation was entirely prevented, and only a small quantity of platinum was required. A quantitative reduction of pyrrole itself, without the occurrence of a coloured solution, was also effected (compare Willstätter and Hatt, A., 1912, i, 545). *α-2-Pyrrolidylpropan-β-ol*, $C_4H_8N \cdot CH_2 \cdot CHMe \cdot OH$, is a viscous oil, b. p.115—120°/15 mm.,with the usual properties of a base and an unsaturated compound. On methylation with methyl iodide and potassium hydroxide, a moderate yield of *α-1-methylpyrrolidylpropan-β-ol* (IV) was obtained as an oil, b. p. 98—103°/16 mm.

2-Pyrrylpropane-βγ-diol (future communication) was also reduced as above, yielding *α-2-pyrrolidylpropane-βγ-diol*

$$C_4H_8N \cdot CH_2 \cdot CH(OH) \cdot CH_2 \cdot OH,$$
b. p. 145—150°/18 mm., which formed a very hygroscopic potassium salt.

The reduction of the isomeric alcohols was first studied in the case of 2-acetylpyrrole. Sodium was added to the boiling alcoholic solution of the substance and *α-2-pyrrolidylethan-α-ol (pyrrolidyl-2-methylcarbinol)*, $C_4H_8N \cdot CHMe \cdot OH$, was extracted from the product as a colourless oil, b. p. 187—192°/759 mm. It smells like acetamide and absorbs moisture and carbon dioxide with avidity. *α-2-Pyrrolidylpropan-α-ol (pyrrolidyl-2-ethylcarbinol)*, $C_4H_8N \cdot CHEt \cdot OH$, was prepared in this way from 2-propionylpyrrole. It is a well-defined, crystalline base, m. p. 50°, b. p. 95—98°/17 mm., 195—200°/756 mm., with a narcotic odour, is hygroscopic, and gives the Liebermann reaction. *α-1-Methylpyrrolidylpropan-α-ol (1-methylpyrrolidyl-2-ethylcarbinol)* (III.) is also a very hygroscopic base, m. p. 45°, b. p. 92—95°/17 mm., 190—195°/757 mm. J. C. W.

Origin of the Cyclic Bases of Coal-tar. LOUIS C. MAILLARD (*Compt. rend.*, 1913, **157**, 850—852).—The humic substances obtained by the condensation of sugars with different amino-acids (compare A., 1912, i, 169) readily yield cyclic bases when heated. The author applies this to the formation of coal from the constituents of cellulose and proteins and to its distillation, yielding coal-tar containing pyridine and other cyclic bases. W. G.

Allylpyrroles. KURT HESS (*Ber.*, 1913, **46**, 3125—3129).—When magnesium pyrryl bromide is treated with allyl bromide, a mixture of approximately equal quantities of 2-allyl- and 2 : 5-diallyl-pyrroles is obtained. The formation of the latter compound is explained by assuming that some magnesium pyrryl bromide reacts with 2-allyl-pyrrole, forming pyrrole and 5-magnesium-2-allylpyrryl bromide, which then unites with more allyl bromide. This view is supported by the fact that carbon dioxide converts the reaction product of 2-allylpyrrole and magnesium pyrryl bromide into 2-allylpyrryl-5-carboxylic acid, acid, from which it follows that allylpyrrole is more acidic than pyrrole.

The reaction between allyl bromide and magnesium pyrryl bromide

was vigorous but was not moderated by cooling. After steam distillation and extraction with ether, 2-*allylpyrrole*,

$$CH<_{CH:C\cdot CH_2\cdot CH:CH_2}^{CH\cdot NH},$$
was obtained as a colourless, mobile liquid, b. p. 82—83°/24 mm., D_4^{24} 0·9376. It has an unpleasant odour, rapidly becomes yellow in the air, finally forming a red, amorphous mass, and is extremely sensitive towards reagents. 2 : 5-Diallylpyrrole, $C_4H_8N(CH_2\cdot CH:CH_2)_2$, is a similar liquid, b. p. 110—115°/17 mm., D_4^{24} 0·9321. The addition of allylpyrrole to magnesium pyrryl bromide caused a change in colour from grey to dark green. After treatment with dry carbon dioxide,

2-*allylpyrrylcarboxylic acid*, $CH<_{CH==C\cdot CH_2\cdot CH:CH_2}^{C(CO_2H)\cdot NH}$, was obtained in indefinite crystals, m. p. 117—118°. It is unstable, and partly decomposes into violet-pink dyes even when boiled with light petroleum.   J. C. W.

Equilibrium in the System Cobalt Chloride and Pyridine. J. NEWTON PEARCE and T. E. MOORE (*Amer. Chem. J.*, 1913, **50**, 218—231).—In order to investigate the formation of compounds of cobalt chloride with pyridine of crystallisation, a study has been made of this system by the solubility method at temperatures between −50·3° and 100°. The results show the existence of three distinct crystalline compounds, $CoCl_2,2C_5H_5N$; $CoCl_2,4C_5H_5N$, and $CoCl_2,6C_5H_5N$. The first two of these have been isolated previously by Reitzenstein (A., 1895, i, 121). The compound $CoCl_2,2C_5H_5N$ has m. p. 195—200°, but the m. p.'s of the other two compounds cannot be ascertained, as they rapidly lose pyridine when heated under the ordinary pressure.

The compound $CoCl_2,6C_5H_5N$ exists as the solid phase between −50·3° and 15°, $CoCl_2,4C_5H_5N$ between 15° and 70°, $CoCl_2,2C_5H_5N$ between 70° and 90°, whilst between 90° and the b. p. of the saturated solution $CoCl_2$ is the stable, solid phase.

The usual methods of estimating cobalt are not satisfactory in presence of pyridine, and the following method was therefore devised. The weighed sample of solution was heated at 120° until all the pyridine had been removed. It was then dissolved in 50% alcohol, and an excess of oxalic acid was added to the solution. The precipitated cobalt oxalate was washed with 50% alcohol, dried at 100°, and dissolved in sulphuric acid (1 : 3). The solution was diluted to 300 c.c., heated nearly to boiling, and titrated with potassium permanganate. This method was found to be very accurate.   E. G.

Cyclic Imines. VIII. Ring Opening in Substituted Indoles and Quinolines. JULIUS VON BRAUN, ALFRED GRABOWSKI, and MARGARETE RAWICZ (*Ber.*, 1913, **46**, 3169—3182).—A number of cyclic imines (substituted quinoline and indole derivatives) have been converted into compounds of the phenylpropane series primarily to determine with what yield the chlorinated amides could be obtained on treating the *N*-benzoyl compounds of the imines with phosphorus pentachloride, and to study the hydrolysis of these amides to the

chlorinated bases. It appears that the substituted anilides are formed even more readily than the unsubstituted compounds previously described, and they are readily purified from unchanged imine. They are hydrolysed with difficulty as the temperatures necessary to ensure hydrolysis and at which decomposition begins lie very near together.

6-*Chlorotetrahydroquinoline*, $C_6H_8Cl\begin{smallmatrix}CH_2 \cdot CH_2\\NH-CH_2\end{smallmatrix}$, obtained by reduction of 6-chloroquinoline and isolated by means of the benzoyl compound, has b. p. 160°/11 mm., m. p. 43°. The *hydrochloride* crystallises in lustrous needles, m. p. 190°; the *platinichloride* is yellow, m. p. 185°. The *benzoyl* derivative has m. p. 84°. The *picrate*, m. p. 151°, and the *nitroso*-compound, m. p. 65°, are also described.

On heating the benzoyl derivative with phosphorus pentachloride at 140°, *benzo*-p-γ-*dichloro*-o-*propylanilide*,

$$CH_2Cl \cdot CH_2 \cdot CH_2 \cdot C_6H_3Cl \cdot NH \cdot COPh,$$
is obtained in a mass of snow-white crystals, m. p. 108°. On prolonged heating with concentrated hydrochloric acid at 125°, p-γ-*dichloro*-o-*propylaniline hydrochloride* is obtained, m. p. 170°. The free base, $C_3H_6Cl \cdot C_6H_3Cl \cdot NH_2$, is a slightly coloured, almost odourless oil. The yellow *platinichloride*, has m. p. 181—182°, and the *picrate* has m. p. 143°.

On diazotisation and treatment with cuprous chloride, 2 : 5-γ-*trichloropropylbenzene*, $C_6H_3Cl_2 \cdot C_3H_6Cl$, is obtained as a colourless oil of agreeable odour, b. p. 152°/16 mm.

7-*Nitrotetrahydroquinoline*, $NO_2 \cdot C_6H_3\begin{smallmatrix}CH_2 \cdot CH\\NH \cdot CH_2\end{smallmatrix}$, prepared by nitrating tetrahydroquinoline in concentrated sulphuric acid, forms a yellowish-red, crystalline mass, m. p. 90°. The *hydrochloride* separates in colourless needles, m. p. 203°; the colourless *benzoyl* derivative has m. p. 141°, whereas the *nitroso*-compound has m. p. 118—120°.

On opening the ring with phosphorus pentachloride, *benzo*-γ-*chloro*-5-*nitro*-2-*propylanilide*, $C_3H_6Cl \cdot C_6H_3(NO_2) \cdot NHBz$, is obtained in well formed, colourless needles, which are converted on hydrolysis at 120° into γ-*chloro*-5-*nitro*-2-*propylaniline*, a red compound, m. p. 76°. The *hydrochloride* has m. p. 217°, the *platinichloride* forming a yellow, crystalline precipitate.

Heating with dimethylamine converts the benzonitroanilide into *benzo*-γ-*dimethylamino*-5-*nitro*-2-*propylanilide*,

$$NMe_2 \cdot C_3H_6 \cdot C_6H_3(NO_2) \cdot NHBz,$$
crystallising in well formed, colourless needles, m. p. 157°. The *hydrochloride* and *picrate* are oily.

γ-*Dimethylamino*-5-*nitro*-2-*propylaniline*, obtained on hydrolysis, separates in yellow crystals, m. p. 65—66°. The *dihydrochloride* has m. p. 191°, and the *dipicrate*, m. p. 146°.

6-*Chloro*-7-*nitrotetrahydroquinoline* forms red crystals, m. p. 84°. The *hydrochloride*, m. p. 184°, becomes red in presence of moisture. The yellow *nitroso*-derivative has m. p. 124°, and the *benzoyl* derivative has m. p. 126°.

Dichlorobenzo-4-γ-*dichloro*-5-*nitro*-2-*propylanilide* is colourless, m. p. 173—174°. Hydrolysed at 120—125° it forms 4-γ-*dichloro*-5-*nitro*-2-

propylaniline : this is yellow, m. p. 90°, and forms a colourless *hydrochloride*, m. p. 150—151°, which becomes bright yellow when wet.

7-*Benzoylaminotetrahydroquinoline*, m. p. 189°, forms a *platinichloride*, m. p. 280—282°.

7-*Aminotetrahydroquinoline*, obtained either on hydrolysis of the above or by reducing the corresponding nitro-compound, forms a colourless oil, b. p. 195°/15 mm., m. p. 60°. The *hydrochloride*, m. p. 240°, and the *dibenzoyl* derivative, m. p. 233°, are described. The 2 : 3-*dibenzoylamino-γ-chloropropylbenzene*,

$$C_3H_6Cl \cdot C_6H_3(NHBz)_2,$$
obtained from this has m. p. 198—200°, forming a colourless powder.

The *acetyl* derivative, $NHAc \cdot C_6H_3 \diagup \substack{CH_2-CH_2 \\ NMe \cdot CH_2}$, of 7-aminokairoline, m. p. 114°, when treated with cyanogen bromide forms 1-*cyano-7-acetylaminotetrahydroquinoline*, m. p. 152°, which is hydrolysed to 7-*aminotetrahydroquinoline*, m. p. 60°.

6-*Nitrodihydroscatole*, $NO_2 \cdot C_6H_3 \diagup \substack{CHMe \\ NH} \diagdown CH_2$, from dihydroscatole, has m. p. 75°; the *hydrochloride* has m. p. 192°, the yellow *nitroso*-compound has m. p. 100°, and the *benzoyl* derivative, which crystallises in lustrous platelets, has m. p. 148°. *Benzo-5-nitro-2-β-chloro*isopropylanilide, $NHBz \cdot C_6H_3(NO_2) \cdot CHMe \cdot CH_2Cl$, crystallises in colourless, matted needles, m. p. 110°. Hydrolysis at 125° converts it into *nitrodihydroscatole hydrochloride*, m. p. 192°.

6-*Nitrodihydromethylindole*, $NO_2 \cdot C_6H_3 \diagup \substack{CH_2 \\ NH} \diagdown CHMe$, has m. p. 50°, and forms a *benzoyl* compound, m. p. 137°, a *hydrochloride*, m. p. 200° after sintering previously, and a nitroso-compound, m. p. 103—104°. *Benzo-5-nitro-2-β-chloropropylanilide*,

$$PhCO \cdot NH \cdot C_6H_3(NO_2) \cdot CH_2 \cdot CHMeCl,$$
is colourless, m. p. 150°, and is converted on hydrolysis into 5-*nitro-2-β-chloropropylaniline*, a yellowish-red, crystalline mass, m. p. 84°. Treatment with dimethylamine converts it into 2-β-*benzo-5-nitro-2-dimethylaminopropylanilide*, $NO_2 \cdot C_6H_3(NHBz) \cdot CH_2 \cdot CHMe \cdot NMe_2$, crystallising in colourless needles, m. p. 122°. The analogous *piperidino*-compound, $NO_2 \cdot C_6H_3(NHBz) \cdot CH_2 \cdot CHMe \cdot NC_5H_{10}$, has m. p. 117°. E. F, A.

Action of Phosphoric Oxide on Benzylideneacetoneoxime. H. BURSTIN (*Monatsh.*, 1913, **34**, 1443—1448).—Goldschmidt (A., 1895, i, 392) by warming benzylideneacetoneoxime with phosphoric oxide could only isolate *iso*quinoline, whereas 2-methylquinoline or 1-methyl*iso*quinoline would represent a normal course for the condensation. The author has obtained a similar product, b. p. 240—250°, which gave a platinichloride, and corresponded with a mixture of the homologous quinolines. By the formation of quinophthalone (Jacobsen and Reimer, A., 1883, i, 812) and quinoline-2-carboxylic acid (Koenigs, A., 1899, i, 390), the presence of 2-methylquinoline was proved, whilst the formation of *iso*quinoline-red (Vongerichten and Homann, this vol., i, 99) indicated the presence of a mixture of 2-methylquinone and *iso*quinoline. J. C. W.

Condensation of Phenyl*iso*oxazolone with Ethyl Mesoxalate. ANDRÉ MEYER (*Bull. Soc. chim.*, 1913, [iv], **13**, 903—909).—By the condensation of these two products it was expected that coloured substances of the general formula $\begin{matrix} \text{N:CPh} \\ | \quad \quad \\ \text{O—CO} \end{matrix}\!\!>\!\!\text{O:C(CO·R)·CO}_2\text{R}'$ would be produced, but instead it was found that two molecules of phenyl-*iso*oxazolone took part in the reaction with the formation of compounds of the type $\begin{matrix} \text{N:CPh} \\ | \quad \quad \\ \text{O—CO} \end{matrix}\!\!>\!\!\text{CH·C(CO}_2\text{R)}_2\text{·CH}\!\!<\!\!\begin{matrix} \text{CPh:N} \\ \quad \quad | \\ \text{CO—O} \end{matrix}$, or their enolic forms.

*Ethyl mesoxalate bisphenyl*isooxazolone [*Bis-3-phenyl*isooxazolone-4-malonate], m. p. 187° (decomp.), forms large octahedra by slow evaporation of its solutions or small, prismatic crystals from acetic acid or boiling alcohol; it is soluble in alkalis and can be titrated, 1 mol. requiring 2 mols. of alkali to produce neutrality in presence of phenolphthalein. The sodium *salt* is crystalline and hygroscopic; those of the heavy metals are colourless and amorphous; ferric chloride gives a violet precipitate.

The sodium salt with ethyl iodide furnishes the *diethyl ether*, m. p. 200—201°, crystallising in silky, slender needles. The *diacetyl* derivative, m. p. 165—166°, forms small, prismatic crystals, and the *dibenzoyl* derivative, m. p. 194°, colourless leaflets or stellate groups of prismatic needles. Cryoscopic determinations of the molecular weight of the latter gave abnormal results. With benzenediazonium chloride, ethyl bis-3-phenyl*iso*oxazolone-4-malonate gave benzeneazo-phenyl*iso*oxazolone.   T. A. H.

The Constitution of Dinitrothiodiphenylamine [Dinitrophenthiazine]. FRIEDRICH KEHRMANN and FERD. RINGER (*Ber.*, 1913, **46**, 3014—3020. Compare Möhlau, Beyschlag, and Köhres, A., 1912, i, 212).—The authors believe that the dinitrophenthiazine obtained by Möhlau and his collaborators (*loc. cit.*) by the condensation of picryl chloride with *o*-benzoylaminophenyl mercaptan and subsequent treatment with sodium hydroxide solution is actually identical with and not an isomeride of the 3 : 5-dinitrophenthiazine described by Kehrmann and Schild (A., 1900, i, 61). In spite of the presence of the benzoyl radicle, the picryl chloride must therefore have made the amino-group and not the mercaptan group its main point of attack. In the action of picryl chloride on free aminophenyl mercaptan as well as on its benzoyl derivative, however, by-products are obtained which probably represent the isomerides of the main products and have the picryl radicle attached at the sulphur atom.

The compound, golden-yellow prisms, m. p. 169°, which is the main product of the interaction of picryl chloride and *o*-benzoylaminophenyl mercaptan, is therefore considered to have the structure

$$\text{SH·C}_6\text{H}_4\text{·NBz·C}_6\text{H}_2(\text{NO}_2)_3,$$
that is, *benzo*-2 : 4 : 6-*trinitro*-2'-*thioldiphenylamide*, whilst the substance, orange-yellow, leafy crystals, m. p. 142°, which results in smaller quantity, is probably the true trinitrophenyl *o*-benzoylaminophenyl sulphide. If the former substance, m. p. 169°, dissolved in alcohol is

treated with dilute sodium hydroxide solution and left at the ordinary temperature, there slowly separates 3 : 5-*dinitro*-6-*benzoylphenthiazine*, $C_6H_4{<}^{NBz}_{S}{>}C_6H_2(NO_2)_2$, straw-yellow leaflets, m. p. 209°, which on hydrolysis by alcoholic sodium hydroxide undergoes conversion into 3 : 5-dinitrophenthiazine, m. p. 188—190°, identical with the product of Kehrmann and Steinberg (A., 1911, i, 1034) ; the m. p. 218°, observed by Möhlau and his collaborators, must be due either to the occurrence of dimorphism or to the presence of impurities.

The substance described by Möhlau as 2 : 4-diaminophenazthionium ferrichloride (*loc. cit.*) is in reality the ferrichloride of 3 : 5-diaminophenazthionium, the experimental conditions deciding whether the ferrichloride or merely the chloride (Kehrmann and Schild, *loc. cit.*) shall separate.

When a suspension of 3 : 5-dinitrophenthiazine in cold acetic acid is gradually treated with powdered sodium nitrite (compare this vol., i, 1231), the substance passes into solution and there separates 3 : 5 : 9-*trinitrophenthiazine* (annexed formula), brownish-red, lustrous prisms, m. p. 214°. This substance by reduction in alcoholic solution by stannous chloride and hydrochloric acid, followed by oxidation of the separated, colourless *zincochloride* with ferric chloride, passes into 3 : 5 : 9-*trinitrophenazthionium chloride*, long needles with a metallic green lustre ; *nitrate*, sparingly soluble ; *platinichloride*, violet-black, crystalline powder.

The identity of the dinitrophenthiazine resulting from the methods of the two above-mentioned groups of investigators was further confirmed by energetic nitration, when 3 : 5 : 7 : 9-tetranitrodiphenylaminesulphoxide (annexed formula) was obtained in each case as well as in the nitration of 3 : 9-dinitro- and of 3 : 5 : 9-trinitro-phenthiazine.

A closer examination of the reaction product from *o*-aminophenyl mercaptan and picryl chloride reveals the presence of a small quantity of a *substance*, straw-yellow tablets, in addition to the 2 : 4 : 6-trinitro-2'-thioldiphenylamine which was described earlier. It is believed that the former is possibly trinitrophenyl aminophenyl sulphide.   D. F. T.

Preparation of *N*-Alkyl-*p*-phenylenediaminesulphonic Acids CHEMISCHE FABRIKEN VORM. WEILER-TER MEER (D.R.-P. 264927).— *N*-Alkyl-*p*-phenylenediaminesulphonic acids are obtained by the action of neutral alkali sulphites on *p*-nitroso-compounds of secondary or tertiary amines of general formula $NO\cdot R\cdot NR_1R_2$, where R is phenyl or a homologue of the same, R_1 hydrogen, alkyl or alkylaryl, and R_2 alkyl or alkylaryl.

p-*Phenylene*-as-*dimethyldiaminesulphonic acid*, $C_8H_{12}O_3N_2S$ (in which the sulphonic group is probably ortho- to the primary amino-group), is obtained when an aqueous solution of *p*-nitrosodimethylaniline (10 parts) is slowly treated at the ordinary temperature with a solution

of sodium sulphite (30 parts), and when the nitroso-compound has completely dissolved the mixture boiled with concentrated hydrochloric acid (90 parts); the acid is extremely soluble in water, but can be purified and finally isolated by means of its crystalline *benzylidene* derivative.

p-*Phenylene-as-diethyldiaminesulphonic acid* (prepared from nitrosodiethylaniline) is more readily isolated in crystalline form, whilst p-*phenylene-as-benzylethyldiaminesulphonic acid* furnishes a sparingly soluble *sodium* salt.

o-*Tolylene-2-ethyldiaminesulphonic acid* is obtained in a similar manner from *p*-nitrosoethyl-*o*-toluidine, and is isolated through its *benzylidene* derivative.   F. M. G. M.

Leuco-bases and Colouring Matters Derived from Diphenylethylene. VI. The First Stage in the Oxidation of the *cyclo*Hexylidene **Leuco-base,** $C_6H_{10}:C[C_6H_4\cdot NMe_2]_2$. **Tetrahydromalachite-green.** PAUL LEMOULT (*Compt. rend.*, 1913, **157,** 597—599. Compare A., 1912, i, 791).—Tetramethyldiaminodiphenyl-*cyclo*hexylidenemethane (formula I), when acted on by lead peroxide, gives a bluish-coloured substance, which spontaneously decomposes in aqueous solution, giving the compound (formula III) having two atoms of hydrogen less than the initial leuco-base (compare *loc. cit.*):

$$\text{(I.) } CH_2 {\textstyle \begin{matrix} CH_2\cdot CH_2 \\ CH_2\cdot CH_2 \end{matrix}} C:C(C_6H_4\cdot NMe_2)_2$$

(II.) $C_6H_9\cdot C(OH)(C_6H_4\cdot NMe_2)_2$ (III.) $C_6H_8:C(C_6H_4\cdot NMe_2)_2$.
The author has now succeeded in isolating the unstable substance (formula II) by precipitating it from acid solution with ammonia, drying it in a vacuum over sulphuric acid, followed by crystallisation from benzene. Heated slowly, it has m. p. 130—135°, heated rapidly, m. p. 160°, whilst the instantaneous m. p. is 145°. If the liquid is allowed to cool and re-melted it has m. p. 165°, which is in accord with elimination of water, giving substance III, m. p. 169° (*loc. cit.*). This transformation is also brought about by simple crystallisation from hot alcohol.

The oxygenated compound on solution in cold alcohol to which one drop of acetic acid has been added, gives a persistent, deep blue solution, thus differing from substances I and II, and in slightly acid solution it dyes cotton, mordanted with tannin, a tint comparable to that given by malachite-green, but appreciably bluer. The absorption spectra of these two compounds, however, show marked differences.
                                                                        W. G.

Leuco-bases and Colouring Matters of Diphenylethylene. VII. Action of Magnesium Methyl and Ethyl Iodides on Michler's Ketone. PAUL LEMOULT (*Compt. rend.*, 1913, **157,** 724—726).—A repetition of Fecht's experiments on the action of magnesium methyl and ethyl iodides on Michler's ketone (compare A., 1907, i, 926). Contrary to Fecht's statements, but in agreement with the results of Freund and Mayer (compare A., 1906, i, 384), the author obtained no carbinols of the type $OH\cdot CMe(C_6H_4\cdot NMe_2)_2$, but a mixture of substances from which he separated unchanged ketone,

an ethylenic derivative of the type $CH_2:C(C_6H_4\cdot NMe_2)_2$, and in the case of magnesium methyl iodide, small quantities of a *substance*, crystallising in yellow needles, m. p. 157—158°, having the composition $C_{18}H_{22}N_2$, but a molecular weight corresponding to twice this, together with two other basic substances, crystallising (*a*) in yellow plates, m. p. 227°, and (*b*) in yellow crystals, m. p. 274°, the constitutions of which have not yet been determined. In the case of magnesium ethyl iodide, no substances corresponding with the last three were found, but a 90% yield of the ethylenic compound, $CHMe:C(C_6H_4\cdot NMe_2)_2$, was obtained.   W. G.

Ditertiary Hydrazines. XVI. Mechanism of the Blue Colour Reaction of Diphenylamine. HEINRICH WIELAND [with CARL MÜLLER] (*Ber.*, 1913, **46**, 3296—3303).—The blue coloration formed in sulphuric acid solutions of diphenylamine by oxidising agents was considered to be an acid sulphate of diphenyl dihydrophenazonium. Kehrmann and Micewicz (A., 1912, i, 1020) have shown that it is more probably a quinonoid derivative of diphenylbenzidine, $PhN:C_6H_4\cdot C_6H_4:NHPh\cdot O\cdot SO_3H$. This explanation is now accepted, although it is not applicable to the colour reactions obtained with diphenylhydrazine, diphenylhydroxylamine, and *p*-dianisylamine.

Diphenylamine in dilute sulphuric acid and acetic acid solution is readily oxidised to the blue dye, which is easily reduced without the formation of by-products to diphenylbenzidine. Tetramethylhydrazine gives only small quantities of diphenylbenzidine as well as amorphous products; its formation cannot, therefore, be regarded as an intermediate stage in the colour reaction.

Triphenylamine shows a similar blue coloration on oxidation, when quinonoid salts of tetraphenylbenzidine are formed. *Tetraphenylbenzidine* crystallises in pale yellow needles, m. p. 226°, to a brownish-yellow liquid.

s-*Diphenyl*-o-*phenylenediamine*, $C_6H_4(NHPh)_2$, obtained by the action of iodobenzene and copper powder on *o*-aminodiphenylamine, crystallises as colourless double pyramids, m. p. 152·5°. On attempting to combine it with *o*-dibromobenzene to diphenyldihydrophenazine, only amorphous products were obtained.   E. F. A.

Ditertiary Hydrazines. XVII. Diphenylhydroxylamine and Some Colour Reactions Related to the Blue Diphenylamine Reaction. HEINRICH WIELAND and CARL MÜLLER (*Ber.*, 1913, **46**, 3304—3314).—Diphenylhydroxylamine reacts with 75% sulphuric acid to form 70% of diphenylbenzidine, together with a little diphenylamine and a green dye of high molecular complexity. The quinonoid-blue salt is formed in this instance by direct elimination of water from diphenylhydroxylamine. When the sulphuric acid is diluted with acetic acid instead of water, the anhydro-product obtained is carbazole together with considerable quantities of *p*-hydroxydiphenylamine.

Even ice-cold sulphuric acid converts diphenylhydrazine into diphenylhydroxylamine, which is converted into diphenylbenzidine

as described. Much ammonia is also formed, also traces of *o*-amino-diphenylamine and some *p*-hydroxydiphenylamine.

p-Tolylhydrazine and concentrated sulphuric acid give at first a bluish-green and green coloration due to hydroxylamine, and ammonia is also formed. Further decomposition yields a yellowish-brown, amorphous substance and much ditolylamine.

Tetraphenyl- and *p*-tetratolyl-hydrazine dissolve in sulphuric acid with a reddish-violet coloration which changes to blue. Diphenylamine and ditolylamine are also formed respectively.

On oxidation of *p*-dianisylamine with persulphate and sulphuric acid, the salt, $OMe \cdot C_6H_4 \cdot N \vdots C_6H_4 \vdots OMe \cdot O \cdot SO_3H$, is first formed, but could not be isolated. A blue sulphate of the character of an indophenol which is red in solution was obtained; it very readily yields *p*-benzoquinone on treatment with dilute acids, and is considered to be the acid sulphate of a polymerised bimolecular *anisylquinone monoimine*,

$$HO \cdot C_6H_4 \cdot N(C_6H_4 \cdot OMe) \cdot C_6H_3(OMe) \cdot N \vdots C_6H_4O.$$
E. F. A.

The Action of Organomagnesium Compounds on Diazomethane and Ethyl Diazoacetate. II. ERNST ZERNER (*Monatsh.*, 1913, **34**, 1631—1638. Compare this vol., i, 1312).—The author makes some observations on the paper by Forster and Cardwell (T., 1913, **103**, 86) on the constitution of aliphatic diazo-compounds, and describes the preparation of benzaldehydephenylhydrazone by the action of diazomethane on magnesium phenyl bromide. The formation of this compound is assumed to follow the course:

$$CH_2 \vdots N \cdot N + PhMgBr \longrightarrow CH_2 \vdots N \cdot NPh \cdot MgBr + PhMgBr \longrightarrow$$
$$CH_2Ph \cdot NMgBr \cdot NPh \cdot MgBr \longrightarrow CH_2Ph \cdot NH \cdot NH \cdot CH_2Ph \longrightarrow$$
$$CHPh \vdots N \cdot NHPh.$$
The ring formula for the fatty diazo-compound would require that at least one nitrogen atom would be involved in the addition of two molecules of the magnesium compound, which is contrary to experience.

J. C. W.

The Condensation of Ethyl Oxalate with Pyrazolones. WILHELM WISLICENUS, HEINRICH ELVERT, and PAUL KURTZ (*Ber.*, 1913, **46**, 3395—3407).—On the addition of a benzene solution of phenylmethylpyrazolone (prepared from ethyl acetoacetate) to a mixture of ethyl oxalate and potassium ethoxide dissolved in ether, there separates slowly the *potassium* derivative, yellowish-white crystals, decomp. between 138° and 145°, of *ethyl 1-phenyl-3-methyl-5-pyrazolone-4-glyoxylate*, $CO_2Et \cdot CO \cdot CH \begin{smallmatrix} CO-NPh \\ OMe \cdot N \end{smallmatrix}$, yellowish-white needles, m. p. 81—82°, which can be liberated by addition to cold dilute hydrochloric acid; the ester gives a deep red coloration with ferric chloride and also with common benzene and sulphuric acid; its tendency to enolisation is further evidenced by the formation of a green *copper* derivative, m. p. 220—223°, and of an *ammonium* derivative, m. p. 120—123° (decomp.). Treatment of the ester with phenylcarbimide caused the formation of the *carbanilate* of *ethyl 1-phenyl-3-methyl-5-pyrazolol-4-gly-*

oxylate, $N{<}^{NPh-C\cdot O\cdot CO\cdot NHPh}_{\ CMe-C\cdot CO\cdot CO_2Et}$, colourless needles, m. p. 97°, which
like the corresponding additive compound from phenylcarbimide and
phenylmethylpyrazolone, namely, 1-*phenyl-3-methyl-5-pyrazolyl carb-
anilate*, colourless needles, m. p. 92—93°, is unstable, and when
heated gives an odour of phenylcarbimide.

Ethyl phenylmethylpyrazoloneglyoxylate gives a *phenylhydrazone*,
almost colourless needles, m. p. 182—183°, in the formation of which a
difficultly isolable *isomeride*, yellow leaflets, is also produced ; p-*bromo-
phenylhydrazone*, yellowish-white needles, m. p. 213—214°.

1-*Phenyl-3-methyl-5-pyrazolone-4-glyoxylic acid*, yellowish-white
needles, m. p. 236—238°, is obtainable by hydrolysis of the ester.
With sulphuric acid it gives on warming a green coloration changing
successively to red and brown, and at 200° it is converted with loss of
carbon dioxide into the already known phenylmethylpyrazolone-
sulphonic acid (Möllenhoff, A., 1892, 1245). Heated with aniline
at 150°, the acid gives rise to the *anil* of 1-*phenyl-3-methyl-5-pyrazolone-
4-aldehyde*, greenish-yellow needles, m. p. 151—152°. The acid reacts
slowly with phenylhydrazine in alcoholic solution at the ordinary tem-
perature, giving rise to a *phenylhydrazone*, almost colourless needles,
m. p. 205—206°, which can be esterified by alcohol and hydrogen
chloride to the previously mentioned phenylhydrazone of the ester. If
phenylmethylpyrazoloneglyoxylic acid is heated with methyl or ethyl
alcohol for an hour in a sealed tube at 160—180°, orange-yellow
needles of 1-phenyl-3-methyl-4-methylene-5-pyrazolone,

$$\begin{matrix} NPh-CO \\ N=CMe \end{matrix}{>}C{:}CH_2,$$
separate (compare Pellizzari, A., 1889, 517), a small amount of a
colourless *substance*, m. p. above 280°, which in alcoholic solution gives
a violet precipitate with ferric chloride being present in the mother
liquor.

1 : 3-Diphenyl-5-pyrazolone condenses with ethyl oxalate under the
same conditions as the above methylpyrazolone, giving the *sodium* or
potassium derivatives of *ethyl 1 : 3-diphenyl-5-pyrazolone-4-glyoxylate*,
which after acidifying is obtainable in yellowish-white, prismatic needles,
m. p. 108—109°. The ester, which gives similar colour reactions to the
analogous 1-phenyl-3-methyl compound, is, however, not hydrolysed on
boiling with alcoholic potassium hydroxide ; it gives a deep green
copper derivative, m. p. 245—246° (decomp.) ; the *phenylhydrazone* as
first obtained from reaction in chloroform or alcohol forms colourless
needles, m. p. 208—209°, but on recrystallisation from alcohol passes
into yellow, prismatic needles of an isomeride, m. p. 204—205°, which
is directly produced in benzene solution.

1-*p*-Tolyl-3-methylpyrazolone, prepared from *p*-tolylhydrazine and
ethyl acetoacetate, undergoes condensation with ethyl oxalate under
the previous conditions, yielding yellow needles of the *potassium*
derivative of *ethyl 1-p-tolyl-3-methyl-5-pyrazolone-4-glyoxylate* ; this
ester, which forms yellow needles, m. p. 87—88°, gives a deep red
coloration with alcoholic ferric chloride, and a red changing to violet
with common benzene and sulphuric acid.

1-p-*Tolyl-3-methyl-5-pyrazolone*-4 - *glyoxylic acid* forms colourless needles, m. p. 218—219°. Treatment of the ester with the calculated quantity of phenylhydrazine gives a mixture of almost colourless needles and yellow leaflets. The former, purified by recrystallisation from alcohol, have m. p. 195—196°, whilst the latter, m. p. 209—210°, are obtained pure by crystallisation from warm chloroform ; these two *phenylhydrazones* are isomeric, the structures :

$$\begin{array}{c}NPh\cdot CO\\ \diagdown\\ N=CMe\end{array}\!\!\!\!>CH\cdot C(:N\cdot NHPh)\cdot CO_2Et \quad \text{and}$$

$$\begin{array}{c}NPh\cdot CO\\ \diagdown\\ N=CMe\end{array}\!\!\!\!>C:C(\cdot NH\cdot NHPh)\cdot CO_2Et$$
being suggested for the colourless and yellow forms respectively. A similar explanation is proposed for the occurrence of the other isomeric phenylhydrazones described above.

Tolylmethylpyrazoloneglyoxylic acid with phenylhydrazine in benzene solution first gives colourless needles, m. p. 201—202°, of a *phenyl-hydrazine* salt, which loses a molecule of water on recrystallisation from hot alcohol, producing the *phenylhydrazone*, yellow leaflets, m. p. 217°. No isomerism was observed with this phenylhydrazone or with the *diphenylhydrazone* of ethyl tolylmethylpyrazoloneglyoxylate, prisms, m. p. 137—138°.   D. F. T.

Preparation of *N*-Halogenalkyl-5 : 5-dialkylbarbituric Acids. E. MERCK (D.R.-P. 265726).—*N*-Halogenalkyl-5 : 5-dialkylbarbituric acids of general formula $CRR_1\!\!<\!\!\begin{array}{c}CO\cdot NX\\ CO\cdot NY\end{array}\!\!>\!CO$ (where R and R_1 are alkyl, X halogenalkyl, and Y hydrogen or halogenalkyl groups) are obtained when *N*-alkylen-5 : 5-dialkylbarbituric acids are treated with the required halogen, or when dialkylmalonyl haloids are combined with halogenated alkylcarbamides.

5 : 5-*Diethyl*-1-*allylbarbituric acid* forms colourless needles, m. p. 77° ; and when treated (in cooled acetic acid solution) with bromine, gives rise to 5 : 5-*diethyl*-1-*βγ-dibromopropylbarbituric acid*,

$$CO\!\!<\!\!\begin{array}{c}CEt_2\cdot CO\\ NH-CO\end{array}\!\!>\!N\cdot CH_2\cdot CHBr\cdot CH_2Br,$$
colourless needles, m. p. 126° (corr.) ; the latter compound can also be prepared by heating βγ-dibromopropylcarbamide,

$$CH_2Br\cdot CHBr\cdot CH_2\cdot NH\cdot CO\cdot NH_2,$$
with diethylmalonyl chloride during fifteen to twenty hours at 120°.

5 : 5-*Dibenzyl*-1: *γ-bromopropylbarbituric acid*, small, hard prisms, m. p. 111°, is obtained in a similar manner from 5 : 5-dibenzyl-1-allyl-barbituric acid.

5 : 5-*Diethyl*-1-*βγ-dichloropropylbarbituric acid* has m. p. 127°, and 5 : 5-*diethyl*-1 : *γ-bromopropylbarbituric acid*, m. p. 100°.

When 5-*phenyl*-5-*ethyl*-1-*allylbarbituric acid*, m. p. 68—69° (prepared from allylcarbamide and phenylethylmalonyl ester) is treated with bromine it gives rise to 5-*phenyl*-5-*ethyl*-1-*βγ-dibromopropyl-barbituric acid*, $C_{15}H_{16}O_3N_2Br_2$, whilst 5 : 5-*diethyl*-*βγβ'γ'-tetrabromo*-1 : 1-*dipropylbarbituric acid*, $C_{14}H_{20}O_3N_2Br_4$, colourless prisms, m. p. 64°, is obtained by brominating 5 : 5-diethyl-1 : 1-diallylbarbituric acid

or by brominating *s*-diallylcarbamide and heating the *tetrabromodipropylcarbamide* with diethylmalonyl chloride at 120—130° for twenty-five hours in a vacuum.   F. M. G. M.

Products of Decomposition of Indigo in the Vat. HERBERT EHRHARDT (*J. Soc. Dyers*, 1913, **29**, 321—322).—The loss of dye which is often experienced when indigo vats are reduced, not by pure solutions of sodium hyposulphite, but by metallic reducing agents, is traced to the formation of anthranilic acid. A vat containing 200 grams of pure 20% indigo-paste, 120 grams of lime slaked with 600 c.c. of water, 200 c.c. of sodium hydrogen sulphite solution of 57° Tw., and 30 grams of zinc was left for a few days. The sediment was then filtered and extracted with boiling water, whilst the solution was oxidised by a current of air and the precipitated indigo extracted with dilute hydrochloric acid. The combined solutions were then cooled, roughly titrated with sodium nitrite, and treated with the requisite amount of β-naphthol, when 2 grams of the azo-dye of anthranilic acid were obtained.   J. C. W.

Formation of Pyrazine Compounds from Quinoxaline Derivatives. K. A. BÖTTCHER (*Ber.*, 1913, **46**, 3084—3087. Compare Gabriel and Sonn, A., 1908, i, 60).—2-*Methylquinoxaline*,

$$C_6H_4\left<{\overset{N\colon CMe}{N\colon CH}}\right>,$$
b. p. 245—247°, is formed by the condensation of *o*-phenylenediamine with oximinoacetone in aqueous acetic acid solution. It solidifies in a freezing mixture of ice and salt, and is rapidly discoloured on exposure to sunlight. The *platinichloride*, unstable, yellow needles, darkens at 130°, and is not melted at 250°, whilst the *gold* salt softens at 122° and has m. p. 135° (decomp.). The *picrate* blackens below 200° and has m. p. 215°. Oxidation with alkaline permanganate converts 2-methylquinoxaline into 2-*methylpyrazine*-5 : 6-*dicarboxylic acid*,

$$\overset{CMe\colon N\colon C\cdot CO_2H}{\underset{CH-N\colon C\cdot CO_2H}{}}$$
which, after purification through the *calcium* and *barium* salts, has m. p. 196°. The *copper* salt, $C_7H_4O_4N_2Cu, H_2O$, pale blue needles which decompose below the m. p., and the *silver* salt, $C_7H_4O_4N_2Ag_2$, were analysed.

2 : 3-Dimethylquinoxaline (compare Gabriel and Sonn, *loc. cit.*) crystallises with $2H_2O$. 2 : 3-Dimethylpyrazine-5 : 6-dicarboxylic acid, after purification by means of the barium salt, has m. p. 190°, instead of 200° as previously recorded. When treated with methyl alcohol and hydrogen chloride, it yields an oily *methyl* ester, which is also prepared by the action of methyl iodide on the silver salt. The *diamide*, needles, m. p. 227°, is obtained by the action of methyl alcoholic ammonia on the ester.   H. W.

Indigoid Derivatives of Phenyl*iso*oxazolone. ANDRÉ MEYER (*Bull. Soc. chim.*, 1913, [iv], **13**, 992—1000).—The author has prepared a number of indigoid derivatives from phenyl*iso*oxazolone or its substituted derivatives as follows. Phenyl*iso*oxazole-2-indole,

prepared by heating indoxylic acid with dibromophenyl*isooxazolone* in acetic acid in the presence of sodium acetate, crystallises from glacial acetic acid in red needles (compare Wahl, A., 1909, i, 261). In order to study the effect of substitution on the colour and properties of this indigoid dye, the author has prepared the following derivatives by the condensation of substituted isatin chlorides with phenyl*isooxazolone*, which gives substances with the general constitution (annexed formula).
*Phenyl*isooxazole-5-*bromo*-2-*indole* crystallises from acetic acid in deep, reddish-brown needles, its properties being closely allied to those of the non-halogenated indigoid dye.

*Phenyl*isooxazole-5 : 7-*dibromo*-2-*indole* crystallises in red plates, its colour being brighter and its solubility in organic solvents much greater than that of the two preceding compounds.

*Phenyl*isooxazole-2-*nitroindole*, scarlet-red needles, m. p. 220°, gives an eosin-red solution in concentrated sulphuric acid.

β-Naphthisatin chloride reacts similarly with phenyl*isooxazolone*, giving *phenyl*isooxazole-2-β-*naphthindole*, crystallising from ethylene bromide in brown needles.

Oxythionaphthen reacts with dibromophenyl*isooxazolone* in acetic acid solution, yielding *phenyl*isooxazole-2-*thionaphthen*, crystallising in scarlet red needles, giving a greenish coloration with sulphuric acid and a deep red precipitate from benzene solution with stannic chloride.
Phenyl*isooxazolone*, unlike other heterocyclic compounds, such as indoxyl and oxythionaphthen, does not condense with cyclic ketones to give any well-defined products, but with benzil in alcoholic solution in the presence of piperidine the author has succeeded in preparing *phenyl*isooxazoledibenzil (annexed [formula), yellow needles, m. p. 208°. W. G.

3 : 6-Diaminoacridine. Relationships between Acridine Derivatives and Analogous Phenazine Compounds. EUGÈNE GRANDMOUGIN and K. SMIROUS (*Ber.*, 1913, 46, 3425—3434).—In view of the similarity in the structure of 3 : 6-diaminoacridine (Benda, A., 1912, i, 651) and 3 : 6-diaminophenazine, the authors have undertaken a comparison of the behaviour of these two compounds and their derivatives, the present paper dealing particularly with the salt-formation and diazotisation of the first-mentioned compound. The salts of 3 : 6-diaminoacridine with one equivalent of acid are quite stable, whilst those with two or three equivalents are readily hydrolysed by water.

Addition of alkali to a concentrated solution of 3 : 6-diamino-10-methylacridinium chloride (trypaflavine of Ehrlich and Benda this vol., i, 904) precipitates the orange-yellow *imine base*,

$$NH_2 \cdot C_6H_3 \underset{NMe}{\overset{CH}{<}}{>} C_6H_3 \cdot NH;$$
ethereal solutions of which, when shaken with water, yield the *ammonium base*, $NH_2 \cdot C_6H_3 \underset{NMe(OH)}{\overset{OH}{<}} C_6H_3 \cdot NH_2$, the latter being converted by heating with water into the *carbinol base*,

$$NH_2 \cdot C_6H_3 \underset{NMe}{\overset{OH(OH)}{<}} C_6H_3 \cdot NH_2.$$
On diazotisation, 3 : 6-diaminoacridine yields a violet monodiazo-compound, which on account of its colour is considered to have a *p*-quinonoid structure : $NH \overset{..}{:} C_6H_3 \underset{NH}{\overset{CH}{<}} C_6H_3 \cdot N_2Cl.$

The diazo-compound combines with resorcinol, β-naphthol, and R-salt to form reddish-brown to reddish-violet *azo-dyes*, and is reduced by alcohol to 3-*aminoacridine*, m. p. 170°, which is orange-yellow in colour, yields yellow aqueous solution having a green fluorescence, and can be further diazotised and reduced to acridine.

On treatment with potassium iodide, the monodiazo-compound yields 3-*iodo*-6-*aminoacridine*, orange crystals, m. p. 230° (decomp.).

Diazotisation with excess of sodium nitrite in concentrated sulphuric acid solution yields a bisdiazo-compound, which, with potassium iodide, gives rise to 3 : 6-*di-iodoacridine*. This forms dark brown crystals of a metallic lustre, m. p. 270° (decomp.), and, when methylated by means of methyl sulphate in nitrobenzene solution and subsequently treated with potassium iodide, is converted into an orange-yellow, crystalline 3 : 6-*di-iodo*-10-*methylacridinium iodide*.

The *dihydrochloride* of 3 : 6-diaminoacridine, prepared by the addition of concentrated hydrochloric acid to an alcoholic solution of the monohydrochloride, crystallises in orange-yellow needles.

The *trihydrobromide*, obtained from the free base and alcoholic hydrogen bromide, forms orange crystals. The *monohydrochloride* of 3 : 6-diacetylaminoacridine forms slender, yellow crystals.

3 : 6-*Diamino*-10-*methylacridinium dihydrochloride*, prepared by the action of methyl sulphate on 3 : 6-diacetylaminoacridine in nitrobenzene solution, and subsequent hydrolysis of the resulting brownish-yellow *methosulphate* by means of hydrochloric acid, forms dark brownish-red crystals of a metallic lustre, and when warmed readily loses hydrogen chloride with the formation of the monohydrochloride.

3 : 6-*Diamino*-10-*methylacridinium bromide* forms Bordeaux-red leaflets of a metallic lustre, the *iodide*, orange needles, and the *nitrate*, reddish-brown needles.

The diazotisation of safranine has also been studied. According to Kehrmann, Havas, and Grandmougin (this vol., i, 1241), the green safranine salts formed by the combination of one molecule of the base with three equivalents of acid, consist of a mixture of the yellow *o*-quinonoid salt I and the blue *p*-quinonoid salt II :

(I.) $NH_3X \cdot C_6H_3 \underset{NPhX}{\overset{N}{<}} C_6H_3 \cdot NH_3X$

(II.) $NH_3X \cdot C_6H_3 \underset{NPhX}{\overset{N}{<}} C_6H_3 \overset{..}{:} NH,HX.$
Of these two salts only the *o*-quinonoid form should be capable of complete diazotisation.

This view has been confirmed by the behaviour of phenosafranine, which on treatment with solid sodium nitrite in concentrated sulphuric acid solution is partly converted into a bisdiazo-compound. If the solution is kept, the p-quinonoid salt II is slowly transformed into the o-quinonoid form and then undergoes complete diazotisation.

Reduction of the resulting solution by means of alcohol yields the phenylphenazonium of Kehrmann (A., 1897, i, 107). F. B.

The Degradation of Allantoin to Hydroxonic Acid, and a New Synthesis of Allantoin. HEINRICH BILTZ and ERHARD GIESLER (*Ber.*, 1913, **46**, 3410—3425).—Allantoin, prepared from uric acid by oxidation with alkaline potassium permanganate solution, was further oxidised to potassium allantoxanate; by treating this in aqueous solution with slightly less than the calculated amount of N-sulphuric acid, more than 90% of the theoretical quantity of allantoxaidin (from decomposition of the unisolable allantoxanic acid,

$$\begin{array}{c} CO\cdot NH \\ \diagdown \\ NH-CO \end{array}>C\overset{..}{:}N\cdot CO_2H),$$
was obtainable (compare Ponomarev, A., 1879, 226, 228, 461); the allantoxaidin, $CO<\begin{smallmatrix}NH\cdot C:NH\\NH\cdot CO\end{smallmatrix}$, was obtained in short prisms containing $1H_2O$, and of m. p. 282° (decomp.); its aqueous solution on heating yields biuret and formic acid, and a similar decomposition ensues on heating the substance with acetic anhydride, the product being *formylacetylbiuret*, probably $CHO\cdot NH\cdot CO\cdot NH\cdot CO\cdot NHAc$, leaflets, m. p. 184—185°.

The reduction of potassium allantoxanate by sodium amalgam and water (compare Ponomarev, *loc. cit.*) gave rise to the product described by Ponomarev as hydroxonic acid, $C_8H_{10}O_7N_6$, but when this was purified by means of the ester, it was found to be of the composition $C_4H_5O_4N_3$, that is, *dihydroallantoxanic acid*,

$$\begin{array}{c} CO\cdot NH \\ \diagdown \\ NH-CO \end{array}>CH\cdot NH\cdot CO_2H;$$
potassium salt, rectangular prisms, rapid decomp. near 333°; *ammonium* salt, colourless needles, unfused even at 340; *silver* salt with $1H_2O$; *methyl* ester, leaflets, m. p. 275° (decomp.); *ethyl* ester, rectangular tablets, m. p. 277° (decomp.).

The above results indicate that allantoin is the amide of dihydroallantoxanic acid, but it was not found possible to convert the esters of the latter substance into allantoin, nor was it possible to obtain allantoxanic acid directly from allantoin, but the existence of the relationship could be demonstrated in the following manner.

When hydroxonic acid is boiled with acetic anhydride for eight hours, it undergoes loss of carbon dioxide with formation of $1:3:6$-*tri-acetyl-5-aminohydantoin*, $\begin{array}{c} CO\cdot NAc \\ \diagdown \\ NAc-CO \end{array}>CH\cdot NHAc$, tablets from acetone or prisms from benzene, m. p. 184—185°; this substance when boiled with alcohol gives leaflets, m. p. 240—241°, of $1:6$-*diacetyl-5-amino-hydantoin*, which on evaporation with concentrated hydrochloric acid is converted into *5-aminohydantoin hydrochloride*, m. p. 218—222°

(decomp.); the free base, of which the *platinichloride* was also prepared, could not be isolated; the action of silver oxide on the hydrochloride produced insoluble 3-*silver*-5-*aminohydantoin*. Allantoin itself was obtainable from the hydrochloride of the aminohydantoin by treatment with potassium cyanate in aqueous solution.   D. F. T.

Ring Formation between the Nitro- and Amino-groups with Production of Triazines. FRITZ ARNDT (*Ber.*, 1913, **46**, 3522—3530).—The preparation and properties of a number of triazines are described which are obtained from o-*nitrophenylguanidine* and o-nitrophenylcarbamide by loss of water under the influence of sodium or potassium hydroxide. Since neither sodium carbonate, ammonia nor acids bring about this change, it seems probable that ring formation is preceded by formation of the alkali salt of the ψ-nitro-form. This is the more likely, since the originally orange-yellow solution becomes red when warmed with alkali, and then yields a yellow precipitate. After ring formation, the reverse change immediately occurs, since the product obtained does not possess the properties of an o-quinone.

If Angeli's formula for the azoxy-group (this vol., i, 658) is adopted, the compounds obtained by the author may be regarded as containing this group in the triazine ring, and it therefore seems to be produced with remarkable ease by loss of water from an amino- and nitro-group, when ring formation can simultaneously occur.

o-*Nitrophenylguanidine nitrate*, pale yellow prisms, m. p. 160°, is obtained by the addition of 2N-nitric acid to the product of the action of concentrated hydrochloric acid on a mixture of o-nitroaniline and cyanamide. Should the latter contain dicyanamide, the white, amorphous *nitrate* of a condensation product of cyanamide and dicyanamide is also formed. o-Nitrophenylguanidine,

$$NO_2 \cdot C_6H_4 \cdot NH \cdot C(:NH) \cdot NH_2,$$
separates as a viscous oil when the finely powdered nitrate is treated with cold 2N-sodium hydroxide. It separates from its aqueous solution in orange-yellow needles which contain 1H_2O, m. p. 53°.

Aminophenotriazoxine [3-*amino*-1 : 2 : 4-*benzotriazine* 1-*oxide*] (annexed formula), shining leaflets, m. p. 269°, is obtained in almost quantitative yield by the action of boiling sodium hydroxide solution on o-nitrophenylguanidine or on the crude reaction mixture obtained
from o-nitroaniline, cyanamide and hydrochloric acid. The *hydrochloride*, *sulphate*, and *nitrate* were examined. The *silver* salt, $C_7H_5ON_4Ag$, was analysed.

Sodium nitrite and hydrochloric acid convert 3-amino-1 : 2 : 4-benzotriazine oxide directly into 3-*hydroxy*-1:2:4-*benzotriazine* 1-*oxide*, yellow leaflets, m. p. 219° (decomp.).

Aminobenzotriazine oxide is readily reduced by tin and hydrochloric acid; when 2N-nitric acid is added to the reaction product, 3-*amino*-

dihydro-1:2:4-*benzotriazine nitrate*, m. p. 195—197°
(decomp.), is obtained. When an aqueous solution
of this salt is treated with sodium carbonate, the
free *base* (annexed formula) separates in white
leaflets which rapidly become oxidised with forma-
tion of 3-*amino*-1:2:4-*benzotriazine*, yellow needles,
m. p. 207°. The latter substance is best obtained
by the action of potassium ferricyanide and sodium hydroxide on a
solution of dihydroaminophentriazine nitrate.
For the preparation of *o-nitrophenylcyanamide*, $NO_2 \cdot C_6H_4 \cdot NH \cdot CN$,
an intimate mixture of *o*-nitroaniline hydrochloride and lead thio-
cyanate is allowed to remain at the ordinary temperature until a
portion does not melt when placed in boiling water ; the mixture is
then heated for six to seven hours on the water-bath, and subsequently
boiled with $2N$-sodium hydroxide ; after removal of lead sulphide,
the solution is cooled, filtered from unchanged *o*-nitroaniline, and
cautiously acidified with hydrochloric acid, when *o*-nitrophenyl-
cyanamide, pale yellow needles, m. p. 152°, separates in poor yield.
Boiling dilute hydrochloric acid transforms it into *o*-nitrophenyl-
carbamide, yellow needles, m. p. 183—184° (Schwartz [A., 1897, i,
411] gives 181°), which is converted by boiling potassium hydroxide
into hydroxybenzotriazine oxide, identical with the product obtained
from aminobenzotriazine oxide.

Attempts to prepare *o*-nitrophenylthiocarbamide were unsuccessful.
H. W.

**A Mode of Decomposition of Halogenated Alkyl Deriv-
atives of Hexamethylenetetramine.** MARCEL SOMMELET (*Compt.
rend.*, 1913, **157**, 852—854. Compare Hock, A., 1903, i, 465).—
Derivatives of hexamethylenetetramine of the type $C_6H_{12}N_4RX$,
where R is an alkyl group and X one of the halogens, are decomposed
by boiling with water. This is particularly true of the derivative
obtained from benzyl chloride, the products of the decomposition being
benzaldehyde (70—80% yield) and a mixture of bases of which the
following were characterised : ammonia, methylamine, dimethylamine,
trimethylamine, and benzylamine. Benzaldehyde is similarly obtained
by boiling benzyl chloride and hexamethylenetetramine together in
aqueous alcoholic solution.

The three xylyl bromides combine directly with hexamethylene-
tetramine in chloroform solution to give the additive *compounds*,
$C_6H_{12}N_4Br \cdot CH_2 \cdot C_6H_4Me$, having melting points respectively,
ortho, 198°; *meta*, 215°; *para*, 216°. Each of these are similarly
decomposed by boiling with water, giving the corresponding
tolualdehydes.

The course of this decomposition reaction is not yet clear, but the
relatively abundant production of methylamine points to the possible
primary production of benzylmethyleneamine, which undergoes
isomerisation to benzylidenemethylamine :
$$CH_2Ph \cdot N:CH_2 \longrightarrow CHPh:NMe. \qquad W. G.$$

Anilinoquinones and their Azine Derivatives.   FRIEDRICH KEHRMANN and MARCELIEN CORDONE (*Ber.*, 1913, **46**, 3009—3014).— The authors have convinced themselves of the correctness of Will-stätter's view as to the holoquinonoid nature of both modifications of *o*-benzoquinone, but believe that these merely represent dimorphous forms of the same substance.   *o*-Benzoquinone is said to present an example of dichroism, on account of which the different crystalline forms appear to be of different colours; the less stable form is stated to be not colourless but green.   Both forms of the substance are, therefore, of diketonic structure.

If catechol is oxidised in the presence of aniline by silver acetate in solution in cold acetic acid, a brown mixture of 4 : 5-*dianilino-o-benzo-quinone* (annexed formula), brownish-red needles, m. p. 193°, with a little of the trianilino-compound separates; the former is easily extracted by sodium hydroxide, in which it is soluble.

$$\text{NHPh}$$
$$\text{NHPh} \diagup \diagup \diagdown \text{:O}$$
$$\dot{\text{O}}$$
When equimolecular quantities of the above dianilinobenzoquinone and *o*-phenylenediamine hydrochloride are heated together in concentrated solution in alcohol, condensation occurs to 2 : 3-*dianilinophenazine*,

$$\text{C}_6\text{H}_2(\text{NHPh})_2 \diagdown^{\text{N}}_{\text{N}} \diagup \text{C}_6\text{H}_4,$$
orange-yellow, apparently rhombohedral crystals, m. p. 218—219°, which separate from alcohol with one $\text{C}_2\text{H}_6\text{O}$; the *hydrochloride*, which is the primary product, forms long, deep red needles.

A similar condensation could be effected between the dianilino-*o*-benzoquinone and phenyl-*o*-phenylenediamine hydrochloride, the product being 2 : 3-dianilino-10-phenylphenazonium chloride,

$$\text{C}_6\text{H}_2(\text{NHPh})_2 \diagdown^{\text{N}\text{------}}_{\text{NPhCl}} \diagup \text{C}_6\text{H}_4,$$

violet tablets, m. p. 235—237° (compare Fischer and Hepp, A., 1896, i, 50).

Under similar conditions to the above, 3-anilino-4-hydroxy-*o*-benzoquinone (Zincke, A., 1885, 787) condenses with *o*-phenylenediamine hydrochloride; producing long, deep red needles of the *hydrochloride* of 2-*anilino-3-hydroxyphenazine*; the free base forms brownish-red needles, decomp. above 200°.   Condensation with phenyl-*o*-diphenylenediamine gave rise to two products which are probably 3-anilino-2-hydroxy-10-phenylphenazonium chloride and 2-anilino*aposafranone*,

$$\text{C}_6\text{H}_4 \diagdown^{\text{------N}}_{\text{NPh}} \diagup \text{C}_6\text{H}_2(\text{NHPh})\text{O},$$

The constitution of the above dianilino-*o*-benzoquinone is demon-strated by hydrolysis with dilute solutions of alkali, which gives rise to the *s*-dihydroxyquinone of Nietzki and Schmidt (A., 1888, 1181). Of the three possible isomerides having the composition of a dianilino-quinone, two are already known, so that to this third isomeride is to be ascribed the remaining structure, 4 : 5-dianilino-*o*-benzoquinone.

                                        D. F. T.

Purines. XII. Carl O. Johns and Emil J. Baumann (*J. Biol. Chem.*, 1913, **15**, 515—521. Compare this vol., i, 774, 1000).— 5-Amino-6-ethylamino-2-hydroxy-4-methylpyrimidine reacts smoothly with the reagents commonly used for the preparation of purines. Thus, when the formyl derivative is heated, 2-*oxy-6-methyl-9-ethyl-purine*,

$$\begin{matrix} N:CMe \cdot C—N \\ CO \cdot NH \cdot C \cdot NEt \end{matrix}\!\!>\!CH,$$

is formed. This crystallises in a net work of silky needles, which begin to melt at 256°, m. p. 275° (decomp.).

Similarly, the corresponding acetyl derivative yields 2-*oxy-6 : 8-dimethyl-9-ethylpurine*, which also forms a network of silky needles, m. p. 265° (decomp.) to a dark oil.

2-*Oxy-8-thio-6-methyl-9-ethylpurine* is formed when the diamino-pyrimidine is heated with thiocarbamide; it crystallises in colourless sheaves, decomp. 295—300°. When the components are mixed in hot water, a thiocarbamide additive product of the pyrimidine is obtained; this has m. p. 204—206° (decomp.), and gives the thiopurine when heated.

The thiopurine reacts with monochloroacetic acid, forming 2-*oxy-6-methyl-9-ethylpurine-8-thiolacetic acid*,

$$\begin{matrix} N:CMe \cdot C—N \\ CO \cdot NH \cdot C \cdot NEt \end{matrix}\!\!>\!CS \cdot CH_2 \cdot CO_2H.$$
This separates as a bulky mass of needles, which darken at 270°. It is stable in hot water, but boiling with concentrated hydrochloric acid hydrolyses it to 2 : 8-dioxy-6-methyl-9-ethylpurine.

The action of thiophosphoryl chloride on 4 : 5-diamino-6-hydroxy-2-methylthiolpyrimidine converts it into 6-*oxy-8-thio-2-methylthiolpurine*,

$$\begin{matrix} NH \cdot CO \cdot C \cdot NH \\ SMe \cdot C—N—C \cdot NH \end{matrix}\!\!>\!CS.$$

This separates in small globules, which begin to decompose at 275°, and give the murexide test. E. F. A.

Purines. XIII. 2 : 8-Dioxy-1 : 6-dimethyl-1 : 2 : 8 : 9-tetra-hydropurine and 5-Nitro-3 : 4-dimethyl-1 : 2 : 3 : 6-tetrahydro-pyrimid-2 : 6-dione (α-Nitrodimethyluracil). Carl O. Johns and Emil J. Baumann (*J. Biol. Chem.*, 1913, **16**, 135—142).—Methyl sulphate and an aqueous solution of the sodium salt of 5-nitro-6-amino-4-methyl-2 : 3-dihydro-2-pyrimidone react at the ordinary temperature to form, in 80% yield, 5-*nitro-6-amino-3 : 4-dimethyl-2 : 3 - dihydro-2-pyrimidone*,

$$CO\!\!<\!\!\begin{matrix} N:C(NH_2) \\ NMe \cdot CMe \end{matrix}\!\!>\!C \cdot NO_2,$$

decomp. 170—195°, prisms containing $\frac{1}{2}H_2O$. The position of the new methyl group is established as follows. By heating with 25% sulphuric acid at 160°, the substance is converted into 5-*nitro-3 : 4-dimethyl-1 : 2 : 3 : 6-tetrahydropyrimid-2 : 6-dione*,

$$CO\!\!<\!\!\begin{matrix} NH—CO \\ NMe \cdot CMe \end{matrix}\!\!>\!C \cdot NO_2,$$

m. p. 191°, slender prisms (the only other possible 5-nitrodimethyl-1 : 2 : 3 : 6-tetrahydropyrimid-2 : 6-dione is Lehmann's 5-nitro-1 : 4-dimethyl-1 : 2 : 3 : 6-tetrahydropyrimid-2 : 6-dione, m. p. 149°), which is oxidised by nitric acid, D 1·5, and concentrated sulphuric acid on the water-bath to 5-nitro-3-methyl-1 : 2 : 3 : 6-tetrahydropyrimid-2 : 6-dione-4-carboxylic acid, which cannot be

isolated, since it loses carbon dioxide and changes to Behrend's 5-nitro-3-methyl-1 : 2 : 3 : 6-tetrahydropyrimid-2 : 6-dione, m. p. 255°.

The reduction of 5-nitro-6-amino-3 : 4-dimethyl-2 : 3-dihydro-2-pyrimidone by aqueous ammonia and ferrous sulphate produces 5 : 6-*diamino-3 : 4-dimethyl-2 : 3-dihydro-2-pyrimidone*, $C_6H_{10}ON_4$, decomp. about 230°, colourless plates, in 40% yield ; the latter and an equal weight of carbamide at 170—180° produce 2 : 8-*dioxy-1 : 6-dimethyl-1 : 2 : 8 : 9-tetrahydropurine*,

$$\begin{array}{c} \text{NMe·CMe:C·NH} \\ \vert \qquad\qquad\qquad \rangle\text{CO, decomp. 260—265°,} \\ \text{CO—N=C·NH} \end{array}$$

prisms containing H_2O ; by evaporating the latter with nitric acid and treating the yellow residue with an alkali, a rose coloration is developed.   C. S.

Bistetrazole and Isomeric Derivatives of Tetrazole. E. OLIVERI-MANDALÀ and T. PASSALACQUA (*Gazzetta*, 1913, **43**, ii, 465—474. Compare A., 1912, i, 144).—When cyanotetrazole (*loc. cit.*) is further acted on with azoimide, or when cyanogen is passed into an aqueous solution of azoimide as in the experiment formerly described, but using a more concentrated solution, bistetrazole and the amide of tetrazolecarboxylic acid are produced in addition to cyanotetrazole, which still forms the chief product of the reaction. Saponification of the cyanotetrazole yields (by way of the unstable carboxylic acid) tetrazole, and this is the best way of preparing this substance. The preparation is conveniently carried out by heating the sodium salt described below with hydrochloric acid, evaporating to dryness, and extracting the tetrazole with warm acetone. *Bistetrazole* (annexed formula) forms prismatic crystals, m. p. 254—255° (decomp.). Bistetrazole and especially its *silver* salt are explosive. The substance has about the calculated molecular weight in freezing water. The *barium* salt, $C_2N_8Ba,3H_2O$, was prepared. Bistetrazole is decomposed by warm, concentrated sulphuric acid according to equation : $C_2H_2N_8 + 2H_2O + O_2 = 3N_2 + 2CO_2 + 2NH_3$, so that the sulphuric acid acts as an oxidiser.
$$\begin{array}{c} \text{N=C—C=N} \\ \vert \quad\; \vert \quad\; \vert \quad\; \vert \\ \text{HN} \;\; \text{N} \;\;\; \text{N} \;\; \text{NH} \\ \diagdown\!\diagup \quad \diagdown\!\diagup \\ \text{N} \qquad\; \text{N} \end{array}$$

The above-mentioned *tetrazole-5-carboxylamide*, $C_2H_3ON_5$, has m. p. 234° (decomp.). *Sodium 2-sodiotetrazole-5-carboxylate*, $C_2O_2N_4Na_2$, is obtained by saponification of the amide or of the cyanotetrazole. The *barium* salt has the composition $C_2N_4O_2Ba,3\frac{1}{2}H_2O$.

5-Cyano-2-methyltetrazole, $C_3H_3N_5$, b. p. 100—102°/16 mm., is obtained by boiling the silver salt of 5-cyanotetrazole with an ethereal solution of methyl iodide. When it is saponified with alcoholic sodium hydroxide, the *sodium* salt of the corresponding acid, $C_3H_3O_2N_4Na$, is produced, and from this the free 2-*methyltetrazole-5-carboxylic acid*, $C_3H_4O_2N_4$ (prisms, m. p. 204—205°, losing CO_2), can be prepared. When this acid is heated at its m. p., 2-*methyltetrazole*, $C_2H_4N_4$, b. p. 145—147°/759 mm., is obtained.

When the silver salt of tetrazole and ethyl iodide are heated in benzene solution for some hours, 2-ethyltetrazole and 1-ethyltetrazole are produced. 2-*Ethyltetrazole*, $C_3H_6N_4$, has b. p. 70—71°/35 mm., or

152—155° at ordinary pressure. 1-*Ethyltetrazole*, $C_3H_6N_4$, has b. p. 162—164°/30 mm. R. V. S.

The Hydrolytic Constants of Some Derivatives of Tetrazole. E. OLIVERI-MANDALÀ (*Gazzetta*, 1913, **43**, ii, 487—493. Compare preceding abstract).—Measurements of the catalysis of methyl acetate give the following values for the constants of hydrolysis : 2-methyltetrazole, 0·00026 ; 1-methyltetrazole, 0·000047 ; 2-ethyltetrazole, 0·00049 ; 1-ethyltetrazole, 0·00014. R. V. S.

Action of Nitrogen Peroxide on Aliphatic Diazo-compounds and on Tetrazens. HEINRICH WIELAND and CURT REISENEGGER (*Annalen*, 1913, **401**, 244—251).—Ethyl diazoacetate and nitrogen peroxide react in cold benzene to form ethyl dinitroacetate and nitrogen, ethyl furoxandicarboxylate being obtained as a by-product. Similarly, at the ordinary temperature, nitrogen peroxide and diazodeoxybenzoin yield ωω-dinitrotoluene, probably by the decomposition of the initially formed benzoyl derivative.

Nitrogen peroxide and diphenyleneazomethylene (Staudinger and Kupfer, A., 1911, i, 751) react in cold benzene in the absence of moisture to form nitrogen and 9 : 9-*dinitrofluorene*, $\begin{matrix} C_6H_4 \\ C_6H_4 \end{matrix}\!>\!C(NO_2)_2$, m. p. 128° (decomp.), colourless needles, which yields fluorenone above its m. p.

Nitrogen peroxide and tetraphenyltetrazen in cold benzene yield a deep green solution of an additive compound, which decomposes at the ordinary temperature with the formation of pp′-*dinitrotetraphenyltetrazen*, $NO_2 \cdot C_6H_4 \cdot NPh \cdot N\!:\!N \cdot NPh \cdot C_6H_4 \cdot NO_2$, decomp. 160°, orange-yellow crystals.

The substance is proved to be a tetrazen by the liberation of nitrogen and the production of an intensely blue solution by treatment with concentrated sulphuric acid ; the positions of the nitro-groups are proved by reduction, whereby ammonia and *p*-aminodiphenylamine (2 mols.) are produced. In a similar reaction, nitrogen peroxide and diphenyldiethyltetrazen yield *di*-p-*nitrophenyldiethyltetrazen*, $C_{16}H_{18}O_4N_6$, orange-red needles, which is converted into *p*-phenylene-ethyldiamine by reduction. C. S.

The Real Nature of the So-called Artificial Globulin. HUBERT W. BYWATERS and D. G. C. TASKER (*J. Physiol.*, 1913, **47**, 149—158) —Several observers have stated that on keeping, the serum albumin in blood and urine is converted into globulin. The artificial product when analysed is found not to be identical with the natural globulin, but it is really alkaline meta-protein. W. D. H.

Colloidal Properties of Hæmoglobin. Modifications of the Viscosity and Surface Tension of Suspensions of Methæmoglobin by the Action of Hydrochloric Acid or Sodium Hydroxide. II. FILIPPO BOTTAZZI (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 263—270).—The viscosity and surface tension of aqueous suspensions of methæmoglobin (compare this vol., i, 1249), previously

purified by dialysis for four months or longer, differ little from those of distilled water. When the methæmoglobin is brought into solution by means of hydrochloric acid or sodium hydroxide, increased viscosity and diminished surface tension are shown by the liquid, which is at first a suspension solution and finally yields a perfect solution. Continued addition of acid or alkali does not lower the surface tension beyond a certain value, which seems to be independent of the concentration of the dissolved methæmoglobin so long as this lies within certain limits; neutralisation of the acid (alkali) with an equal volume of alkali (acid) causes precipitation of the methæmoglobin and increase of the surface tension.

The increased velocity caused by hydrochloric acid diminishes considerably when excess of acid is added, and tends to return to its original value, although no precipitation occurs. This seems to be due to the influence of the acid in lowering the dissociation of the methæmoglobin chloride, and hence the concentration of the methæmoglobin ions, on which the increased viscosity depends.

Addition of sodium chloride to solution of sodium methæmoglobinate produces a further small, constant diminution in the surface tension, although the salt has no appreciable effect on a solution of pure methæmoglobin (compare Bottazzi and d'Agostino, this vol., ii, 115).

T. H. P.

Action of Quinones on Wool and Other Protein Substances. LOUIS MEUNIER (*Zeitsch. angew. Chem.*, 1913, **26**, 616).—The results described by Scharvin (this vol., i, 661) have already been published by Meunier and incorporated in certain patents (compare A., 1908, i, 586, and D.R.-P. 240512).   J. C. W.

Products of Hydrolysis of Thynnine and Percine. ALBRECHT KOSSEL and F. EDLBACHER (*Zeitsch. physiol. Chem.*, 1913, **88**, 186—189).—Thynnine yields an aminovaleric acid, proline, and tyrosine on hydrolysis. The same acids were obtained from percine. Acids of the C_5-series play the chief part in the constitution of the protamines, C_6-acids being only occasionally present. The latter play the more important part in the higher proteins.   E. F. A.

The Stability of Invertase. CARL NEUBERG (*Biochem. Zeitsch.*, 1913, **56**, 495—497).—The invertase was found to be still intact in an expressed yeast juice which had been allowed to autolyse for 470 days.   S. B. S.

Amylases. VI. A Comparison of Amyloclastic and Saccharogenic Powers. HENRY C. SHERMAN and M. D. SCHLESINGER (*J. Amer. Chem. Soc.*, 1913, **35**, 1784—1790).—In the investigation of the action of amylase on starch, the amount of reducing sugar produced is not always proportional to the amount of starch apparently digested.

The authors find that with specimens of pancreatic amylase the amount of starch apparently digested (amyloclastic power) is about twice the amount of maltose produced (saccharogenic power), whilst

with malt amylase the ratio of maltose formed to st irch apparently
digested is much higher ; indeed, with some specimens of the latter,
the amount of maltose exceeds the quantity of starch apparently
digested. The application of the starch-iodine coloration is therefore
evidently not well adapted for the measurement of the starch-digesting
power of malt amylase.   D. F. T.

**Amylases. VII. The Forms of Nitrogen in Amylase
Preparations from the Pancreas and from Malt, as Shown
by the Van Slyke Method.** HENRY C. SHERMAN and A. O.
GETTLER (*J. Amer. Chem. Soc.,*. 1913, **35**, 1790—1794).—Analysis
has been made of various specimens of pancreatic and malt amylase by
the Van Slyke method, and the results as to the nature and relative
quantity of the hydrolytic products indicate that the amylase pre-
parations used were essentially protein substances. All the eight
forms of nitrogen recognisable by the Van Slyke method were present,
the proportions being within the range of variation shown by typical
protein substances.   D. F. T.

The Partial Purification of the Esterase from Pig's Liver.
GEORGE PEIRCE (*J. Biol. Chem.*, 1913, **16**, 1—3).—Pig's liver was
ground up, strained, and water added, incubated at 37° for one day,
and, after remaining several weeks at room temperature, was filtered.
This crude enzyme solution was dialysed and filtered ; dialysis removed
about 90% of the solids, and the solution lost about 20% of its activity.
Ammonium sulphate was then added nearly to half saturation and the
liquid filtered. The precipitate was inactive. The filtrate was then
fully saturated with the same salt, and filtered ; the filtrate was inactive.
The precipitate was then dissolved in water and dialysed until free
from sulphate. This represents the most highly purified solution
obtained ; it was very active ; no attempt was made to obtain a solid
from it.   W. D. H.

**The Compound Formed between Esterase and Sodium
Fluoride.** GEORGE PEIRCE (*J. Biol. Chem.*, 1913, **16**, 5—18).—The
compound formed between esterase (from pig's liver) and sodium
fluoride has little if any action on ethyl butyrate. The formation of
this compound is reversible. When the concentration of the fluoride
is varied from 0·009 to 0·27 mg. per litre, the inhibition increases
from 20 to 88%. The inhibiting effect hardly varies at all with the
concentration of the enzyme. The conclusion is drawn that one mole-
cule of the inactive compound contains 1 molecule of enzyme and
1 molecule of sodium fluoride.   W. D. H.

The Stability of Carboxylase. CARL NEUBERG (*Biochem. Zeitsch.*,
1913, **56**, 497—498).—In a maceration juice prepared from an old
dried yeast obtained by Lebedev's method, the carboxylase was found
to be active when the zymase was no longer existent. The former
ferment appears, therefore, to be the more stable.   S. B. S.

Mercury Naphthalene Derivatives. JOHANNES GADAMER [with
R. BRIEGER and WERNER SCHULEMANN] (*Zeitsch. anyew. Chem.*, 1913,
26, 627—631).—A lecture delivered before the Verein deut. Chemiker

at Breslau. Some mercury compounds of substituted naphthalenes are discussed, and it is shown how their unusual behaviour and incoustant composition may be explained by considering the residual affinities of the atoms and groups involved.

When the sodium salt of 8-amino-1-naphthol-3 : 5-disulphonic acid (K-acid). is digested with mercuric acetate, a bright red mercuriated substance is obtained. From its method of formation and its colour, it might be expected that the mercury is attached to a carbon atom, but the fact that ammonium sulphide causes precipitation of mercuric sulphide suggests that the metal is linked with nitrogen. The colour was destroyed by the addition of alkali or sodium chloride, but was reproduced on acidifying with a mineral acid. The varying mercury-content of the product suggested that not a chemical, but rather an adsorption, compound was present, but the fact that salt or strong acetic acid decolorised solutions of the substance is not in harmony with this view.

The influence of various substituents in the naphthalene nucleus was studied, and the following conclusions are drawn : the presence of $-OH$ or $-NH_2$ in the β-position hinders the fixation of mercury, only one atom of which enters the ortho-position ; the presence of $-OH$ or $-NH_2$ in the α-position permits of the entry of two mercury atoms in the ortho- and para-positions, giving compounds which are stable towards ammonium sulphide, but tend to form unstable, coloured quinonoid compounds in the presence of reagents which reduce the acidity of their solutions ; when attempts are made to introduce more mercury into naphthol derivatives, alkali is found to remove the excess of mercury as the hydrosol of the hydroxide, but the naphthylamines can loosely fix more mercury, giving substances which are turned deep red by alkalis and decomposed by ammonium sulphide ; sulphonic acid groups render the mercury compounds more unstable.

In K-acid, the various effects indicated above are cumulative. These effects are discussed on theoretical grounds, and it is explained why these naphthalene derivatives can form compounds with indefinite quantities of mercury, in which there is no distinction between true chemical combination and adsorption.   J. C. W.

Physiological Chemistry

Water in Expired Air. WILLIAM OSBORNE (*Proc. physiol. Soc.,* 1913, xii ; *J. Physiol.,* 47).—Galeotti states that the expired air is not fully saturated with aqueous vapour, but only about three-quarters saturated. Loewy and Gerhartz point out that this is incorrect, for the temperature of expired air is not 37°, but between 32·5° and 33·5°. The present experiments confirm the latter view, and the correct theoretical figures were obtained if the

temperature is assumed to be 33·9°. The experiments were made on men in whom loss of water by the skin was prevented by a rubber suit. Such experiments are only safe in winter, as a dangerous fever may arise if the external air is too warm.

W. D. H.

Acidosis. ERNEST L. KENNAWAY, MARCUS S. PEMBREY, and EDWARD P. POULTON (*Proc. physiol. Soc.*, 1913, x—xi; *J. Physiol.*, 47).—In healthy men the value of the alveolar carbon dioxide pressure may fall below the normal (40 mm.) if carbohydrate food is withheld; in diabetes it may be normal; the determining factor is the extent of acidosis. It falls suddenly one or two days before the onset of fatal coma; a value of 25 is grave; one of 20 means that coma is imminent. Estimation of the acetone substances is not such a good guide, and suggestions are put forward to explain variations in the ratio between these substances. Their equilibrium point is probably connected with the degree of acidosis, and the high proportion of β-hydroxybutyric acid in marked cases may be due to a washing out of acetone from the blood by the increased pulmonary ventilation.

W. D. H.

The Carbon Dioxide and Oxygen Content of the Blood after Clamping the Abdominal Aorta and Inferior Vena Cava Below the Diaphragm. JOHN R. MURLIN, LEO EDELMANN, and B. KRAMER (*J. Biol. Chem.*, 1913, 16, 79—101).—The changes found are consistent with the mechanical explanation of the altered respiratory quotient after clamping the vessels. When the quotient rose, the carbon dioxide of the blood fell; when it remained stationary, the carbon dioxide did not change; when it fell, the carbon dioxide rose. Clamping off the blood from the abdominal organs therefore does not alter the character of the metabolism.

W. D. H.

The Dissociation of Carbon Dioxide from Human Blood. JOHANNE CHRISTIANSEN, CLAUDE G. DOUGLAS, and JOHN S. HALDANE (*Proc. physiol. Soc.*, 1913, ii; *J. Physiol.*, 47).—The experiments here briefly referred to show that the effect of oxygen on the carbon dioxide-carrying power of the blood is even more important than the well-known effect of carbon dioxide on its oxygen-carrying functions.

W. D. H.

The Combination of Hydrogen Arsenide in the Blood. RICHARD MEISSNER (*Chem. Zentr.*, 1913, ii. 705—706; from *Zeitsch. expt. Path. Ther.*, 1913, 13, 284—300).—The absorption capacity of the various constituents of blood for the gas was estimated by Reckleben and Lockemann's method. All solutions or suspensions were shaken for the same period with the same amount of the arsenic compound. The various lipoids in suspension or in ether and chloroform solution have practically no combining capacity in quantities in which they occur in the blood. Even the brain can combine with no more hydrogen arsenide than can physiological

saline in which it is suspended. Of the other constituents, hæmatin possesses a marked combining capacity, and blood containing carbon monoxide is less liable to hæmolysis by the arsenic compound than normal blood. The combining capacity of the iron-free hæmatoporphyrin is much smaller than that of hæmatin. It appears that the iron plays some part in the combination of the various iron compounds investigated; only sodium nitroprusside evinced any marked combining capacity, for it yielded with hydrogen arsenide a solid substance containing both iron and arsenic. The antagonistic action of various substances to hydrogen arsenide poisoning was also investigated. Cholesterol and iodipin were without effect. Various colloidal silver and mercury preparations were also tried, but, although they combine with the arsenic compound, they were too toxic to the kidneys for *intra vitam* use. Of the other substances investigated, only cadmium chloride exhibited a high combining capacity. The *in vitro* action of the hydrogen arsenide on blood gives a product with a spectrum similar to thiomethæmoglobin.   S. B. S.

The Fermentative Properties of Blood. II. The Peptolytic Ferments of Normal Animals. LUDWIG PINCUSSOHN and HELLMUTH PETOW (*Biochem. Zeitsch*, 1913, **56**, 319—329).—In continuation of the work of Pincussohn (this vol., i, 788), many examples are given to illustrate the fact that the sera of animals are capable of degrading the peptones prepared (by sulphuric acid method) from the proteins of their own organs, but not from the organs of other animals and foreign proteins. An exception was found in the case of guinea-pig serum, and attention is called to the fact that this serum is used generally for supplying the complement in various hæmolytic systems. Guinea-pig's serum also degrades silk peptone. The serum also degrades peptones prepared from the organ proteins of closely allied species. Thus the serum from the fox also degrades peptones prepared from the organs of dogs, and dog's serum degrades peptones derived from fox tissues, but not from those of any other animals. The method may therefore be applied for determining the relationship of various species.

                                                    S. B. S.

Phosphatides of the Stromata of the Red Blood Corpuscles of Sheep and Man. M. BÜRGER and H. BEUMER (*Biochem. Zeitsch.*, 1913, **56**, 446—456).—The stromata of sheep were precipitated by carbon dioxide from the lysed blood and dried. They yielded an ethereal extract, which consisted, to the extent of 70%, of cholesterol The residue, after extraction with ether, was partly soluble in alcohol at 37°. Of the alcoholic extract, part remained insoluble after treatment with ether. This was obtained in the form of a white powder of stearin-like consistency, which swelled on treatment with water, and had m. p. 180—185°. Its analysis indicated a diaminomonophosphatide, similar in its properties to the myelins. Of the ether-soluble portion of the alcoholic extract, the greater part was precipitable by acetone, and of the acetone

precipitate, part was insoluble in hot alcohol, although soluble in ether and chloroform. This was a monophosphatide with the properties of a kephalin. The stromata of sheep's corpuscles contain therefore about 5% cholesterol and 12% phosphatides, of which about half is sphingomyelin, and kephalin is a constituent of the remainder. The blood of normal individuals and of carcinomatous individuals (drawn in the latter case from the cadaver) was examined in a similar manner to that employed in the case of sheep's blood. No essential differences in the chemical composition of the stromata of normal and cancerous individuals could be found, the ethereal extract containing 71·6 and 74% of cholesterol, and the alcoholic extracts 35 and 31% of sphingomyelin. There was isolated, in addition to kephalin, from the acetone precipitate from human blood small quantities of a phosphatide with 3·3% phosphorus and 4·33% nitrogen, which yielded a clear solution in water, but was insoluble in hot alcohol and ether.   S. B. S.

Distribution of Ions in the Blood Serum. PETER RONA and PAUL GYÖRGY (*Biochem. Zeitsch.*, 1913, **56**, 416—438).—According to Zuntz and Hamburger, part of the sodium of the serum is non-diffusible, as it is in combination with the proteins. On treatment of the serum with carbon dioxide, part of this sodium should be convertible into sodium hydrogen carbonate. If therefore, serum treated with carbon dioxide is submitted to dialysis (by the compensation method repeatedly used by Rona), the outer liquid should contain more sodium hydrogen carbonate than the dialysate of a serum which has not been so treated. This was actually found to be the case, and the results confirm the statements of Zuntz. The carbon dioxide should, however, convert the serum proteins into a carbamic acid derivative. There would therefore exist in the dialysor sodium salt of a non-diffusible acid. Attention is called to the fact that, according to Donnan's theory (A., 1911, ii, 848), arrived at by thermodynamic considerations, the amount of sodium hydrogen carbonate on both sides of the dialysing membrane will not be the same when equilibrium is established, for on one side there is an electrolytically dissociated substance with a non-dialysable ion. The sodium hydrogen carbonate in the dialysor could not be estimated in a satisfactory manner by incineration. The contents were therefore submitted to ultra-filtration in a Bechhold apparatus, and the filtrate was analysed. The distribution of the chlorine was also investigated, when the [H·] concentration of the serum was altered by the addition of acetic acid. In concentration above $H\cdot = 10^{-5}$, equilibrium exists with a higher concentration of chlorine inside than outside the membrane, whereas in lower [H·] concentrations the reverse is the case. The critical point of change is the isoelectric point, through which the protein changes from the anionic to the cationic state. The Donnan theory is also applicable in this case to the determination of the distribution of the chlorine.   S. B. S.

Salts in the Coagulation of Blood. C. GESSARD (*Compt. rend.*, 1913, **157**, 799—802).—A study of the influence of various salts

on the blood of a horse. The amount of salt necessary to prevent coagulation varied with the salt employed, and the plasma obtained could be made to coagulate according to the kind and amount of salt used either by dilution or by addition of a calcium salt, or by addition of serum. Magnesium chloride and sulphate are the most appropriate for the study of these phenomena, since they do not precipitate calcium salts, give no apparent reaction with the saline constituents of blood, and for small differences in weight give different types of plasma.   W. G.

The Inactivation of Complement by Mechanical Agitation. HANS SCHMIDT (*J. Hygiene*, 1913, **13**, 291—313).—The complement in serum is inactivated by shaking. This does not seem to be associated with the precipitation of protein, which also occurs. No explanation of the inactivation is at present forthcoming.
                                                    W. D. H.

Complement Action in Regard to Surface Tension. HANS SCHMIDT (*J. Hygiene*, 1913, **13**, 314—334).—No relationship between the surface tension and complement action of serum was found.
                                                    W. D. H.

The Rate of Elimination of Nitrogen as Influenced by Diet Factors. I. The Influence of the Texture of the Diet. LAFAYETTE B. MENDEL and ROBERT C. LEWIS (*J. Biol. Chem.*, 1913, **16**, 19—36).—A standard diet was arbitrarily selected for dogs, and a constant curve of nitrogen elimination was obtained. This shows a rise reaching a maximum in the second three hours, and then a fall to the initial level early the next day. Delay in elimination is caused by adding indigestible materials, such as mineral oil, vaselin, bone ash, paraffin, filter paper, cork, agar-agar; the effect increases in the order these are enumerated. The last four cause a higher rate of elimination in the later periods. This is attributed to a slower rate of absorption, which in its turn may be produced by (1) rapid emptying of the stomach, and a consequent early exclusion of gastric digestion; (2) the indigestible material may make the digestible material less readily accessible to digestive enzymes; or (3) the final digestion products may be adsorbed by the indigestible substances. Sand gives exceptional results; it causes more rapid elimination of nitrogen during the first six hours. This is not due to increased excretion and reabsorption of digestive juices, for in starvation it has no effect.   W. D. H.

The Rate of Elimination of Nitrogen as Influenced by Diet Factors. II. The Influence of Fats and Carbohydrates in the Diet. LAFAYETTE B. MENDEL and ROBERT C. LEWIS (*J. Biol. Chem.*, 1913, **16**, 37—53).—Carbohydrates delay the elimination of nitrogen when added to a protein meal; their effect increases in the order: starch, soluble starch, sucrose, dextrose. This may be explained by the tentative suggestion that it is due to the protein-sparing action of carbohydrates. In reference to fats, cottonseed oil delays

the elimination of nitrogen, but lard and "oleo-stearin" hasten it in the early periods. The last-named effect is, however, only due to removal of sucrose from the diet. ` W. D. H.

The Rate of Elimination of Nitrogen as Influenced by Diet Factors. III. The Influence of the Character of the Ingested Protein. LAFAYETTE B. MENDEL and ROBERT C. LEWIS (*J. Biol. Chem.*, 1913, **16**, 55—77).—Extracted meat lowers the rate of nitrogen elimination; the explanation advanced is that extracted meat contains relatively more connective tissue, and therefore is not so digestible. The curves following the ingestion of caseinogen, ovovitellin, edestin, "glidine," and gelatin show no more differences than those noted in the two meat products. Egg-white or albumin and soy bean give different curves due to rate of digestion and absorption, or, in the case of soy bean, to the presence of sucrose. Proteins do not differ materially in their rate of metabolism. The opposite findings of others are discussed. W. D. H.

The Metabolism of Infants During Starvation. ARTHUR SCHLOSSMANN and HANS MURSCHHAUSER [and, in part, KARL MATTISON] (*Biochem. Zeitsch.*, 1913, **56**, 355—415).—The authors, in confirmation of their previous investigations, show that the metabolism during starvation depends on the diet consumed in the period preceding the fast, and that the more nitrogen consumed during the period the greater is the amount of body protein decomposed during the first two or three days of starvation. Similar results were obtained in the case of infants. The breast-fed children metabolise less nitrogen than the artificially fed. There is, however, a marked difference between the metabolism of the two classes during starvation, for whereas the artificially fed children excrete less nitrogen during the period of fast than during the nutrition period, the reverse is the case with the breast-fed infants. In spite of this fact, however, the breast-fed children still excrete less nitrogen during the starvation period than the hand-fed children, and the authors draw the conclusion that the former are more capable of resisting the effects of deprivation of food. The excretion of the acetone substances during starvation was also investigated. The amount excreted rapidly increased in the second day of hunger, running nearly parallel with the increased output of nitrogen in the case of the breast-fed children. In the case of the hand-fed children, the acetone substances increased with diminishing nitrogen output. A few measurements of the respiratory exchanges were also made by the authors. S. B. S. `

The Method and Places of Formation of Conjugated Glycuronates in the Organism. JUHO HÄMÄLÄINEN (*Chem. Zentr.*, 1913 ii, 1319—1320; from *Skand. Arch. Physiol.*, 1913, **30**, 196—198).—The small intestine of a rabbit under ether narcosis, after washing, was perfused with Ringer's fluid from the mesenteric artery to the portal vein. *a*-Santenol and dextrose were then injected into the intestine. After six hours' perfusion, the per-

fusion fluid and intestinal contents were examined, and a non-crystalline substance with the properties of α-santanolglucoside was isolated. Glucoside formation appears to take place therefore in the intestinal wall.   S. B. S.

Fat Absorption by the Gastric Mucosa. CHARLES W. GREENE and WILLIAM F. SKAER (*Amer. J. Physiol.*, 1913, **32**, 358—368).— Evidence is adduced that absorption of fats occurs in the stomach of mammals (cats, dogs, rats). The gastric epithelium contains fat even in fasting; this is increased by feeding on fats. The fat in the gland cells, especially in the pyloric region, may be increased by fasting. This has no relation to absorption fat, but is due to mobilisation of the body fat. The observations throughout are histological.   W. D. H.

The Processes of Absorption in the Intestine. N. A. DOBROWOLSKAJA (*Biochem. Zeitsch.*, 1913, **56**, 267—290).—The author discusses the various views as to the method of utilisation of the proteins in the organism, including those of Heidenhain, Hoffmeister, Abderhalden, etc., and attempts by various experimental methods to throw some light on the mechanism. In the first series of experiments, he analyses the serum of portal blood of dogs, estimating the changes of total non-protein nitrogen, and the amino- and peptide-nitrogen produced by the introduction of the chymus obtained from intestinal fistulæ of other animals into the small intestines. No definite results were obtainable by this method, as it was shown that the operative procedure alone, without introduction of digestion products, produced changes in the composition of the serum of the experimental animals. In a second series of experiments, the *in vitro* changes on the amino-nitrogen produced by serum, intestinal extracts, pancreas, etc., on amino-acids and digestion product of proteins, were investigated. The results again lead to no definite conclusions, in some cases indicating synthesis, and in others peptide degradation. In the third series of experiments, an anastomosis was made between the portal vein and the kidneys by the junction of the central end of the *vena lienalis* with the peripheral end of the renal artery. It was assumed that, in the event of introduction of digestion products in the intestine, and a consequent resorption of amino-acids into the portal vein, the excess would be eliminated by the kidneys. To increase the pressure in the kidneys, the portal vein was partly constricted above the junction with the *vena lienalis*. In the majority of cases, the kidney not connected with the portal vein was extirpated. In all of these cases, the animals died. In two cases, when the second kidney was left intact, a certain number of experiments were performed, and the nitrogen of the amino-groups, the hippuric acid, and ammonia nitrogen of the urine excreted were estimated. The introduction of nitrogen into the alimentary tract (by feeding) lead in many cases, especially that of alanine, to an increased amino-nitrogen in the urine. Owing to the fact that the second kidney was intact, these experiments could hardly be considered

satisfactory. In the fourth series of experiments, a portal vein fistula was made according to the method of London and the author, and blood was removed by way of the fistula at various periods after feeding. The results showed a periodic fluctuation in both the portal blood and the blood of the general circulation (removed from the jugular vein). The general result of the experiments is to indicate the difficulty of artificially increasing the amino-nitrogen of the portal vein under conditions approaching the normal physiological. S. B. S.

The Indispensability of Lipoids for Life. The Relation of the Necessary Substances to the Lipoid Extracting Agents. WILHELM STEPP (*Zeitsch. Biol.*, 1913, 62, 405—407 Compare A., 1911, ii, 1002).—This is a continuation of the author's previous work on mice. A mixture of lecithin, cholesterol, kephalin, cerebron, and phytin added to a diet freed from lipoids by alcohol-ether extraction, does not supply the missing necessary material. If the primary acetone extract of egg-yolk is added to lipoid-free food, the result is that the necessary material is still lacking; the same is true for the secondary alcoholic extract. But the primary alcoholic extract restores the value of the lipoid-free food. The materials necessary for life are therefore soluble in alcohol, but not in acetone. If the material is extracted with acetone first, part only of the indispensable material goes into solution; the acetone-soluble substances are soluble also in alcohol. Extraction with ether does not remove the indispensable material; fat is therefore for the mouse not indispensable. Extraction of the food with alcohol entirely removes its power to support life. W. D. H.

Are there Substances at Present Unknown in Food-stuffs which are of Importance for the Maintenance of Life? EMIL ABDERHALDEN and ARNO E. LAMPÉ (*Chem. Zentr.*, 1913, ii, 522—523; from *Zeitsch. gesamte. expt. Med.*, 1913, 1, 296—354).—As a result of a critical experimental investigation on a broad basis of the work of Suzuki, Shimamura and Odake, and of Funk and others, the authors draw the conclusion that up to the present time there has been no absolute proof of the existence of unknown substances in foods, of general significance, which are essential to the maintenance of life. They do not consider that the action of the so-called oryzanin of the Japanese authors, or of Funk's vitamine, has as yet been definitely established. S. B. S.

The Biological Significance of the Fat-content of Fish, with Special Reference to their Habitat. OSW. POLIMANTI (*Biochem. Zeitsch.*, 1913, 56, 439—445).—Attention is called to the fact that during the development of fish embryos, the amount of visible fat diminishes, during which time the habitat gradually alters from that of an organism living on the surface of the water to one living deeper in the sea. It seemed therefore possible that the nectonic fish, which move rapidly about the surface, should contain more fat than the less active, more slowly moving, benthonic fish. Numerous analyses of various species were carried

out, which tend to confirm the above theory, the fat varying from 1·115 to 20·447% of the solid substance. S. B. S.

Proteins of Fish Sperm. ALBRECHT KOSSEL (*Zeitsch. physiol. Chem.*, 1913, **88**, 163—185).—The protamines from the sperm of a number of species of fish have been isolated and investigated. (The figures given are % of total nitrogen.)

Percine from the yellow perch (*Perca flavescens*) contains 85·5% of diamino-acid nitrogen, and 9·8% of monoamino-acid nitrogen, the former being mainly arginine (78·1%) with some histidine (5·6%). No lysine was present. The protamine from the pike perch (*Stisostedion vitreum*) proved to be identical with this.

That from the tunny (*Thynnus thynnus*) (compare Ulpiani, A., 1903, i, 215), which is termed thynnine, contains 80% of arginine nitrogen, no lysine or histidine, and 10% of monoamino-acid nitrogen. The sulphate, like that of other protamines, separates from aqueous solution as an oil. Thynnine also contains tyrosine. *Pelamys sarda* contains a very similar protamine.

The protamine of the sword fish contained 81·5% of arginine nitrogen, and 14% of monoamino-acid nitrogen. Neither histidine nor lysine were present.

The protamine of *Oncorhynchus tschawytscha*, the Chinook salmon (compare A. E. Taylor, A., 1909, i, 344), is identical with the salmine from Rhine salmon (Kossel and Dakin, A., 1904, i, 355, 702).

In the white fish (*Coregonus albus*) the proportions of arginine and monoamino-acid nitrogen are 87·3 and 9·4. In the lake trout (*Salvelinus*) they are 88·9 and 7·1, whilst in *Esocine*, the protamine of the pike (*Esox lucius*), they are 86·3 and 11·3.

In general, these protamines contain two molecules of arginine to one molecule of monoamino-acid—in a few protamines the proportion of monoamino-acids is larger. The protamines are thus to be expressed by the formula a_2m, where a is arginine, or $(alh)_2m$, when all three diamino-acids are present, the proportion of diamino-acid being again as 2 to 1.

A table is given of the known protamines and their formulæ. E. F. A.

The Lipoids of Nervous Tissue. CESARE SERONA and ANOTOINETTE PALOZZI (*Chem. Zentr.*, 1913, ii, 1064—1065; from *Arch. Farm. sperim.*, 1913, **15**, 375—384).—The composition of the brain (white and grey matter) of ox and calf was as follows: 14·25—16·13⁰/₀₀ cholesterol and the esters of cholesterinolic and palmitic acids, 39·8—44·1⁰/₀₀ oleic acid and palmitic acid lecithins, 14·6—14·8⁰/₀₀ cerebrin, and 3·76—5·8⁰/₀₀ homocerebrin or cerasin. To separate the constituents, the following process was employed. The brain was extracted with 5—6 times its weight of a mixture of equal parts of alcohol and ether. From the residue a substance could be extracted with hot alcohol with m. p. 164—165°, which had the properties of homocerebrin or cerasin. The alcohol-ether extract yielded, after evaporation of the ether, a flocculent mass A, and the alcoholic residue on evaporation, a waxy mixture B.

Each of these fractions was treated successively with cold acetone, cold ether, and hot alcohol. The acetone extract was fat-free, and contained, besides some phosphatic lipoids and cerebrin, which became insoluble on solution and reprecipitation with acetone, chiefly cholesterol and its fatty esters. The ethereal extract could be separated into two fractions, one, insoluble in cold alcohol, yielding a substance corresponding with Thudichum's and Koch's kephalin, which appears, on further investigation, to be an impure lecithin mixed with cerebrin, and a soluble fraction, consisting also chiefly of impure lecithin mixed with cerebrin. The alcoholic extract was also separated into fractions soluble and insoluble in cold alcohol. The former consisted of cerebrin, m. p. 190—192°, which on hydrolysis yielded a fatty acid, m. p. 74—75°, presumably cerebrotinic acid, and a reducing sugar with $[a]_D^{20} + 27·5°$, and a substance which is possibly galactosamine. The part soluble in cold alcohol, m. p. 160—165°, is apparently impure homocerebrin or cerasin.　　　　　　　　　　　　　　　　　　　　S. B. S.

Influence of Activity on Automatic Rhythm in Heart Muscle. GEORGE R. MINES (*Proc. physiol. Soc.*, 1913, xiii ; *J. Physiol.*, 47).—If a frog's or mammal's heart is made to beat faster, the subsequent automatic rhythm is slowed; in the octopus the reverse occurs. In both cases, forced activity leads to formation of acid, but in different hearts, and different parts of the same heart, the optimum hydrogen ion concentration is different. In some cases the increase will be towards this value, in others away from it.
　　　　　　　　　　　　　　　　　　　　　　　　　W. D. H.

Hydrogen Ion Concentrations Limiting Automaticity in Different Regions of the Frog's Heart. (Miss) DOROTHY DALE and C. R. A. THACKER (*Proc. physiol. Soc.*, 1913, i—ii ; *J. Physiol.*, 47).—The different heart chambers develop rhythm with varying degrees of hydrogen ion concentration. The sinus will beat in solutions which are too acid for the auricle, and the same holds between auricle and ventricle. Similar differences appear on the alkaline side. The actual figures are given in the paper.　　　W. D. H.

Synthetic Sugar Formation in the Artificially Perfused Liver. GUSTAV EMBDEN, ERNST SCHMITZ and MARIA WITTENBERG (*Zeitsch. physiol. Chem.*, 1913, 88, 210—245).—The perfusion fluid employed was Ringer's solution, containing in it dog's blood-corpuscles washed by centrifugalising. If the liver (dog) is freed from glycogen by phloridzin poisoning, the perfusion leads to a slight but constant formation of sugar. If then dihydroxyacetone is added, the amount of sugar formed (dextrose) is increased. The addition of dl-glyceraldehyde to the perfusing fluid increases the sugar formation greatly; this sugar is in part d-sorbose. The aldehyde appears to be directly transformed into the sugar with previous rupture into short carbon chains. Glycerol forms dextrose less than the two trioses.　　　　　　　　　　　W. D. H.

Formation of Acetoacetic Acid from Acetic Acid [in the Liver]. GUSTAV EMBDEN and ADAM LOEB (*Zeitsch. physiol. Chem.*, 1913, 88, 246—258).—A study of the formation of acetoacetic acid

in the liver indicates that it is not formed from acetic acid by oxidative changes. The presence of *n*-valeric acid or of propionic acid prevents its formation from acetic acid. Formic acid is without influence, and is but little attacked on passing it through the liver. *dl*-Lactic acid has less effect on the reaction than propionic acid.

The conversion of acetic acid into acetoacetic acid is greatly retarded when the liver is full of glycogen. The addition of glycollic acid to the blood stream increases the formation of acetoacetic acid in the liver, although to a less extent than acetic acid.

E. F. A.

The Effect of Pituitary Extract on Renal Activity. C. E. KING and O. O. STOLAND (*Amer. J. Physiol.*, 1913, **32**, 405—416).— The view is disputed that pituitrin directly stimulates the renal epithelium; the vascular changes (vaso-dilatation) are considered sufficient to account for the diuresis.   W. D. H.

The Heat-production of Fatigue and its Relation to the Production of Lactic Acid in Amphibian Muscle. RUDOLPH A. PETERS (*J. Physiol.*, 1913, **47**, 243—271).—By a modification of A. V. Hill's calorimeter it was found that the heat produced by the indirect stimulation of frog's muscles until fatigue set in has a maximum value of about 0·9 cal. per gram of muscle. The heat liberation is roughly exponential, and about 70—80% of it is liberated in the first two minutes. The figure 0·9 is about half of that obtained in chloroform rigor. No processes other than contraction arise in the production of rigor. The lactic acid figures agree with those of Fletcher and Hopkins; heat production and lactic acid liberation are intimately associated.   W. D. H.

The Presence in the Vascular Walls of a Ferment Setting Free a Reducing Sugar at the Expense of the Virtual Sugar of the Blood, and Decomposing Phloridzin. RAPHAEL LEPINE and RAYMOND BOULUD (*Compt. rend.*, 1913, **157**, 627—628. Compare this vol., i, 1274).—The experiments show the presence of a ferment in the vascular walls of the kidneys, lungs, and aorta, capable of setting free a reducing sugar in the blood, a function previously ascribed to the liver alone. The ferment is also capable of partly hydrolysing phloridzin.   W. G.

Amylogenesis and its Relation to Glycolysis in the Animal Organism. CESARE PAUERI (*Chem. Zentr.*, 1913, ii, 1316; from *Arch. Farm. sperim.*, 1913, **16**, 54—96)—From his own results and those of other investigators, the author draws the conclusion that glycogen formation is a necessary preliminary process in the utilisation of sugar in the organism, and that a disturbance of this function results in diabetes mellitus. For the treatment of this condition, therefore, substances must be employed which assist the glycogen formation. Extract of muscles and of pancreas, both alone or combined, were found to be incapable of degrading dextrose at 37°. Disappearance of this substance under these

conditions can be attributed to bacterial action. Lactic and acetic acids were formed from the sugar under the combined action of pancreas extract and micro-organisms. The formation of these acids accounts for the fact that the addition of dextrose inhibits a far-reaching putrefaction of pancreas. No alcohol could be detected as a result of the combined action of pancreas and bacteria on sugar. A fasting animal exhibited appreciable formation of glycogen in the liver. Addition of extract of pancreas did not inhibit sugar formation in the transfusion of a surviving liver.

S. B. S.

A Comparison of the Observed and Computed Heat Production of Cattle. HENRY PRENTISS ARMSBY (*J. Amer. Chem. Soc.*, 1913, **35**, 1794—1800).—Experimental evidence that in the case of men and carnivora the usual equivalence exists between chemical energy, heat energy, and mechanical energy, is already forthcoming, but hitherto such investigations have not, as a rule, included an examination of herbivorous animals.

The present paper gives an account of results obtained during the last decade on cattle (steers), and in the aggregate of fifty-seven experiments the observed heat production differs from the computed by only 0·4%. **D. F. T.**

Constituents of Animals Fats. The Fat of Cervus elaphus. ISIDOR KLIMONT and E. MEISL (*Monatsh.*, 1913, **34**, 1489—1492).— A lard from the red deer, with the following constants, has been examined: D 50°, 0·9066, acid number 20·5, saponification number 203·5, iodine number 19·3, m. p. 48° (Pohl), solidification point 47·5°. The fat was recrystallised eleven times from hot acetone, when β-palmityldistearin, m. p. 62·5—63·5°, was obtained (compare Bömer and Limprich, this vol., i, 442). **J. C. W.**

The Organic Substance in the Skeletal Tissues of Anthozoa. IV. Isolation and Identification of Bromogorgonic Acid. CARL TH. MÖRNER (*Zeitsch. physiol. Chem.*, 1913, **88**, 138—154. Compare A., 1907, ii, 283; A., 1908, ii, 310).—3 : 5-Dibromo-*dl*-tyrosine has been identified as a product of the hydrolysis of *Primnoa* gorgonin with barium hydroxide. This is the first organic bromo-compound obtained by the hydrolysis of a naturally occurring protein. The whole of the bromine present in the gorgonin molecule is not dibromotyrosine. Other products of the hydrolysis of gorgonin are tyrosine, glycine, alanine, leucine, aspartic, glutamic, and oxalic acids. **E. F. A.**

The Secretion of Cerebro-spinal Fluid. WALTER E. DIXON and WILLIAM D. HALLIBURTON (*J. Physiol.*, 1913, **47**, 215—242).—An intravenous injection of an extract of the choroid plexuses (choroid gland) produces an increased secretion of cerebro-spinal fluid, as tested by its rate of outflow through a cannula. The active principle is thermostable, soluble in water and in alcohol, and does not pass the pores of a Chamberland filter. Other effects of the

injection are increase of respiration, and a slight fall of blood-pressure. Extracts of brain produce the same effect, but less markedly; no other animal extracts act in the same way. Probably as a result of cerebral activity, some waste product acts as a hormone to stimulate the activity of the choroid cells, and from the richness of the cerebro-spinal fluid in carbon dioxide, it is suggested that one function of the fluid may be to enable the brain to get rid of this material. Reasons are given why this hormone is considered to act on the gland cells and not on secretory nerves. The hormone in question is not found in the cerebro-spinal fluid itself except in cases where catabolism is in excess, as in degenerative processes of the central nervous system.

Other agents which produce an increase of the fluid are excess of carbon dioxide in the blood, and drugs which interfere with respiration. The volatile anæsthetics have a similar action; these may act by interfering with oxygenation or by altering the physical condition of the secreting cells. A large number of substances were investigated, but all the remainder gave negative results, if respiratory and vascular effects were excluded.   W. D. H.

The Comparative Composition of Human and Cow's Milk. EDWARD B. MEIGS and HOWARD L. MARSH (*J. Biol. Chem.*, 1913, **16**, 147—168).—Human milk differs from cow's milk in three important ways. It contains more lactose, less protein, and more substances of unknown nature. The following figures are averages in percentages of the whole milk:

	Fat.	Lactose.	Protein.
Human milk	2 to 4	6 to 7·5	0·7 to 1·5
Cow's milk	2 ,, 4	3·5 ,, 5	2·5 ,, 4

The unknown constituents are soluble in alcohol and ether; they contain little or no nitrogen, and are of importance as food. Some are crystalline, and the crystalline form of one is figured and described at length. (This contains sulphur, but is free from nitrogen.) They are most plentiful in early human milk (1%); as lactation proceeds they sink to 0·5%. Cow's milk at the latter period contains 0·3%. The paper contains analytical tables, and descriptions of methods. Much of the work was done by the late Arthur V. Meigs.   W. D. H.

The Soluble Caseins of Milk. LÉON LINDET (*Bull. Soc. chim.*, 1913, [iv], **13**, 1001—1006   Compare this vol., i, 1116).—Further experiments are quoted in support of the author's views as to the presence of an *a*- and *β*-caseinogen in milk and the relationship between them. The sum of these two substances present is fairly constant in milk, but the proportions of each are very variable.   W. G.

Solubility of the Proteins of Milk in the Elements of the Serum; Reduction of their Solubility under the Influence of Calcium Chloride. LÉON LINDET (*Bull. Soc. chim.*, 1913, [iv]. **13**, 929—935). —The soluble proteins of milk include casein (distinguished as

α-casein), having $[\alpha]_D$ −116°, and a second, called β-casein, which differs only in specific rotation, $[\alpha]_D$ −30°. Milk serum, from which all the proteins had been removed by means of phenol, on evaporation and incineration yielded ash of the following composition, expressed in grams per litre of milk: alkali chlorides, 1·949; alkali citrates (calculated from the carbonate found), 0·765; alkali phosphates, 0·514; calcium phosphate, 0·638; magnesium phosphate, 0·458; iron and aluminium phosphates, 0·108; calcium sulphate, 0·341; undetermined, 0·387. An artificial serum containing lactose, 5; sodium chloride, 0·2; sodium citrate, 0·08; and sodium phosphate, 0·05 per cent., can dissolve 3·456 grams of casein per litre, and probably as much more of the β-casein. In milk, probably all the β-casein is in solution, and about 10% of the α-casein, the rest of the latter being in suspension. The addition of calcium chloride to milk before coagulation by rennet increases the nitrogen and phosphate content of the coagulum and accelerates the action, due to its converting the sodium salts into insoluble calcium salts, and thereby destroying the solvent action of the former on the casein. T. A. H.

Psychic Hyperglycæmia in Rabbits. IVAN BANG (*Zeitsch. physiol. Chem*, 1913. 88, 44—46).—Hirsch and Reinbach (*ibid.*, 1913, 87, 122) have described a hyperglycæmia and glycosuria in rabbits as the result of fright. The non-recognition of this condition produced by psychical causes renders much work on the general subject untrustworthy. The existence of such a psychic condition in rabbits and other animals is confirmed in the present paper.
W. D. H.

Pentosuria from the Chemical Point of View. ERNST ZERNER and RUDOLFINE WALTUCH (*Monatsh.*, 1913, 34, 1639—1652).—In most cases of pentosuria which have been investigated, optically inactive urines have been encountered, from which osazones apparently corresponding with *i*-arabinose or *l*-arabinose have occasionally been isolated.

Two new cases of pentosuria have now been examined. The urines were inactive, which is taken as an indication of the absence of *l*-arabinose, since this has a very high specific rotation. The osazone obtained had m. p. 162—163°, and a small *d*-rotation, which was insufficient to distinguish it from *d*-arabinosazone. Diphenylmethanedimethyldihydrazine (Braun, 1910, i, 525) gave no indication of arabinose. A mixture with an equal weight of *l*-xylosazone had m. p. 208—210°, whereas *i*-xylosazone has m. p. 210—215° (Fischer, A., 1894, i, 566). The osazone from these urines is therefore *d*-xylosazone, and very probably the pentose is *d*-xylose. Further experiments are being carried out definitely to determine the nature of the sugar. J. C. W.

The Sugar in Pentosuric Urine. CARL NEUBERG (*Biochem. Zeitsch.*, 1913, 56, 506—507).—Zerner and Waltuch (preceding abstract) have maintained that the sugar isolated by them in a

case of pentosuria was *d*-xylose, as the mixture of its osazone with that of the corresponding *l*-derivative has a higher melting point than the pure substance. A mixture of the *l*-form of osazone with the osazone obtained from the urine of the cases of pentosuria of the author did not produce a corresponding rise in the melting point. The author does not see, therefore, any reason to suppose that the sugar in his case is other than the *dl*-arabinose, as originally suggested. It is conceivable that various forms of pentosuria exist.   S. B. S.

Physiological Action of Colloidal Carbon. GUIDO IZAR and C. PATANÉ (*Biochem. Zeitsch.*, 1913, **56**, 307—318).—The so-called mellogen, produced by the disintegration of a carbon anode by a galvanic current, was used in these experiments. It can be dispersed in water made slightly alkaline by sodium hydroxide, which mixture is afterwards neutralised by passing in carbon dioxide and heating. This preparation has no influence on the total autolysis of the liver. It increases the amount of uric acid formed by autolysing ox-spleen and liver, and inhibits the uricolytic action of ox-kidneys and washed pulp of dog's liver. Intravenous injections of large quantities into rabbits, white rats, pigeons, etc., produce dyspnœa, but only a few of the animals succumb. The intravenous injection has no appreciable effect on body temperature (rabbits), but increases the amount of carbon dioxide in expired air (as compared with control injection of distilled water). The amount of increase is approximately proportional to the amount of mellogen injected.   S. B. S.

Action of Colloidal Sulphur on Autolysis. ANTONIO FAGIUOLI (*Biochem. Zeitsch.*, 1913, **56**, 291—294).—Colloidal sulphur increases the autolysis of liver tissue (ox, dog, and monkey), and to a still larger extent that of tumour tissue (rat sarcoma and human liver carcinoma).   S. B. S.

Pharmacological Action of Ethyl Alcohol on the Isolated Mammalian Heart at Different Temperatures. GIUSEPPE BRANDINI (*Chem. Zentr.*, 1913, ii, 524; from *Arch. Farm. sperim.*, 1913, **15**, 178—192, 193—212).—The experiments were carried out on a rabbit's heart in a Langendorff perfusion apparatus. At normal temperatures the alcohol in small doses (1 in 50,000—1,150,000) exerts a stimulant action, in medium doses, the heart activity is depressed, but in higher concentrations ($30^0/_{00}$) the action is toxic. At lower temperatures (33°) the effect is weaker, and higher concentrations of alcohol are required to produce the same effects described as resulting at 37°.   S. B. S.

The Scission of the Benzene Ring in the Animal Body. II. Behaviour of Muconic Acid and Benzene in Liver-perfusion Researches. MARIE HENSEL and OTTO RIESSER (*Zeitsch. physiol. Chem.*, 1913, **88**, 38—43).—When muconic acid is added to a fluid employed for perfusing the liver, the amount of acetone formed

by that organ is greatly increased, it may be fourfold. No certain result was obtained by perfusing the liver with benzene; this substance is strongly toxic. W. D. H.

The Conjugated Excretion Products of Bromobenzene and *p*-Iodophenol. ERBERTO ANGELO RABBENO (*Chem. Zentr.*, 1913, ii, 1070; from *Arch. Farm. sperim.*, 1913, **15**, 535—546).—It was presumed that it should be possible, by the estimation of the total sulphur, the conjugated sulphuric acid, and the rotation of the urine of dogs, to which bromobenzene and *p*-iodophenol had been administered *per os*, to ascertain whether the halogen derivatives of benzene undergo conjugation with glycuronic acid as well as with cystine and sulphuric acid. It was found as a result of the experiments that the bromine derivative is excreted conjugated only with cysteine and sulphuric acid, whereas the iodo-derivative is excreted conjugated with glycuronic and sulphuric acids, but not with cysteine. S. B. S.

The Influence of the Administration of Creatine and Creatinine on the Creatine Content of Muscle. VICTOR C. MYERS and MORRIS S. FINE (*J. Biol. Chem.*, 1913, **16**, 169—186).— The subcutaneous administration of creatine to rabbits causes a small increase in the creatine content of muscle (about 5% in five experiments). This is quite insufficient to account for the creatine, which does not reappear in the urine. The administration of creatinine exerts a similar effect, the creatine content of the muscles being 6% above the normal, an amount sufficient to account for the creatinine which was not eliminated by the kidneys. This apparent increase in the muscular creatine was not due to a retention of unchanged creatinine. Of the creatine given, 25—80% (the quantity depending on the amount injected) reappeared in the urine unchanged, whilst 2—10% was eliminated as creatinine. When creatinine was administered, 77—82% (average 80%) reappeared in the urine, and no elimination of creatine was detected. W. D. H.

Narcosis and Oxygen Consumption. JACQUES LOEB and HARDOLPH WASTENEYS (*Biochem. Zeitsch.*, 1913, **56**, 295—306).— The authors discuss the relationship between inhibition of oxidation and narcosis. When the embryos of *Fundulus* are not narcotised, they respond by rapid movement to a stimulus of $N/25$-hydrochloric acid. It was found that they only become insensitive to this stimulus when their oxidation rate has been reduced to 1/14 of the normal value by potassium cyanide; a reduction by this method to 1/9 is without influence on their response to the stimulus. On the other hand, they become unresponsive to chloroform treatment, without any appreciable reduction of the oxidation rate. Ethyl ether and butyl alcohol can produce insensitiveness to the strongest stimuli with the diminution of the oxidation rate by only 26%. Medusæ loose their mobility and reactivity to stimuli by direct reduction of oxidation by potassium cyanide only

when this reduction is 3—6 times as great as that which results when the motility and reactivity are destroyed by ethylurethane. The conclusion is drawn that narcosis cannot be due directly to reduction of oxidative capacity, and that the latter is a result either of inactivity of the tissues due to narcosis, or it is a secondary action of the narcotis, which stands in no direct relationship to the narcosis itself.   S. B. S.

Biological Oxidation of Certain Glucosides. Juho Hämäläinen (*Chem. Zentr.*, 1913, ii, 1319; from *Skand. Arch. Physiol.*, 1913, **30**, 187—190).—After injection of the glucosides of certain terpene alcohols, the corresponding glycuronates appear in the urine. There is therefore no preliminary scission of the glucoside into sugar and alcohol, for neither in the blood nor in the organs could any terpene be detected. On the contrary, both glycuronate and the corresponding glucoside could be found. The facts confirm the theories of Fischer and Piloty and of Sundvik on the formation of conjugated glycuronates in the organism. Furthermore, more glycuronate is excreted after administration of the glucoside than after administration of the free substance.   S. B. S.

The Influence of Certain Quinoline and Naphthaquinoline Derivatives on the Excretion of Uric Acid. Riccardo Luzzato and Riccardo Ciusa (*Chem. Zentr.*, 1913, ii, 1318—1319; from *Arch. Farm. sperim.*, 1913, **16**, 6—40).—The following derivatives were investigated : 2-*p*-methoxyphenylquinoline-4-carboxylic acid, 2-*p*-dimethylaminophenylquinoline-4-carboxylic acid, 6-amino-2-phenylquinoline-4-carboxylic acid, 3-phenyl-β-naphthaquinoline-1-carboxylic acid, 2-*p*-dimethylamino-β-naphthacinchonic acid, 2-phenyldihydro-β-naphthaquinoline-4-carboxylic acid, 2-*o*-hydroxylphenyl-β-naphthacinchonic acid, 3-phenyl-β-naphthaquinoline, and 2-phenylcinchonic acid (atophan). Of these it was found that 3-phenyl-β-naphthaquinoline-1-carboxylic acid (the so-called diapurin) and atophan caused an intense excretion of uric acid, the action of the latter being somewhat less than that of the former. It caused, however, no turbidity of the urine, and was better tolerated, and a dose of 5 grams caused no bad symptoms in a dog of 12 kilos. weight, and could be taken by a man in doses of 2 grams for several days without ill effects. The action of diapurin is attributed to the mobilising effects on the uric acid, which already exist in the organism as a result of purine degradation, as the increased excretion of the acid is not accompanied by an increased phosphoric output, which should result if the nucleins are broken down. Furthermore, the increased output of uric acid ceases two or three days after administration of the drug. The particular action on the uric acid is due to the presence of a phenyl group in the 2-position, the quinolinecarboxylic acid group being inactive. The action is neutralised by the presence of the methoxyl and amino-groups in the 6-position. On the other hand, 2-phenyl-6-methylquinoline-4-carboxylic acid (paratophan) and 8-methoxy-2-phenylquinoline-4-carboxylic acid (isatophan) are fairly active. The introduction of the OH,

NMe$_2$, or OMe group into the 2-phenyl ring inhibits or weakens the action on uric acid. As hydroxyphenylquinoline-4-carboxylic acid is, according to Sk'orczewski and Sohn, a degradation product of atophan, the latter appears to exert its influence before oxidation. The reduction of the pyridine ring destroys or weakens the action. The general methods of Doebner, Kuntze, Lachs, and Steinert were employed in the preparation of the compounds, and the following substances were obtained: 2-p-*anisylquinoline-4-carboxylic acid*, m. p. 217°; 2-*dimethylaminophenylquinoline-4-carboxylic acid*; 6-*amino-2-phenylquinoline-4-carboxylic acid*, m. p. 160° (decomp.).

S. B. S.

The Behaviour of Certain Rhamnosides in the Animal Body. MARIO GARINO (*Zeitsch. physiol. Chem.*, 1913, **88**, 1—8).—Rutin, quercitrin, hesperidin, and hesperetin, after intravenous or oral administration, pass through the animal organism, and are excreted almost entirely unchanged. Hydrolysis of these substances appears to occur either not at all, or in the merest traces, in the body.

W. D. H.

The Action of Strophanthin on the Excised Frog's Heart. A. J. CLARK and GEORGE R. MINES (*Proc. physiol. Soc.*, 1913, vii—viii; *J. Physiol.*, 47).—The effect of perfusing the heart with one part of strophantin in a million of Ringer's fluid is at first beneficial, and later toxic. The observations were made on the mechanical activity of the ventricle, the length of the A.V. interval, and on the electrical concomitant of activity.

W. D. H.

Mechanism of the Biological Action of the Röntgen Rays. EUGEN PETRY (*Biochem. Zeitsch.*, 1913, **56**, 341—352).—The author has investigated the influence of Röntgen rays on the toxicity of various metals, following a similar line of research to that of Tappeiner and his pupils on the sensitising influence of eosin on actinic rays. Amœbæ obtained from hay-infusion were used as the objects of experiments, and these were submitted to the action of uranium nitrate, sodium tungstate, zinc sulphate, and colloidal zinc sulphide in the dark, in the presence and the absence of Röntgen radiation. As a result, it was found that the rays had no appreciable effect in increasing the toxicity of the metals. Compounds were purposely chosen which fluoresce when submitted to radiation. The rays exerted no action on the sensitising activity. Experiments were also carried out to ascertain whether organs which are highly sensitive to Röntgen rays contain substances which act as light-catalysts for these rays. Testicles and lymph glands were chosen, and the effect of radiated and unradiated extracts on hæmolysis, the mobility of amœbæ, and the milk-clotting by rennin, were investigated. The results were negative, and the author draws the conclusion that no substances have been discovered which act as catalysts for the Röntgen rays in the same way that eosin acts as catalyst for actinic rays. S. B. S.

Purine and Xanthine Bases as Intermediary Products in Poisoning by Nucleoproteins. HENRI DE WAELE (*Chem. Zentr.,* 1913, ii, 519—520 ; from *Zeitsch. Immun. expt. Therapie,* 1913, **18,** i, 410—422).—Just as, according to the author, the proteins use the amino-acids as intermediary products in developing their thromboplastic action, the nucleoproteins act by intermediation of the purine bases. Thus nucleoproteins, otherwise harmless, can be rendered toxic by degradation of their molecule, or by the addition to them of degradation products, or even amino-acids. Under these conditions, curves were obtained similar to those described by the author for proteins, showing, in an oscillatory manner, thromboplastic and antithrombic phases. The first of these is short, and may be overlooked. The nucleins produce a strong antithrombic secretion. The antithrombic phase is of short duration, but produces a distinct, although short-lasting, immunity. The nucleoproteins can be activated either by purines (affecting the nucleic acid part of their molecule) or by amino-acids (affecting the protein part). Nucleohistones, owing to the presence of the histone group, are directly toxic. For many nucleoproteins, such as those from the thymus, animals are directly anaphylactic, in the same way that carnivora are sensitive to peptones.   S. B. S.

The Removal of the Poisonous Properties of Protein Cleavage Products by Substitution of the Cyclic Nucleus. GEORGE BAEHR and ERNST P. PICK (*Arch. expt. Path. Pharm.,* 1913, **74,** 73—91).—The proteins of horse- and ox-serum yield, on gastric digestion, poisonous products. But if these proteins are iodised, nitrited, or diazotised, the products of pepsin digestion no longer produce "peptone-shock," causing neither fall of arterial pressure nor loss of coagulability in the blood. The iodine, nitro- and diazogroups in question enter the cyclic nucleus of the protein molecule.
                                                                W. D. H.

Nature of the Coagulant of the Venom of Echis carinatus, a Small Indian Viper. J. O. WAKELIN BARRATT (*Proc. Roy. Soc.* 1913, [*B*], **87,** 177—190).—The effect of the intravenous injection of thrombokinase is essentially different from that of injection of thrombin. The latter causes an abundant intravascular formation of fibrin and a reduction of the amount of fibrinogen in the circulating fluid. Little or no fibrinogen is removed after the injection of thrombokinase, which thus has an essentially different action on blood plasma than on a solution of fibrinogen *in vitro* in presence of calcium chloride, which it causes to coagulate. The coagulant of viper venom, as exhibited by its effect in causing intravascular separation of fibrin when injected into the bloodstream and also indicated by its behaviour when heated, is a thrombin and not a thrombokinase.   E. F. A.

Chemistry of Vegetable Physiology and Agriculture.

Biochemistry of Micro-organisms. VIII. Fermentation of Formic Acid by Bacillus Plymouthensis in a Medium of Constant Composition. HARTWIG FRANZEN and FRITZ EGGER (*Zeitsch. physiol. Chem.*, 1913, **88**, 73—102. Compare this vol., i, 322; A., 1912, ii, 669).—Further data are given obtained from experiments with *B. Plymouthensis*, made in the same way as previously with *B. kiliense* and *B. prodigiosus*. The results show the same divergence in different series of cultures. *B. Plymouthensis* ferments formic acid during the first twenty-four hours. The maximum amount of formic acid fermented was 9·95% at 17°, 16·8 and 26·47% at 21°, and 22% at 27°. No general conclusions are drawn.   E. F. A.

Chemistry of Bacteria. II. SAKAE TAMURA (*Zeitsch. physiol. Chem.*, 1913, **88**, 190—198).—*Mycobacterium laticola* contains the same organic constituents whether it is grown on nutritive bouillon or on a medium lacking protein. The aromatic units in its composition are formed in quantity when only short open-chain carbon compounds are supplied as food—for example, lactic acid, glycerol, asparagine.

The inorganic constituents of the cells of *Bacterium tuberculosis* or of *Mycobacterium laticola* undergo considerable quantitative variation according to the nature of the environment in which the culture is made.   E. F. A.

Violet Colouring Matter and its Production by a Certain Bacterium. W. J. HARTLEY (*Sci. Pr.·c. Roy. Dubl. Soc.*, 1913, **14**, 63—73).—The pigment of a bright, violet bacterium obtained from a creamery water has been examined. The pigment turns green with acid, blue with alkali; it does not dye silk. The absorption spectrum has been characterised; it has no bands in the ultraviolet, absorbs continuously the rays in the red less refrangible than λ 6600, and transmits nearly all the rays from λ 6600 to λ 6439. The cultures, when macerated, gave a positive test with picrate paper for hydrogen cyanide.   E. F. A.

Influence of Radioactivity on Nitrogen-fixing Micro-organisms or on those Transforming Nitrogenous Substances. JULIUS STOKLASA (*Compt. rend.*, 1913, **157**, 879—882).—Air activated by pitchblende has a markedly favourable influence on the fixation of atmospheric nitrogen by *Azotobacter chroococcum*, the influence being slightly more favourable with weak radioactive intensity than with a stronger intensity. On the other hand, the transformation of organic nitrogen into ammoniacal nitrogen and the fixation of free nitrogen is much weaker in solutions submitted to the influence of β- and γ-rays than in control solutions.

Soil submitted to air charged with radium emanations showed an increased nitrogen content of 0·021% over the control sample. The reduction of nitrates by denitrifying bacteria is considerably lessened under the influence of radium emanation, although there is ample development of the denitrifying bacteria.   W. G.

Butylene-glycol Fermentation of Dextrose by Staphylococci and Tetragenes. M. LEMOIGNE (*Compt. rend.*, 1913, **157**, 653—655. Compare A., 1912, ii, 1199).—Staphylococci and tetragenes only attack carbohydrates slowly, and do not develop unless they have an abundant supply of organic nitrogenous food. The products of the fermentation of the sugar are dimethyl diketone, acetylmethylcarbinol, and butylene $\beta\gamma$-glycol.   W. G.

The Optical Behaviour of Yeast Maceration Juice. CARL NEUBERG and P. ROSENTHAL (*Biochem. Zeitsch.*, 1913, **56**, 498—500).—The maceration juices from Lebedev's preparations were found to vary when freshly prepared from $-0\cdot10°$ to $-0\cdot42°$ in optical rotation. On keeping, the optical rotation of the juices diminished in some cases, whereas in others it increased. S. B. S.

Osmotic Pressure and Electrical Conductivity of Yeast, Beer, and Wort HENRY H. DIXON and WILLIAM R. G. ATKINS (*Sci. Proc. Roy. Dubl. Soc.*, 1913, **14**, 9—12).—Pressed yeast gives higher values than wort, both in osmotic pressure and electrical conductivity. Comparing beer and wort, it is shown that whilst the electrical conductivity remains the same, the osmotic pressure becomes three times as great during fermentation.   E. F. A.

Extraction of Zymase by means of Liquid Air. HENRY H. DIXON and WILLIAM R. G. ATKINS (*Sci. Proc. Roy. Dubl. Soc.*, 1913, **14**, 1—8).—Immersion of yeast in liquid air from ten to fifteen minutes renders the protoplasm permeable. On thawing, the yeast liquefies, and after centrifuging, the sap of the cells is obtained as a faintly opalescent, brown liquid. This contains zymase in as active a form as that prepared by Lebedev's maceration method. The amount of zymase extracted may be increased by dilution and maceration. The sap is practically free from glycogen, and does not show autofermentation.

The sediment froths actively, due to hydrolysis of the glycogen in the cells and fermentation of the sugar formed.   E. F. A.

The Complete Hydrolysis of Yeast Albumin. HANS PRINGSHEIM (*Woch. Brauerei*, 1913, **30**, 399—400).—The hydrolysis of yeast furnished the following compounds, which were obtained by distillation in the form of esters (Fischer's method). The esters obtained from leucine and valine were the chief product; those from proline, phenylalanine, and glutamic acid were obtained in small quantities; the presence of serine is considered questionable, whilst alanine and glycine were not apparently present.

F. M. G. M.

Influence of Acids on Alcoholic Fermentation. M. ROSENBLATT and (Mme.) M. ROSENBLATT (*Bull. Soc. chim.*, 1913, [iv], 13, 924—929. Compare A., 1909, ii, 752; 1910, ii, 643; Johannesohn, this vol., i, 143).—None of the acids tried has any accelerating action on the activity of yeast, and each of them begins to retard the activity at the concentrations quoted: Hydrochloric ($M/6000$), formic ($M/5000$), acetic ($M/300$), propionic ($M/250$), n-butyric ($M/200$); sulphuric ($M/6000$), tartaric ($M/1000$); phosphoric ($M/5000$), citric ($M/3000$). Potassium hydrogen sulphate behaves similarly. The following salts accelerate the activity, and the optimal concentrations are quoted: Potassium hydrogen oxalate ($M/200$), dipotassium hydrogen citrate ($M/10$), potassium dihydrogen citrate ($M/5$), sodium dihydrogen tartrate ($M/4$), potassium dihydrogen phosphate ($M/3$). T. A. H.

Formation of Acid by Fermentation. ED. MOUFANG (*Zeitsch. f. ges. Brauwesen*, 1913, 36, 297—299).—Dilute solutions of dextrose, lævulose, maltose, and sucrose were treated with yeast in the presence of malt, and the acids formed subsequently estimated by methods which have been described by Mösslinger. F. M. G. M.

Reduction of Chloral Hydrate by Yeast During Alcoholic Fermentation. CARL J. LINTNER and H. LÜERS (*Zeitsch. physiol. Chem.*, 1913, 88, 122—123).—Living yeast in the act of fermenting sucrose reduces added chloral hydrate to trichloroethyl alcohol. E. F. A.

The Uselessness of Zinc for the Culture of Aspergillus niger. CHARLES LEPIERRE (*Compt. rend.*, 1913, 157, 876—879).— *Aspergillus niger* will grow on a culture medium, free from all traces of zinc, providing the ratio, volume of liquid/surface exposed, is always greater than 2. If this ratio falls below 2, however, then the maximum growth is never obtained. This explains the difference between the author's results and those of Javillier (compare A., 1908, ii, 317), who grew the mould on liquid where the ratio v/s was 1·5. W. G.

Polyatomic Alcohols as Sources of Carbon for Lower Fungi. RAY E. NEIDIG (*J. Biol. Chem.*, 1913, 16, 143—145).—Methyl alcohol and ethylene glycol are not capable of producing normal cultures of *Aspergillus* and other moulds when they are introduced into Czapek's medium in place of sugar. Glycerol is readily available, and gives cultures as good as when sucrose is employed. With increasing carbon, the availability does not increase; adonitol, for example, does not compare favourably with glycerol or even erythritol, and two of the hexatomic alcohols failed to yield cultures equal to those on glycerol. No connexion between availability and carbon asymmetry could be established. There may, however, be some relation between availability and the nature of the intermediate oxidation products, since all the substances which are available, including glycerol, yield oxidation products containing one or more asymmetric carbon atoms. W. D. H.

Attempts to Produce Citric Acid from Alcohol and Lactose by Fungi. CARL WEHMER (*Chem. Zeit.*, 1913, **37**, 1393—1394. Compare Mazé and Perrier, A., 1904, ii, 676; Herzog and Polotzky, A., 1909, i, 285; Wehmer, this vol., i, 229).—Unsuccessful attempts are recorded to produce citric acid from alcohol or from lactose by means of fungi. The author thus confirms Herzog and Polotzky's conclusion with regard to the non-formation of citric acid from alcohol (contrast Mazé and Perrier), but differs from them in finding that it is also not produced from lactose.

Two species of *Citromyces* were grown during several months in a nutrient solution containing ammonium nitrate, potassium phosphate, magnesium sulphate, calcium carbonate, and alcohol (2·5 and 5%). The latter exerts a marked retarding effect on the growth of the fungi, which differs in extent for the two species. Citric acid could not be detected.

Under similar conditions, a like result was obtained with lactose solutions, in which, however, growth of the fungi occurred readily.

H. W.

Disinfectants which Dissolve Lipoids. JOSEF GÖSSL (*Zeitsch. physiol. Chem.*, 1913, **88**, 103—108).—Overton and Meyer pointed out that certain anæsthetics owe their activity to the fact that they are soluble in the cell-lipoids. A large number of chemical substances are examined in the present research to see if this also holds for their disinfecting powers, with the result that the answer is in the affirmative. The experiments were made on yeast cells.

W. D. H.

Nitrate and Nitrite Assimilation. OSKAR BAUDISCH (*Zeitsch. angew. Chem.*, 1913, **26**, 612—613. Compare A., 1911, ii, 523; 1912, ii, 286; this vol., i, 324).—Some new experiments in support of the view that nitroxyl, NOH, plays an important part in the assimilation of nitrogen have been carried out, partly on the heights of Monte Rosa, where the activity of the light was nearly equal to that of a mercury lamp. It was found that the liberation of oxygen from solutions of potassium nitrite or nitrate was greatly accelerated by carbon dioxide. Nitric oxide in presence of formaldehyde or methyl alcohol soon produced formhydroxamic acid. Nitric oxide and water, with yellow phosphorus as catalyst, gave ammonium nitrate in sunlight, and ammonium nitrite in mercury light. Nitric oxide itself was detected in moist air which had been passed through dilute alkali and then exposed to brilliant sunlight. Substances of the nature of α-amino-acids were obtained by the action of mercury light on potassium nitrite in presence of carbon dioxide, with ferric chloride as catalyst. A new course for the photo-synthesis of organic substances from air, carbon dioxide, and water is thus indicated. Ammonia was oxidised to nitrous acid in presence of oxygen under the influence of mercury light.

A diagram is given which summarises the numerous photo-reactions between simple carbon, nitrogen, and oxygen compounds, which Baudisch, Piloty, and Stoklasa have already discovered.

J. C. W.

The Influence of Sodium Sulphate on the Growth of Plants. EMIL HASELHOFF (*Landw. Jahrb.*, 1913, **44**, 641—650).— An account of numerous culture experiments undertaken for the purpose of demonstrating the influence of sodium sulphate on the growth of *Vicia faba*, *Phaseolus vulgaris*, *Hordeum vulgare*, and *Zea mays*; the results are exhibited in tabular form.

F. M. G. M.

Uniformity of Structure of the Proteins. Their Changes in Vegetable and Animal Organisms. DMITRI N. PRIANISCHNIKOV (*Bied. Zentr.*, 1913, **42**, 679—682; from *J. exper. Landw.*, 1912).— Certain plants, such as barley, when supplied with ammonium chloride produce amides at the expense of proteins, whilst the ammonia is also converted into asparagine or glutamine. No accumulation of ammonium salt takes place. In the case of peas and vetches, ammonium salts do not increase the amount of asparagine, and may even diminish it. When, however, calcium carbonate is supplied along with an ammonium salt, the latter is converted into asparagine. With lupines, the presence of ammonium salts, both alone and with calcium carbonate, diminishes the amount of asparagine, whilst the plant accumulates ammonia, chiefly from cleavage products of the proteins.

Lower plants can accumulate ammonia without injurious effects. In lower animals proteins are degraded to ammonium salts, which are not completely converted into amides. N. H. J. M.

Effect of Chloroform on the Respiratory Exchanges of Leaves. D. THODAY (*Ann. Bot.*, 1913, **27**, 697—717).—Different varieties of leaves, when treated with small amounts of chloroform, showed increased absorption of oxygen and a similarly increased production of carbon dioxide. In starved leaves the stimulation was generally prolonged.

When the amount of chloroform was sufficient to cause visible disorganisation, the production of carbon dioxide was diminished, whilst the absorption of oxygen was no longer closely correlated with the production of carbon dioxide.

Leaves of *Tropaeolum*, which contain no tannin, showed a depression of oxygen absorption greater than that of the production of carbon dioxide. In leaves of cherry, Portugal laurel, and *Helianthus*, which contain tannins, the absorption of oxygen was very rapid for a short time, and, although quickly falling, remained at a much higher level than the production of carbon dioxide.

N. H. J. M.

Methyl Alcohol of Leaves. MAURICE NICLOUX (*Bull. Soc. chim.*, 1913, [iv], **13**, 939—943).—The author has applied his method (this vol., ii, 1080) to distillates from various leaves, and has found the following quantities of methyl alcohol: ivy, 0·36 gram; spindle-tree (*Euonymus*), 0·45 gram, per kilo. of leaves. In the case of the ivy leaves, the calculations give a negative quantity for formaldehyde, due possibly to the presence of a small quantity of

ethyl alcohol or some similar substance which consumes potassium dichromate without yielding carbon dioxide. It is suggested that methyl alcohol may originate in plants in accordance with the equation $CO_2 + 2H_2O = CH_3 \cdot OH + O_3$. Such an action would require a chlorophyll coefficient above 1, and thus be in harmony with Maquenne and Demoussy's observations (this vol., i, 232 and 429).   T. A. H.

Oxydases and their Inhibitors in Plant Tissues. WILLIAM R. G. ATKINS (Sci. Proc. Roy. Dubl. Soc.. 1913, 14, 143—156. Compare Keeble and Armstrong, A., 1912, ii, 673; this vol., i, 325, 803).— The absence of a brown colour in the sap expressed from plant tissues may be due: (1) to the absence of organic peroxide; (2) to the presence of tannin, preventing the action of the oxydase; or (3) to the presence of some reducing agent or inhibitor. It is considered that oxydase is concerned in the production of cork and sclerenchyma. The distribution of oxydase and of a reducing agent in Iris species is described. The colours of Iris are due to the presence or absence of a yellow plastid pigment and an anthocyan pigment. A reducing substance active in aqueous solution may inhibit the production of anthocyan pigment.
E. F. A.

The Presence of a New Diastase, Salicinase, in Almonds. GABRIEL BERTRAND and ARTHUR COMPTON (Compt. rend., 1913, 157, 797—799. Compare A., 1912, i, 592).—From a study of the temperature and the reaction of the medium, which, under definite conditions, favour the greatest activity of preparations of emulsin from almonds on salicin, the authors consider that their results point conclusively to the presence of a specific enzyme, salicinase, capable of hydrolysing salicin.   W. G.

Flower Pigments of Antirrhinum majus. II. Pale Yellow or Ivory Pigment. MURIEL WHELDALE and HAROLD LLEWELLYN BASSETT (Biochem. J., 1913, 7, 441—444).—The pale yellow or ivory pigment present in each of the main classes of varieties of Antirrhinum with the exception of the white is identified as apigenin. In the plant it exists as a glucoside, and is present in the inner tissues.   E. F. A.

The Trypsin of Calotropis procera R.Br. and the Poison which Accompanies It. C. GERBER and P. FLOURENS (Compt. rend., 1913, 157, 600—603).—The latex of Calotropis procera contains a proteolytic enzyme, which is very resistant to heat, and more active in alkaline than in neutral medium. It coagulates milk, and digests casein and fibrin. Separated from the latex by the usual methods, it is eight to ten times less active than the latex itself, owing to its lability towards the agents used in the separation. Its physiological action varies according to the animal used, and is due to a poison which accompanies it. Subcutaneously injected into a white rat, a rabbit or a fowl, it produces only a local effect

on the skin and muscle, which disappears in a few days. In the case of the guinea-pig, pigeon, and certain cold-blooded animals, it is rapidly fatal. The deaths and premonitory symptoms are similar in character to those observed with the latex of *Broussonetia papyrifera*. The toxic substance can be extracted in the form of a brown solid, by maceration with alcohol.   W. G.

Partial Decomposition of Yeast-nucleic Acid by the Press Juice of Cortinellus edodes. KWANJI TSUJI (*Zeitsch. physiol. Chem.*, 1913, **87**, 379—381).—The pressed juice of the fungus *Cortinellus edodes* produces guanosine from yeast-nucleic acid, indicating that it contains enzymes converting nucleic acid into nucleosides and hydrolysing the latter.   E. F. A.

Capoc and Acon and their Bitter Constituents, Waxes, and Resins. HERMANN MATTHES and LOTHAR STREICHER (*Arch. Pharm.*, 1913, **251**, 438—452).—An examination of capoc and acon fibres. Java capoc, in contrast to cotton, contains cellulose 64·3%, lignin 13%, and pentosans 23—24%. Capoc and acon fibres are brittle, and contain 8·6% and 7·2% respectively of moisture, and about 5—10% of constituents soluble in water. Acon wax (4·63%), m. p. 30·5°, n_D^{40} 1·4682, acid number 65·09, ester number 106·43, saponification number 171·52, iodine number 70·52, Reichert-Meissl value 1·76, Polenske value 1·05, contains about 31% of unsaponifiable constituents, consisting of melicyl alcohol, a *hydrocarbon*, $C_{20}H_{42}$, m. p. 69° (probably laurane), and liquid and solid phytosterols; from the latter, a *phytosterol*, m. p. 136°, and another, m. p. 170° (probably stigmasterol), have been isolated. The fatty acids obtained from acon wax consist of about 20% of solid, and about 80% of liquid, acids. The solid acid consists only of palmitic acid; the liquid acids contain about 61% of oleic acid, 38% of linolic acid, and 1% of linolenic acid.

Capoc wax, m. p. 24°, n_D^{40} 1·4618, acid number 59·85, ester number 110·29, saponification number 170·14, iodine number 69·44, Reichert-Meissl value 2·02, Polenske value 0·97, contains about 28% of unsaponifiable constituents, and yields about 15% of palmitic acid, and 85% of liquid acids similar to those obtained from acon wax.

Capoc and acon possess a bitter taste. This is due to a substance which has been isolated from acon. It is a yellow substance, which is strongly poisonous, dissolves in water, reduces ammoniacal silver oxide and Fehling's solutions, develops with sulphuric acid and potassium dichromate a blue colour changing to green, and gives precipitates with the alkaloidal reagents, although it does not contain nitrogen. It resembles picrotoxin in being decomposed by boiling chloroform into a soluble and an insoluble component. Acon fibres contain chlorophyll and a resin.   C. S.

The Existence of a Cyanogenetic Compound in a Member of the Papaveraceæ (Papaver nudicaule). MARCEL MIRANDE (*Compt. rend.*, 1913, **157**, 727—729).—The author has examined the

leaves of plants of *Papaver alpinum*, of hybrids between this and *P. nudicaule*, and of nearly pure *P. nudicaule* for a cyanogenetic compound. The aqueous distillate of the leaves contains hydrocyanic acid in the case of the hybrids and *P. nudicaule*, but none in the case of *P. alpinum*. The plants with yellow flowers contain more of this compound than those with red or white flowers, and the nearer the plant is to the pure type, *P. nudicaule*, the higher is the yield of hydrogen cyanide. This is the first instance of a member of the Papaveraceæ containing a cyanogenetic compound.   W. G.

Robin and the "Phasin" of Robinia Seeds. ROBERT KOBERT *Landw. Versuchs.-Stat.*, 1913, **79-80**, 176—181. Compare succeeding abstract.—The name "robin" was applied by Kobert to a protein first prepared from the bark of *Robinia pseudacacia* by Power in 1889 (*Pharm. Rundschau*, 1890, **8**, 29), and subsequently characterised more completely by the same author (A., 1901, ii, 679), who showed especially (1) that it was toxic, but lost its poisonous properties when heated; (2) that it hydrolysed amygdalin and sinigrin; and (3) coagulated milk like rennet ferment. These observations, especially as regards the physiological action of the substance, were confirmed and extended by Lau (*Diss.*, Rostock, 1906 (?1901)), Ehrlich (*Klin. Jahrb.*, 1898, **6**, 315), and others, including the present author. In the present paper it is shown: (1) that "robin" undoubtedly behaves as a agglutinant with blood of various kinds; (2) is not toxic when injected subcutaneously into rabbits in quantities of 1 to 10 c.c. of a 4% solution; (3) does not hydrolyse sinigrin; (4) does not coagulate milk; and (5) does not precipitate ricin-serum. The toxicity of the "robin" preparations examined by Lau is ascribed to impurity or to the use of abnormally large doses of the material. The toxicity of the bark, it is suggested, may be due to the alkaloid or the glucoside it contains. From Robinia seeds a similar "phasin," which agglutinates blood, but is not toxic and has no glucosidolytic activity, has been prepared.   T. A. H.

Poisonous Constituent of the Bark of Robinia pseudacacia. FREDERICK B. POWER (*Amer. J. Pharm.*, 1913, **85**, 339—344. Compare *Pharm. Rundschau*, 1890, **8**, 29; A., 1901, ii, 679).—The author traverses the statements made by Kobert (preceding abstract) as regards the toxicity, glucosidolytic activity, and milk-clotting property of "robin." Repetition of some of his previous experiments with a sample of "robin" prepared in 1904 shows that the material is still poisonous, and is capable of hydrolysing sinigrin and amygdalin.   T. A. H.

Hydrogen Cyanide in Salt-Grass (Triglochin). JAN J. BLANKSMA (*Pharm. Weekblad*, 1913, **50**, 1295—1302. Compare Greshoff, *ibid.*, 1908, **45**, 1167).—Greshoff's observation of the occurrence of hydrogen cyanide in salt-grasses is confirmed. The proportion is highest in the flowers and young fruit, and falls off as the fruit ripens. These grasses contain no acetone, but

maceration with water produces ethyl alcohol and acetaldehyde, even from varieties not containing hydrogen cyanide. The mode of combination of the hydrogen cyanide in the grasses is a matter of doubt. A. J. W.

The Presence of a Nitrogenous Substance in the Seedlings from Vicia Faba. TORQUATO TORQUATI (*Chem. Zentr.*, 1913, ii, 517—518; from *Arch. Farm. sperim.*, 1913, **15**, 213—223).—A *substance* of the approximate formula $C_{11}H_{15}O_5N$, m. p. 273—275°, was isolated from the seedlings in the following way. The disintegrated material was extracted with hot water acidified with acetic acid. The proteins and pectins were separated from the filtrate by lead acetate. The filtrate from these, on neutralisation with ammonia, yielded a light yellow precipitate. This was decomposed with hydrogen sulphide, and a substance precipitated from the solution thus obtained by basic lead acetate. On decomposing the precipitate thus formed by hydrogen sulphide and concentration of the solution, the above-mentioned substance separated in crystalline form. The substance is neutral and rapidly darkens, especially in the presence of alkalis. With potassium ferrocyanide and ammonia it yields a ruby-red solution, which rapidly darkens. Permanganate is quickly reduced by it in acid solution, and it also reduces various mercuric, silver, and copper salts. S. B. S.

The Presence of a Nitrogenous Substance in the Green Pods of Vicia faba. TORQUATO TORQUATI (*Chem. Zentr.*, 1913, ii, 518; from *Arch. Farm. sperim.*, 1913, **15**, 308—312).—In addition to tyrosine, discovered by Bourquelot and Hérissey, the author has succeeded in obtaining the same chromogenic substance as that got by him from the seedlings (see preceding abstract). This substance is not contained in the seeds themselves nor in the pods of *Pisum*.

S. B. S.

Calcareous Chlorosis of Green Plants. Rôle of the Root Excretions in the Absorption of Iron from Calcareous Soils. PIERRE MAZÉ, M. RUOT, and M. LEMOIGNE (*Compt. rend.*, 1913, **157**, 495—498. Compare A., 1912, ii, 1088).—The chlorosis, which is induced in plants grown in water cultures containing an excess of calcium carbonate in suspension or soluble calcium salts in solution, can be destroyed by the addition of small quantities of organic acid to the culture solutions, the green colour returning to the leaf. The appearance of chlorosis is accompanied by a pink coloration of the culture liquid, and this gradually disappears after the addition of the acid. W. G.

[**The Lime-Magnesia Ratio.**] JOHN A. VOELCKER (*J. Roy. Agric. Soc.*, 1912, **73**, 325—358).—Wheat was found to be benefited by the addition of magnesia to soil in which magnesia is deficient, provided that the magnesia does not exceed the lime. An excess of magnesia over lime has a toxic effect, and diminishes the yield. Addition of lime will then be beneficial, and an excess of lime does not possess the toxic effect which magnesia in excess has.

Both magnesia and lime are capable of modifying the growth of wheat, and altering the character of the root and the composition of the grain. N. H. J. M.

[**Influence of Lithium, Zinc and Lead Salts on Wheat.**] JOHN A. VOELCKER (*J. Roy. Agric. Soc.*, 1912, 73, 314—325. Compare A., 1911, ii, 922).—The results of pot experiments showed that lithium salts are toxic when the soil contains 0·003% or more of lithium, whilst amounts not exceeding 0·002% have a stimulating effect. The best results are obtained with the nitrate (which is the most stimulating, as well as the most toxic of the different salts) when the amount of lithium does not exceed 0·001%.

Zinc salts have a slightly stimulating action on wheat when the soil contains less than 0·02% of zinc. Larger amounts of zinc have a toxic action.

Lead salts have no toxic effect when the soil contains as much as 0·03% of lead. The nitrate seems to have a stimulating effect.

It is worthy of note that much larger amounts of zinc than of lithium may be present in the soil without having any injurious action on wheat, the relative amounts being 10 : 1.

As regards the period in which the stimulating action takes place, the results so far obtained seem to indicate that it is during the germination of the seed rather than later. The action may result in considerable alterations in the development of the plant, in root production, and even in the character of the grain. N. H. J. M.

The Conditions which Affect the Activity of the Amylolytic Enzymes in Wheat Flour. C. O. SWANSON and JOHN W. CALVIN (*J. Amer. Chem. Soc.*, 1913, 35, 1635—1643).—It is known that flour when mixed with water and allowed to digest for four hours at 60° shows great diastasic activity. The results of this investigation show that the optimum temperature for the production of the maximum amount of reducing sugars is near 65°, and that the best proportions of flour and water lie between 1 : 4 and 1 : 10, little difference being observable between these limits. The transformation is mainly effected in the first hour (approx. 88% of the total change), and under favourable conditions more than two-fifths of the flour undergoes conversion into soluble substances (calculated as maltose). Small quantities of sulphuric acid, sodium hydroxide, dipotassium hydrogen phosphate, and sodium chloride all exert an inhibitory effect on the action of the enzymes of the flour, the influence being most marked with sodium hydroxide, and least with sodium chloride. Although little difference is observable between the quantities of reducing sugars formed in the action of water on various grades of flour from the same wheat, the inhibitory effect of the chemicals named is less marked with a low grade than with a straight flour. D. F. T.

The Amounts of Sulphur and Chlorine in the Rice Plant. ALICE R. THOMPSON (*J. Amer. Chem. Soc.*, 1913, 35, 1628—1634).— An investigation on the effect of fertilisers on the sulphur and

chlorine content of the plant grown in natural soil conditions and in sand cultures. The plant was analysed before flowering, the foliage and roots being examined separately; a second examination was made of the panicles, leaves, stems, and roots at the flowering period, and a third was made of the chaff, grain, leaves, stems, and roots at maturity. Analysis was also made of the soil of the rice field and of the water supplied.

The results of the analyses are tabulated in the original.

D. F. T.

Relationship between the Weight of the Sugar Beet and the Composition of its Juice. J. ARTHUR HARRIS and ROSS A. GORTNER (*Biochem. Bull.*, 1913, **2**, 524—529).—The wide-spread belief that large beets contain less sugar % than small beets is shown to rest upon very slender foundations.　　　　W. D. H.

The Influence of Growth in the Shade on the Various Constituents of Tobacco. ALBERT STUTZER and SAMUEL GOY (*Biochem. Zeitsch.*, 1913, **56**, 220—229).—Comparisons were made of the nicotine and potassium contents of the leaves from plants which were grown in pots in the shade, and from those grown under similar conditions in direct sunlight. There was less organic matter in those grown in the shade, but the percentages of nitrogen were higher. Both series of plants were richly fed with urea nitrate. In the lower leaves from the shaded plants the amount of nicotine was both absolutely and relatively higher than in the leaves of the other plant. In the upper leaves, however, the relative percentage of nitrogen in the form of nicotine in the shaded plants was less than that in the unshaded. The dried material of the shaded plants contained more potassium than that of the unshaded.

S. B. S.

Lævulose in the Leaves of Kentucky Tobacco Grown in Italy. FILIPPO TRAETTA-MOSCA (*Gazzetta*, 1913, **43**, ii, 428—430).— By dialysis of the leaves of this tobacco, the author has isolated a sugar which was identified as lævulose by means of its phenyl-glucosazone, rotatory power, and other properties.　　　R. V. S.

The Ferments of Plants of Kentucky Tobacco Grown in Italy. FILIPPO TRAETTA-MOSCA (*Gazzetta*, 1913, **43**, ii, 431—437).— A glycerol extract of the green leaves of this tobacco appears to contain oxydases, peroxydases, catalases, invertase, amylases, lipases, emulsin, and proteolytic ferments.　　　R. V. S.

Titanium and Rare Metals in the Ashes of Leaves of Kentucky Tobacco Grown in Italy. FILIPPO TRAETTA-MOSCA (*Gazzetta*, 1913, **43**, ii, 437—440).—In the leaves of this tobacco, the author has detected lithium, cæsium (both spectroscopically), titanium (spectroscopically and by colour reactions), and barium, as well as the other elements previously found in this plant.

R. V. S.

The Ethereal Extract of the Leaves of Kentucky Tobacco Grown in Italy. FILIPPO TRAETTA-MOSCA (*Gazzetta*, 1913, **43**, ii, 440—445).—That portion of the substances extracted with ether which is insoluble in cold alcohol yields a white *substance*, m. p. 62—63°, which gives the Liebermann-Burchard reaction for the ethers of the sterols, and contains 8·54% of oxygen (compare Thorpe and Holmes, T., 1901, **79**, 982). The resin of the leaves is a substance of high molecular weight (690), which yields a bromo-derivative, m. p. 118° (decomp.), and contains 64·89% of bromine but no oxygen. Oxidation of the resin with nitric acid yields a *substance*, $C_8H_{12}O_4$, m. p. 55—56°, possibly a hexahydrophthalic acid. Its *ammonium* salt yields colloidal solutions of a very typical character.   R. V. S.

First Results of Manuring Vines with Manganese Sulphate. F. A. SANNINO and A. TOSATTI (*Atti R. Accad. Lincei*, 1913, [v], **22**, ii, 237—242).—In one year's experiment the yield was considerably increased (possibly owing to the added sulphate), but the dextrose of the product was less than in the case of the unmanured vines, and the acidity was greater. In the second year the increase in yield was not so marked, and the dextrose and acid were present in about normal amounts. Details are given of the testing of the wines made from the manured and from the unmanured vines.

                                                        R. V. S.

Typical Peats. HERMANN MINSSEN (*Landw. Jahrb.*, 1913, **44**, 269—330).—A comprehensive study of different kinds of peat obtained from many localities, by which the author attempts to draw up a classification. Two great groups of peat formation are indicated, that is, the peats of "high" bogs and those in "low" positions, and between these many minor types exist. The different plants of which peats are formed are studied, and the results of numerous analyses tabulated, with a discussion on the possible significance of the facts observed.   F. M. G. M.

Manurial Experiments with Calcium Cyanamide, Sodium Nitrate, and Ammonium Sulphate on Sand and Peat Soils. BRUNO TACKE and FR. BRÜNE (*Landw. Versuchs.-Stat.*, 1913, **83**, 1—100).—Frank's calcium cyanamide and Polzeniuss's calcium cyanamide (which contains calcium chloride) give similar results on sandy soils. On peaty soil the latter only had 81% of the value of Frank's manure.

Calcium cyanamide should be applied not with the seed, but at least a week beforehand; and it should at once be harrowed in. Different crops show different degrees of sensitiveness; rye being more sensitive than oats and potatoes when the manure is applied as top dressing, whilst oats is specially liable to injury when the manure is applied at the same time as the seed. As regards the utilisation of nitrogen, calcium cyanamide was far behind ammonium sulphate and sodium nitrate.   N. H. J. M.
